" By letting the stocks remain until they be large enough to be grafted in the boughs ; namely, until the trained boughs be about an inch in diameter ; those evils are avoided, the grafting becomes more certain, there being more chances of success ; and the trees, by forming their ramifications in the natural way, are much less liable to be torn to pieces by the winds. Some time, it is true, may seem to be lost ; the trees certainly will not come so soon to bear ; but it is highly probable, that they will begin to bear a burden of fruit sooner, and will it is much more than probable, continue to bear longer than trees grafted in the stock.

" It has been already mentioned, that, in Herefordshire, the soil of orchards is generally kept under tillage ; in Gloucestershire, in grass. Not, however, I apprehend, so much in pursuance of different principles in the managing of orchards, as from the circumstances of Herefordshire being an arable, Gloucestershire a grass-land country.

" Either practice has its disadvantage. Fruit trees, when fully grown, especially if they are of a spreading growth, and are suffered to form drooping branches, are very injurious to arable crops : their roots, their drip, and their shadows, are destructive, not to corn only, but to clover and to turneps : besides being, under these circumstances, still farther injurious, by preventing a free circulation of air ; and in being in the way of the plough-teams ; which, when the trees are loaded with leaves and fruit, can frequently with difficulty creep under them.

" It is observable, however, that tillage is favourable to the trees ; especially to the growth of young trees. While in grass grounds (under ordinary management) their progress is comparatively slow ; for want of the earth's being stirred about their roots ; and by being injured by the grazing stock ; especially low-headed, drooping trees.

" After the trees begin to bear, stock are equally inconvenient, in a fruit ground. Cattle not only destroy all the fruit within their reach, but the fruit is dangerous to the cattle by being liable to lodge in their throats, in the manner of small turneps. In the fruit season, especially in windy weather, the cows are frequently obliged to be kept out of their grounds, at a time, perhaps, when the grass is wanted. Prudent men, however, endeavour to provide against this inconveniency, by eating the fruit-grounds bare, before the gathering season : and every prudent man ought to keep the boughs out of their reach, that no injury may be sustained, previous to that season ; as well as to give air and sun-beams to his grass.

" From these circumstances we may conclude, that, in situations, in which fruit grounds can with propriety and conveniency be kept either in tillage or in grass, they ought, while the trees are young, to be kept under the plough ; and that, when the trees become particularly injurious to the arable crops, the ground ought to be converted to a state of grass.

" In the deep-soiled district about Dymmock and Marcle, where the whole country may be said to be a forest of fruit trees, the occupiers of fruit grounds, experiencing the evil of trees, in arable lands, are planting in their grass grounds. This, however, appears to be a wrong principle. Let them lay their old orchards to grass : and, if they plant, breaking up their young orchards to arable : this will be changing the course of husbandry, and be at once beneficial to the land and the trees.

" In the Bromyard quarter of Herefordshire, where considerable quantities of hops are raised, it is common to plant young fruit trees in the hop-grounds. The trees, while young, do little injury to the hops ; while the mowing and cultivation of the hop-grounds is highly beneficial to the young trees. Before they acquire an injurious size, the grounds are worn out for hops, and returned to the common course of husbandry.

" If we view the common practice of the district through-

out, we may safely conclude, that after the trees are out of danger of being thrown down by cattle, no attention whatever is paid to them, other than that of collecting the fruit, when they happen to hit.

" Water boughs are seen dangling, as bell-ropes, perhaps to the ground, while the upper part of their heads are loaded with wood, as impervious to the sun and air as the heads of pollard oaks, or neglected gooseberry bushes ; with, perhaps, an additional burden of mistletoe and moss to bear.

" Indolence and false economy are, no doubt, the principles on which this slovenly conduct is pursued. The improvident occupiers of those neglected orchards, unmindful of the damage they annually sustain by the incumbrance of the trees, refuse to bestow a little leisure time, or lay out a few shillings, to render them productive.

" This shameful management, however, is not universal. There are orchards in every quarter of the district, which appear to have some little attention paid them ; and some few, which are in a degree of keeping, equal to the Kentish orchards.

" By taking a view of the natural enemies of fruit trees, we shall be the better able to judge of the art requisite to their preservation.

" The enemies of the fruit trees under notice are, a redundancy of wood ; the mistletoe ; moss ; spring frosts ; blights ; insects ; an excess of fruit ; old age.

" Some of them are beyond human reach ; but most of them are within the controul of art.

" A redundancy of wood is the cause of numerous evils. The roots, or rather the pasturage, which supports them, is exhausted unprofitably ; the bearing wood robbed of part of its sustenance, and the natural life of the tree unnecessarily shortened ; while the superfluous wood, which is the cause of this mischief, places the tree in perpetual danger, by giving the winds additional power over it ; and is injurious to the bearing wood, by retaining the damps, and preventing a due circulation of air.

" The underhanging boughs weigh down, especially when loaded with leaves, the fruit-bearing branches they are preying upon ; giving them a drooping habit ; or at least preventing their taking, as they ought, and otherwise would, an ascending direction ; while those which grow within the head are equally injurious in crossing and chafing the profitable branches.

" The outer surface, only, is able to mature fruit properly. Every inward and every underling branch ought therefore to be removed : and, in some cases, part of those, which reach the surface, might with propriety be taken out, to give due health and vigour to those which were left. It is no uncommon sight to see trees, in this district, with two or three tires of boughs pressing down hard one upon another ; with their twigs so intimately interwoven, that, even when the leaves are off, a small bird can scarcely creep in among them. Trees, thus neglected, acquire, through a want of due ventilation and exercise, a runty, stunted habit ; and the fruit they bear becomes of a crude, inferior quality.

" The great object of the fruit farmer is to produce a crop every year : and nothing is more likely to obtain it than keeping the trees in perfect health, and endeavouring to prevent their bearing beyond their strength, in a general fruit year.

" The mistletoe is, in this country, a fatal enemy to the apple-tree. The native crab-tree is frequently killed by it, and apple-trees too often injured ; and this, notwithstanding it is easily overcome, and is applicable to a profitable purpose, sheep affecting it as they do ivy : yet such is the power of indolence, and such the plentifulness of hay in this country, that a considerable portion of the produce of many orchards, is cut off by this singular plant.

" The ordinary method of clearing trees from it is to pull it out with hooks, in frosty weather ; when being brittle, it readily breaks off from the branches.

" Moss is chiefly, perhaps, owing to the nature of the soil, and cannot be altogether prevented ; but it may in most cases be checked, and its evil effect in a great measure avoided. In Kent, there are men who make a business of cleaning orchard trees ; being paid so much a tree, or so much for the orchard, according to the state of foulness.

" In Herefordshire, I saw several orchards, in which the trees were almost entirely subdued by this vegetable vermin. Some of the trees, perhaps, with only one bough left alive, and

and others entirely killed; yet suffered to remain an incumbrance to the ground, and a disgrace to the country.

"What avails the number of trees, if they are not productive? It is healthy, bearing trees, which fill the drink-house, and send a surplus to market. Their encumbrance on the soil is nearly the same, whether they are barren or fruitful; and it may be a moot point, whether, even many of those which are productive, much more than pay for their encumbrance: how ridiculous, then, to spare any reasonable expence in preserving them in a state of health and productiveness; or to suffer those to encumber the soil, which are past recovery.

"Spring frosts are an enemy against which, perhaps, it is most difficult to guard orchard trees. Dry frosts are observed to have no other effects than keeping the blossoms back; consequently, are frequently serviceable to fruit-trees. But wet frosts, namely, frosts after rain or a foggy air, and before the trees have had time to dry, are very injurious even to the buds. An instance is mentioned in which a flying, hazy shower, in the evening, was succeeded by a smart frost: that side of the trees, against which the haze drove, was entirely cut off; while the opposite side, which had escaped the moisture, likewise escaped the effect of the frost.

"Much, however, may depend on the strength of the blossoms. The spring of the year (1788) had its frosts; and all hope of fruit was more than once given up; yet for quantity and quality, taken jointly, there has seldom perhaps been so favourable a fruit year. But this year, the buds formed, and the blossoms broke forth with unusual vigour; and were enabled, in their own strength, to set common enemies at defiance. On the contrary, the preceding spring, many of the blossoms sickened in the bud; and those which opened were weak and languid: the consequence was, in the instances I observed, scarcely an apple succeeded.

"The assistance, therefore, required from art, in this case, is by keeping the trees in a healthful, vigorous state, to enable them to throw out a strength of bud and blossom; and by keeping them thin of wood, to give them an opportunity of drying quickly before the frost set in.

"The term *blight* is as common and as vague in this as in other districts. Black blighting winds are talked of every where; but no definite idea is anywhere affixed to the expression. That corn and fruit become unproductive without any visible cause, and that fruit trees are liable to be infected with insects, are certainly facts. But whether the insects be the cause or the effects of blights does not seem to be yet settled.

"This year, if the alarm from spring frosts was great, that from black blighting winds was terrible. Yet the consequence is an excess of fruit. The cause appears to me evident in the acquired strength of the trees: they had not borne fruit during four years. The great hit, in 1784, had exhausted them. They were unable to withstand the attack of common enemies. But having, by three years rest, fully recovered their strength and vigour, they this year set the same black blighting winds at defiance, which, next year, may render them altogether unfruitful.

"Two bearing years seldom come together. Next year, however, will have more than a fair chance to set this rule aside, as the interval of rest has been unusually long. A full fruitage every second or third year is all that is expected.

"Are we to suppose, from these circumstances, that because insects are abundant one year, they become few in number the year ensuing? Or, on the contrary, that because they were few in number this year, they shall be numerous the next? It would be much more reasonable to infer, that the trees having been exhausted the preceding year, by an excessive burden of fruit, are not, without some extraordinary circumstances, able to throw out the succeeding season a sufficient strength of blossom, to withstand the natural enemies, with which they are every year assailed: or if, through extraordinary circumstances, they should throw out sufficient blow, that the fruit, for want of a due supply of sustenance, drops abortively from the boughs.

"Hence, perhaps, with respect to blights, all the assistance which art can render, is to keep the trees in a state of healthfulness; and prevent, as much as possible, an excess of fruit.

"Insects are not only hurtful to the blossoms and the leaves, but the larger species are destructive of the fruit; especially of pears. In 1783, a scarce year of fruit, the wasps, which were that year particularly abundant, destroyed

a great share of the pears that were produced. In a fruit-liquor country, it might be prudent to set a price on the female wasps in the spring; by which means the number of nests might be considerably lessened.

"An excess of fruit has several injurious effects: it stunts the growth of young trees, and renders trees in general barren for two or three years afterwards; while the weight of the fruit is frequently fatal. I have this year seen numberless instances, in which the main branches of trees have been split off, solely by the weight of fruit; and many, in which the entire tree had sunk under the weight of its burden.

"The ordinary guards against the mischievous effect of an excess of fruit, are props, forked poles, set under the boughs. Twenty of these props are sometimes employed in supporting the branches of one tree. These, however, are chiefly used in close orchards, where the lower boughs, being less broken by cattle, are longer and more luxuriant than they are in cow-grounds, where props cannot conveniently be used.

"It would be difficult to describe the burden which many trees, this year, had to bear. Notwithstanding the trees were as full of wood as neglect could fill them, every twig, within and without, was loaded with fruit. Of trees of luxuriant growth, the most upright shoots, even to the summit, were rendered pendant with the weight of their produce, hanging down on every side as strings of onions; the fruit appearing, to the distant eye, to cover the entire surface of the tree. I have nowhere else seen fruit trees bear such extraordinary burdens.

"The means of preventing, as much as may be, the evil consequences of an inordinate quantity of fruit, in any one year, is to graft in the boughs; and, when the trees are fully grown, to thin the bearing branches; thereby endeavouring, like the gardener, to grow fruit every year. Young trees which have been whip-grafted, planted out while weak in the stem, and had afterward shot freely, I have seen bowing with their heads to the ground with the weight of fruit, which had been injudiciously suffered to mature upon them.

"Old age cannot be prevented; but the natural life of fruit trees may, no doubt, be protracted, by proper management. Stocks of the native crab, grafted in the boughs, is, in this intention, the most eligible basis; as taking off the underling and crossing boughs while growing, keeping the head within due bounds, and lessening the quantity of bearing wood when the heads are fully grown, are the most likely means to give a lasting superstructure.

"The stage of decline will nevertheless arrive, and a deficiency in fruitfulness will long precede the general decay.

"During the decline of fruitfulness, there is a stage, in which the fruit no longer repays the encumbrance which the ground is subjected to by the tree. Nevertheless, we see trees standing, a burden to the soil, in every stage of decay. But how injudicious, in such a case, is the conduct of their occupiers! If it be a disputable point, whether trees in full fruit be beneficial to a farmer, he may safely conclude, that, after their fruitfulness has in great part declined, they become injurious to him; and if the occupier, through friendship from long acquaintance, or gratitude arising from the many comfortable draughts they have afforded him, cannot muster up resolution to remove them, those who have the management of the estate should see them taken down, while the wood remains in a valuable state; and not suffer them, while the wood is wasting, to remain an incumbrance to the estate.

"In the Vale of Gloucester, I saw an instance of some healthy bearing apple-trees, which now wear the second tops to the same stems. The first tops, being worn out, were cut off, and the stumps saw-grafted. In orchards about a house this expedient may frequently be eligible.

"It is here observable, that the same judicious manager, in whose practice I saw this instance of renewing the heads of trees, could never raise young trees with any success, in an old orchard ground. If, in a close orchard, convenient to an habitation in a country where fruit is scarce, such an attempt should be made, the species of fruit ought certainly to be changed; as from apples to pears; or pears to apples.

"It is likewise observable, in this place, that pear-trees, especially in a strong deep soil, are of much longer duration than apple-trees; outliving, it is said, two or three generations; consequently the two species ought never to be mixed together in the same fruit ground.

"Supposing the ground to have been in grass since the

being now holes nearly large enough to admit the hand, almost to the center of the stem : a premature decay of the tree must be the inevitable consequence.

" In Herefordshire, I saw another orchard, (which has been planted in the same manner, and which has got about the same growth), in which the trees cleave in the crowns ; both grafts having in this case succeeded. The wind having split some of them, and others being in danger of sharing the same fate, the judicious occupier of this orchard has secured them with iron bolts, put through the crowns ; having a broad head at one end, and a long iron pin or key at the other. The heads are already overgrown, and some of the keys nearly buried.

" By letting the stocks remain until they be large enough to be grafted in the boughs ; namely, until the trained boughs be about an inch in diameter ; those evils are avoided, the grafting becomes more certain, there being more chances of success ; and the trees, by forming their ramifications in the natural way, are much less liable to be torn to pieces by the winds. Some time, it is true, may seem to be lost ; the trees certainly will not come so soon to bear ; but it is highly probable, that they will begin to bear a burden of fruit sooner, and will it is much more than probable, continue to bear longer than trees grafted in the stock.

" It has been already mentioned, that, in Herefordshire, the soil of orchards is generally kept under tillage ; in Gloucestershire, in grass. Not, however, I apprehend, so much in pursuance of different principles in the managing of orchards, as from the circumstances of Herefordshire being an arable, Gloucestershire a grass-land country.

" Either practice has its disadvantage. Fruit trees, when fully grown, especially if they are of a spreading growth, and are suffered to form drooping branches, are very injurious to arable crops : their roots, their drip, and their shadows, are destructive, not to corn only, but to clover and to turneps : besides being, under these circumstances, still farther injurious, by preventing a free circulation of air ; and in being in the way of the plough-teams ; which, when the trees are loaded with leaves and fruit, can frequently with difficulty creep under them.

" It is observable, however, that tillage is favourable to the trees ; especially to the growth of young trees. While in grass grounds (under ordinary management) their progress is comparatively slow ; for want of the earth's being stirred about their roots ; and by being injured by the grazing stock ; especially low-headed, drooping trees.

"It is likewise observable, in this place, that pear-trees, especially in a strong deep soil, are of much longer duration than apple-trees; outliving, it is said, two or three generations; consequently the two species ought never to be mixed together in the same fruit ground.

"Supposing the ground to have been in grass since the

trees first acquired their growth, it will, on their removal, be ready for a change of management. The larger roots being removed, suffer the ground to remain in grass, until the smaller roots be decayed; and then break it up for a course of arable crops; in order to assimilate the roots with the soil, and do away the sownness of sward, which low-spreading trees, as those of fruit, will always produce.

"Thus, considering the fruit trees as a crop in husbandry, the general management appears to be this. Plant upon a recently broken up, worn-out sward. Keep the soil under a state of arable management, until the trees be well grown; then lay it down to grass, and let it remain in sward until the trees be removed, and their roots be decayed; when it will require a course of arable management."

Mr. Young, in his *Annals of Agriculture*, vol. V. says, that "Mr. Chevallier, of Aspal in Suffolk, has by much the finest orchards he has seen in the county. A few particulars of them will shew, that the deficiency in this branch of rural œconomy, general through the eastern part of the kingdom, is very unpardonable. In the year 1727, Clement Chevallier, esq. brought from Jersey 144 apple-trees, which were planted on two acres of land; and between that time and 1743, he planted, by grafting, ten acres more, of various sorts; and in order to be able to make the cyder in perfection, he erected such a mill as is used in that island. A circular stone like a mill-stone is drawn round, moving in a circular stone trough, for mashing the apples. The three stones of this trough cost 7l. ready cut and hollowed, in the isles of Chausee, on the coast of Normandy. The mash is taken from the trough, and laid on a square platform, in layers four inches thick, between clean wheat straw, the whole five feet high. The trough holds 20 bushels, and the platform five troughs full; the heap is cut by a hay-knife to three feet square, and the cuttings laid at top. The power of pressure by a lever and screw is so great, that the marc of the apples will burn immediately on taking from the press. A bushel of apples yields four gallons, and the quantity is one sixth more than can be gained by any other press in this country. By means of it, 150 hhds. have been made in three months, of Mr. Chevallier's own crop; and 54 hhds. for his neighbours, at 1d. a gallon; which produced 14l. or enough to pay for the labour of the whole. One man does all; who being a cooper, and working at the casks two days in six, has 2s. a day. The expence of the whole, on an average, is about 1s. 2d. an hhd. The year the orchards produced the 150 hhds. which was 1778 or 1779, it sold in this beer country at 1l. 11s. 6d. per hhd. and some years so high as 3l. 3s. But in 1775 the produce not 1 hhd. For seven years the average has been 40 hhds. and the price we may call 2l. 2s. This is 80 guineas from 12 acres, or 7l. an acre. Now to shew the vast profit of orchards, it is to be noted, that the land occupied by the trees is worth as much as the adjacent grounds within, 3s. an acre; so that, properly speaking, the rent of that ground, which yields this crop of 84l. per annum, is just 1l. 16s. a year.

"The Jersey trees have, upon the whole, produced more fruit than the others. Mr. Chevallier's uncle has trees brought also from thence, that have yielded 15 bush. each tree in a year, or 1 hhd. of cyder.

"Expressing a doubt, whether the mixture of straw with the apples, which is necessary to keep the heap together on an open platform, did not affect the taste of the Cyder, I was assured not; and also that juice, which came first with little or no pressure, was not at all better than that which received the most."

ORCHARD-GRASS, the name of a small, coarse, but very sweet grass. It is of very quick growth, and may possibly hereafter be cultivated to advantage.

There is not any thing which purges a beast so naturally as the green weedy grass which grows under trees in orchards; nor any medicine better than tar, butter, and sugarcandy mixt, and given in balls as big as a hen's egg.

ORE-WEED, a general name for weeds growing at the bottom of the sea, and also on the muddy and rocky parts of the shore.

Sea-weeds are so beneficial a manure, that farmers ought not to grudge the expence of carrying them a few miles. In Devonshire, Cornwall, and other maritime parts of England, these weeds are laid in heaps till they are rotten, and then spread upon the land, about a load to three rods; but this lasts only one year, unless sand, or a stiff earth,

according to the quality of the soil intended to be improved, be laid on or mixed with them; and then they become a lasting manure. In some places these weeds are gathered in heaps, and burnt as soon as they are dry; after which about a bushel of their ashes is laid on upon, three rods of ground. But these, like all other ashes, should be mixed with sand, or stiff earth, if you would have the land last good: otherwise, they are only an improvement for a year. These ashes are particularly good for grass grounds over-run with moss. Loose sandy soils are likewise peculiarly benefited by this weed; but being a submarine plant, the wind and soil soon exhale its moisture; so that the more speedily it is taken from the shore, where storms often throw it up in great quantities, the better it is. When spread on the ground, and afterwards covered over, it soon dissolves into a salt oily slime, proper to fertilize and bind light soils. This is the most approved way of applying it: though some lay it naked and fresh from the sea, upon their barley land, towards the end of March and beginning of April, and have a good crop of corn: but such quantities of rank weeds are apt to shoot up afterwards, that no wholesome plant is to be expected that year.

The value of the lands all along the coast of Scotland has been more than doubled by the use of this excellent manure. It is chiefly used there for barley; and the farmers watch every opportunity, when it is thrown in by the sea, and lay it on at all seasons, in autumn, winter, and spring. But if they could choose their time, it would probably do best about the month of March; for being then ploughed into the ground, and afterwards ploughed up again to the seed, it would be incorporated and blended with the soil; whereas, if it be laid on in autumn, before the fallowing or first ploughing, it is too much wasted before the spring; and if it be laid on the seed furrow, it is apt to burn the ground in a dry season, though it will do very well in this method in a wet summer. Its effects are but just felt the second year; though it is laid on thicker upon strong clay land, which receives no other manure for three crops, viz. barley, oats, pease, and beans; a method which might, perhaps, be altered for the better, by omitting the oats, and sowing alternately barley, and pease and beans, and laying on the sea-ware, as these weeds are commonly called, for every second crop of pease and beans.

We see, by the abridgement of Mr. Scott's account of the manner of using sea-ware in Scotland (published by Mr. Maxwell in his *Miscellaneous Papers*), that much of this valuable manure must necessarily be lost through want of proper management: for they have no reservoirs to keep it in, when thrown ashore at a season in which they cannot use it, or where there is no ground in tilth, as is generally the case in winter, and during the busy part of their hay and corn harvest. It should be collected on these occasions, and lodged in a place free from any running water; and, as it is equally beneficial to strong or light lands, it might be there covered with sand or clay, according to the nature of the soil for which it is intended. This will prevent its being parched by the sun, or its dissolving into a putrid mass, which if not secured in this manner, would either be washed away by rains, or fly off into the air; whereas, when thus covered, it would greatly enrich the clay or sand, and render them good manures for their opposite soils. If it be thrown ashore at a time when it can be ploughed in directly, that is certainly the best manner of using it.

Mr. Scott observes, that there is a kind of land all along the coast, which is gravelly, and covered over so thick with sea-stones, that, to look at it, one would not think corn could spring through them; and another sort of land, which is a deadish sand. To both these grounds sea-ware is the only manure; for dung of all kinds has been often tried, but with no success; and yet sea-ware makes them bring excellent crops of barley. This kind of ground is seldom ploughed more than twice, and the sea-weed is generally laid on before the first ploughing. Barley is sowed during two years, and pease the third; a fresh manure of sea-weed being laid on each year that barley is sown. As little wheat is cultivated in the country where Mr. Scott lived, the farmers there might probably improve their practice of raising barley and pease, by sowing them alternately, and laying the sea-ware to the pease. In the summer it is carried to a distance from the sea, and laid upon ley-ground, (arable land under grass), which, though in very ill heart, will bear a good crop of oats with only once ploughing, or of barley if ploughed again in the spring.

Another

Another kind of sea-ware, of a much stronger nature than that which is thrown up by the waves, is cut from the rocks at low water, and will last three years. It costs more labour, but brings greater recompence. Mr. Scott thinks the best time of laying this on the ground would be in autumn, before the land is ploughed rough for a spring crop.

The farmers on the coast of Scotland (and I believe the same may be said, in general, of those in most of the maritime parts of England) prefer this manure to any other, especially for their light grounds; and it has the advantage of being much more easily transported, because one load of it will go as far as two of dung.

It does very well in kitchen gardens, where Mr. Scott says he has seen pot-herbs and roots of an extraordinary size produced by its help; to which he adds, that he has known fruit-trees, perfectly barren before, rendered extremely fruitful by laying this manure about the roots.

Mr. Duhamel likewise informs us, that these sea-weeds are used with great success in the maritime provinces of France.

OSSELETS, are little bones and hard excrescences in the knees of some horses, so called in French.

There are also three kinds of osselets, which are of the same nature as splints, and some persons take them for the same thing; but there is this difference, however between them, that splints come near the knees, and osselets near the fetlocks. Their seat is indifferently within or without the leg.

The first is the simple osselet, which does not grow near the joint of the fetlock or the nerve.

This need not hinder any man from buying a horse, because it puts him to no inconvenience, and very often goes away of itself without a remedy. The second is, that which descends into the fetlock, and hinders the motion of that joint; this occasions a horse to stumble and fall, and with a very little work to become lame. The third has its seat between the bone and the nerve, and sometimes upon the nerve; it so much incommodes a horse that he cannot stand firm, but limps on every little occasion.

OST, *Oost*, or *Oust*. See **OUST**.

OTTER. Some are of opinion, that the otter is of the beaver kind, being an amphibious creature, living both in the water and on the land; besides, the outward form of the parts bears a likeness of the beaver; some say, were his tail off, he were in all parts like the beaver, differing in nothing but habitation; for the beaver frequents the salt water as well as the fresh, but the otter never goes to the salt.

Though the otter lives in the water, yet he does not, like fishes, breathe through the benefit of the water; he taketh breath like other four-footed beasts; yet will remain a long time underneath the water without respiration.

These animals are great devourers of fish, and will travel ten or twelve miles in the space of a night. Their chief haunts are under the roots of trees near the water. Some take them with hunting-dogs; some by means of snares; and others kill them with spears.

The shortest way of destroying them is to lay, near their haunts, an eel, slit on the back, with raskane put in the slit, and then sew it up again. Place the eel, from the navel upwards, out of the water, and the Otter will eat it so far, but seldom farther; and his destruction is certain.

If he wants prey in the waters, then he will quit them for the land; and if by painful hunting on shore he cannot fill his belly, he will feed on herbs, snails, or frogs; neither will he take less pains in the water to satisfy his hunger; for he will swim two miles together against the stream, that so, when he has filled his belly, the current may carry him down again to his designed lodging, which is always near the water, very artificially built with boughs, sprigs, and sticks couched together in excellent order, wherein he sits to keep him from the wet.

In the hunting of fish, he often puts his nose above water to take breath: he is a creature of wonderful swiftness and nimbleness in taking his prey; and for greediness, takes more than he knows what to do with.

He is a very crafty and subtle beast, and endowed with a wonderful sagacity and sense of smell.

The flesh of this beast is both cold and filthy, because it feedeth on stinking fish.

OVER-DONE, **OVER-RID**, or **OVER-WORKED**; a

horse is so called, when his wind and strength are broken and exhausted with fatigue.

OVER-REACH. A Horse is said to over-reach, when he brings his feet too far forwards, and strikes his hinder toes against the spunges of his fore-shoe.

A horse over-reaches through a weakness in the back, or by being suffered to bear too much upon the shoulders.

OVER-REACH, is also a wound in the fore-heel of a horse, made by the point of the hind-shoe.

When this wound is only slight or superficial, it is, in general, very easily cured by washing it clean, and applying the wound-ointment: but it should be observed, from the nature and manner of the injury, where the blow has been smart, that it differs widely from a common cut; the part here being both torn and bruised, and consequently it requires to be properly digested, in order to lay a good foundation for healing.

For this purpose, after washing out any dirt or gravel with sope-suds, &c. let the wound be digested, by dressing it with dossils of lint dipped in an ounce of Venice turpentine, divided with the yolk of an egg, to which half an ounce of tincture of myrrh may be added: over this dressing it would be advisable to apply the turnep poultice, or that with strong-beer grounds and oatmeal, three or four times, or oftener, till the digestion is procured, and then both these dressings may be changed for the precipitate medicines, or the lime-water mixture: observing always to apply the dossils carefully to the bottom, to fill up the sore with the same, even to the surface, and to bind all on with a compress and roller: and if any cavities appear that cannot conveniently be dressed to the bottom, they should always be laid open, or no proper foundation for healing can be obtained. The hoof also should be kept supple, or pared away, when the growth of it interrupts this end, as is sometimes the case. *Bartlett's Farriery*, page 244.

OUGHTS, leavings.

OUST, a kiln, generally applied to that used in drying hops.

It is built with fire-places, in the nature of malt-kilns; and at a proper distance over the fire is an hair-cloth strained upon laths; and thereon the hops are laid, and raked even, to the depth of about six or seven inches, for the better conveniency of drying them equally: and when they are properly cured on the under side, they are carefully turned; and by that means the upper side becoming the under, the whole shares the fire alike. The person that performs this part is called the dryer, whose business it is to manage the fires.

The fuel commonly made use of is charcoal, for its freedom from smoke, and affording a steady heat. Great nicety is required in this part; a small fire being to be made, at first, that they may heat gradually, and so raised as they dry, that it may be done without scorching; and the fire is to be lowered by degrees, against they are ready to be taken off: the time required is about eight hours.

But as charcoal is very dear, being three or four pounds per load, many people have adopted the method of drying with sea-coal, upon what they call cockle-ousts, which are square iron boxes placed upon brick-work, and a flue and chimney in the back part of the building for the smoke to go off. The computation is, that a chaldron of sea-coal, at about twenty-four shillings, will dry a load of hops, and that a load of charcoal will do no more. It is indeed expensive to erect such ousts, as there must be no timber near them; and an iron beam and iron laths are to be used, and they covered with plates of tin or iron properly fastened together.

A gentleman has lately claimed the merit of having invented a new method of drying hops with sea-coal, or any kind of fuel whatever, by means of a moveable iron furnace: it is in form of an horizontal cylinder, stopped at both ends: it lies on an iron carriage, which rolls on four iron wheels: in the fore-end of the cylinder is the furnace door, and a hollow iron flue runs in an horizontal direction along the upper surface of the cylinder from the back, till it reaches the fore-end of it, when it takes a vertical direction, and is carried as high as is necessary to convey the smoke out of the oust. We cannot pretend to say what are the particular advantages resulting from the use of this rolling furnace, never having seen it at work.

OUST-HOUSES, out-houses, or such as belong to, and are adjoining to the dwelling-houses.

OX, the name of an animal well known, being a bull castrated.

Oxen, like other domestic animals, vary in colour, though the dun seems the most common; and the redder it is, the more it is esteemed. A black coat is also valued; and bay oxen are said to be vigorous and long-lived; whereas the brown soon decay. The grey, the dappled, and the white, are proper only for slaughter; no care can render them fit for labour; but whatever be the colour of an ox's coat, it should be glossy, thick, and smooth to the touch; for if it be harsh, tough, or thin, there is reason to suppose that the animal is out of order, or at least not of a strong constitution. A good ox for the plough must be neither too fat nor too lean; the head short and thick; the ears large and shaggy; the horns strong, glossy, and of a middling size; the forehead wide; the eyes full and black; his muzzle large and flat; the nostrils wide and open; the teeth white and even; the lips black, a fleshy neck, large and heavy shoulders; the breast broad; the dew-lap hanging down to the knees; the reins very broad; a spacious descending belly; the flanks firm; the haunches large; and the rump thick; large and nervous thighs and legs; the back straight and full; the tail reaching to the ground, and well covered with thick and fine hair; the feet firm; the hide thick and pliable; the muscles raised; the hoof short and broad: he must also answer to the goad, be obedient to the voice, and well trained; but it is only gradually, and by beginning early, that the ox can be brought willing to bear the yoke, and be easily governed. At the age of two years and a half, or three at the latest, you must begin to tame him and bring him under subjection; if delayed longer, he becomes froward, and often ungovernable. The only method of succeeding is, by patience, mildness, and even caresses; for compulsion and ill treatment will only disgust him irreclaimably; stroaking him gently along the back, clapping him, giving him occasionally boiled barley, ground beans, and such other aliments as please him best, all of them mingled with salt, of which he is very fond, will prove of the greatest use. At the same time his horns should be often tied, and some days after, the yoke is to be put on his neck, and fastened to a plough, with another ox of the same size ready trained; these are to be tied together at the manger, and in the same manner led to the pasture, that they may become acquainted, and accustomed to have one common motion. The goad is never to be made use of in the beginning, as that would only render him more untractable; he must also be indulged, and labour only at short intervals: for till he is thoroughly trained, he tires himself very much; and for the same reason he is to be fed more plentifully than at other times.

Mr. Marshall made several experiments on their utility in the plough, and strongly recommends the use of them for most draft purposes, as no horses draw better. He remarks that full grown oxen in general are much longer made than horses, too long for common shafts, not having room to back the Cart; for which reason the shafts should be made long enough to admit it. Ox-collars are strongly recommended. See COLLARS.

The comparative merits and demerits of beasts of labour, depend on their first cost, their keep, their work, and their value after working.

A powerful, handsome, six-years-old ox, may be purchased for ten or twelve guineas; but a powerful handsome six-years-old horse will cost from twenty to twenty-four guineas. Suppose that ten guineas a head are saved by purchasing oxen instead of horses, and that a farmer has occasion for three teams, he will have an addition, every ten or twelve years, of one hundred and twenty-guineas to stock and manage his farm with.

Their keep depends in some measure on the prices of hay and corn, and on the size and voraciousness of the beast to be fed. Taking into the account the unavoidable pilfering of carters, perhaps, on an equality of time, an ox may be kept at two thirds of the expence of a large cart-horse.

In their work, it is unnecessary here to contend for superiority, but you may aspire at equality. Oxen are equally tractable and equally versatile. Their strength depends upon their age and breed, and their activity on their make and strength.

A two-years-old ox is as worthless in work as a two-years-old horse; and the working of either is unpardonable. An ox does not arrive at full strength, especially if worked while young, until he be six years old. At that

age, a large deep-chested ox is equal in strength to a strong well-made cart-horse. Mr. Marshall says he is not so partial to oxen as to imagine that they can do whatever horses can do: he is nevertheless nearly positive, that whatever farming-horses do, oxen (of a proper age and properly managed) can do. On the road they are beyond all doubt, equal to horses, and at plough they are not inferior, except their work be very heavy. In heavy work they will not strive like horses, but will in defiance keep their steady pace. In this point of view, and in this only, oxen are unequal to horses. Indeed also, he never worked oxen all the year round, as horses are done, but he has always given a month's marshing in the spring, and they have generally had some idle days in winter; their fodder however, in this case, has been proportionable.

For their value after working, see CART-HORSE.

In his Rural Economy of Yorkshire he says, "the long-agitated dispute about the superiority of oxen or horses, as beasts of draught, may here be considered with singular propriety. But I am afraid even this country will not furnish sufficient evidence for a final decision.

"Formerly, and from time immemorial, four or six oxen in yokes, led by two horses, also double, were the invariable draught or team of the country; not only upon the road, but in ploughing. Even in stirring a fallow, four oxen and two horses were generally considered as requisite. And in breaking up a fallow, two men and a boy were the common attendants of this unwieldy, expensive team.

"At present, there is not perhaps, throughout the Vale, a single ox employed in tillage: two horses with whip-reins, without a driver, is now the universal plough-team for all soils, in almost every state.

"Upon the road, however, that is to say, in farm carriages, oxen are still in use: but seldom more than a single pair to a carriage; generally at the pole, with two or three horses at length before them. Beside, a number of entire horse-teams now travel upon the roads; things which formerly were unknown in the country.

"Even the timber-carriers (an industrious, wary set of men) continue to use them; though their sole employment be upon the road. They not only find them able to stand working every day, provided their feet do not fail them; but, what is much in their favour, they are found to stand long hours better than horses going in the same pasture. An ox in a good pasture soon fills his belly, and lays himself down to rest; whereas a short summer's night scarcely affords a horse time enough to satisfy his hunger.

"Another advantage of oxen is here held out. In stiff pulls of every kind, most especially in going up steep hills, a pair of oxen are considered as a sheet-anchor. Horses, it is argued, are fearful, and soon lose their feet in a steep slippery road; while oxen, where they are unable to proceed, will always stand their ground. Indeed oxen seem to be considered as essentially necessary in an awkward hilly country.

"If we had no other species of animals adapted to the purpose of draught in the island, nor any one which could be naturalized to the climate, cart-horses would be truly valuable; they being much superior to the breed of saddle-horses for the purpose of draught.

"But it appears to me evident, from the experience I have had, and the observations I have made, that were only a small share of the attention paid to the breeding of draught oxen, which now is bestowed on the breeding of cart-horses; animals equally powerful; more active; less costly; equally adapted to the purposes of husbandry, (if harnessed with equal judgment); less expensive in keep and attendance; much more durable; and infinitely more valuable after they have finished their labours, might be produced."

An ox is to draw the plough only from his third to his tenth year, when it will be advisable to fatten and sell him, as being then of a better flesh than if he was kept longer. The age of this creature is known by his teeth and horns. The first fore-teeth, which he sheds at the end of ten months, are replaced by others, larger, but not so white; at six months the teeth next to those in the middle, fall out, and are also replaced by others; and in three years all the incisive teeth are renewed. They are then equal, long, and pretty white; but as the ox advances in years, they wear, become unequal, and black. It is the same

same in the bull and cow : so that the growth and shedding of the teeth are not affected by castration, or the difference of sexes. Nor is the shedding of the horns affected by either; as both bull, ox, and cow, lose them alike at the end of three years; and these also are replaced by other horns, which, like the second teeth, remain; only those of the ox and cow are larger and longer than those of the bull. The manner of the growth of these second horns is not uniform, nor the shooting of them equal. The first year, that is the fourth of the ox's age, two small pointed horns make their appearance nearly formed, smooth, and towards the head terminated by a kind of button. The following year, this button moves from the head, being impelled by a corneous cylinder, which also lengthening, is terminated by another button; and so on; for the horns continue growing as long as the creature lives. These buttons become annular joints, which are easily distinguished in the horn, and by which the age of the creature may be readily known; counting three years for the point

of the horn to the first joint, and one year for each of the other intervals.

OX-BOOSE, an ox-stall, or cow-stall, where these creatures stand in the winter.

OX-HARROWS, very large harrows, called in some counties, drags.

OX-GANG, or *Ox-gate*, a quantity of land measuring fifteen acres, being as much ground as a single ox is supposed to be capable of ploughing in a year.

OX-FEET, in a Horse, is when the horn of the hind-foot cleaves just in the very middle of the fore-part of the hoof, from the coronet to the shoe: they are not common, but very troublesome, and often make a horse halt.

OX-LEGS. An imperfection in some horses, which, though they have the back sinew of their fore-legs somewhat separate from the bone, yet their sinews are so small, and so little set off, that their legs will become round, after small labour.

P.

P**ACK-SADDLE**, a saddle adapted to the carriage of heavy packs or burdens.

PAD, the road, a foot-path; also an easy-paced horse; likewise a low saddle.

PADLLE-STAFF, an instrument used by the ploughman to free the share from stubble, clay, &c. which hinder its action.

PADDOCK, a small field or inclosure. It also signifies a large frog or toad.

PAIGLE, a cowslip.

PAIL, a wooden vessel in which milk or water is commonly carried.

PAINTING CHEESES. See **CHEESE**.

PALATE, the upper part or roof of the mouth.

In a horse, the palate should be lean, for if it be fat, i. e. full and high, so as to be almost equal with the extremities of his upper teeth, the least height in the liberty of a bitt will be troublesome, and make him either chack in the bridle, and be always throwing up his head, or otherwise carry it too low, which, besides the unsightliness, will much annoy the rider's hand.

Horses are commonly bled in the palate with a sharp-pointed horn, to refresh and give them an appetite.

PALMS, the male flowers of the willow.

PALSY, a disease common to horses, wherein the body, or some of its members, lose their motion, and sometimes their sensation of feeling.

In paralytic disorders, where the use of a limb or limbs is taken away, the internals (recommended under the article **STAGGERS**) should be given in order to warm, invigorate, and attenuate the blood; and the following stimulating embrocation should be rubbed into the parts affected:

Take oil of turpentine four ounces; nerve ointment and oil of bays, of each two ounces; camphor rubbed fine, one ounce; rectified oil of amber, three ounces; tincture of cantharides, one ounce.

With this liniment the parts affected should be well bathed for a considerable time, to make it penetrate; and when the hind parts are chiefly lame, the back and loins should be well rubbed with the same: to the nervous medicines above recommended, may be added snake-root, contrayerva, mustard-seed, horse-raddish root steeped in strong beer, or wine, where it can be afforded. Take the following for an example, which may be given to the

quantity of three pints a day alone, or two hornsfull may be taken after the nervous balls:

Take snake-root, contrayerva, and valerian, of each half an ounce; mustard-seed and horse-raddish root scraped, of each two ounces; long-pepper two drams: infuse in three pints of strong beer or wine.

When the horse is recovering from any of the above disorders, the following alterative purge may be repeated two or three times, as it operates very gently:

Take succotrine aloes one ounce; myrrh half an ounce; assa foetida and gum ammoniacum, of each two drams; saffron one dram: make into a ball with any syrup.

Where a retention of dung is the cause of this disorder, the great gut should be first raked thoroughly with a small hand; after which plenty of emollient oily clysters should be thrown up, and the opening drink given, till the bowels are thoroughly emptied of their imprisoned dung. Their diet should for some days be opening, and consist chiefly of scalded bran, with flour of brimstone, scalded barley, &c.

PANIC, a plant resembling millet in its stalks, leaves, and roots; but differing in its spikes, or ears, which are about the thickness of a man's finger at their base, and growing taper toward their points. They are about eight or nine inches long, and closely set with a small roundish grain, sometimes white, sometimes red and purple, and sometimes yellow. It is raised and reaped in the same manner as millet, but does not require so much rain. This plant grows naturally in both the Indies, and is cultivated in several parts of Europe for the food of men. Cakes and bread are made of it in Germany, Italy, and the southern parts of France; but it is not reckoned so good nourishment as millet; nor is the German sort so much esteemed as the Italian; though the former ripens best in cold countries, where it is frequently sowed in land which will not produce better grain. It thrives most in a dry stiffish soil, such as the sides of hills, and even in stony ground; grows to the height of about four feet, and branches very much; for which reason the horse-hoeing husbandry is by far the fittest for it. The plants, if managed rightly, should stand at least eighteen inches asunder, in rows three feet apart, that

that there may be room to hoe the ground between them, and to keep them clear from weeds. When grown pretty tall, they should be supported by stakes, lest the wind break them down, and particular care must be taken to guard against birds, when their seeds begin to ripen.

PANNAGE, the food which swine feed upon in woods, as acorns, and the mast of beech. It also signifies the money taken by the king's agiftors, for the privilege of feeding hogs in the king's forests.

PANNEL, a low saddle.

PARING *the sole.* See the article **SHOEING HORSES.**

PARSNAP, the name of a plant propagated for the sake of its root.

Parsneps require a rich, mellow, and deep soil; in order that their roots, according to the bigness and length of which they are esteemed, may have full room to thicken and run downward. The seeds of these plants should be sown in February or March, either alone or with carrots, especially if it be intended to draw these last very young; because parsneps seldom spread much before the latter end of summer, by which time the carrots will, in this case, be gone. The practice of those gardeners who sow leeks, onions, and lettuces, with parsneps, is very wrong; because so many different growths must impoverish one another.

The young parsneps must be hoed and weeded, or if they were sown in rows, the ground between those rows must be dug three or four times in the spring, or whenever else many weeds appear. By the latter end of the summer their leaves will cover the ground, and prevent the farther growth of weeds; so that they will not require any more care after that season.

When their leaves begin to decay, their roots may be dug up for use: but they are seldom well tasted before that time; nor are they good for much late in the spring, after they have shot out again. They, therefore, who would preserve them for spring use, should dig them up in the beginning of February, and bury them in sand in a dry place, where they will remain good until the middle of April, or later.

To save the seeds of this plant in the most advantageous way, some of the longest, straightest, and largest roots should be singled and planted out about two feet asunder, in a place where they will be defended from the strong south and west winds; for the stems of the parsneps generally grow to a great height, and are very apt to be broken by strong gusts of wind, if they are exposed thereto. This ground should also be kept clear from weeds; and if the season should prove dry, watering of these plants moderately, twice a week, will increase the quantity, and improve the quality of their seeds, which will be about the end of August or the beginning of September, when the heads should be carefully cut off, and spread upon a coarse cloth for two or three days to dry. The seeds should then be beaten off, and put up for use. But neither these nor carrot-seeds should be depended on after they are above a year old.

Parsneps are an excellent, wholesome, and very nourishing food for cattle. Their culture, as I have just observed, is exactly the same as that of carrots, with which they may be sown in the same ground. Their leaves will decay at nearly the same time, when the roots may be dug up, and laid by for use; likewise buried in dry sand, in a dry place.

Parsnep-seeds seldom grow after they are above a year old.

It has long been a custom, in some parts of Britany, to sow parsneps in the open field for the food of cattle; as we are informed by the first volume of the Transactions of a society instituted in that province, for the encouragement of the economical and commercial interests of their country. "It is of great importance," say they, "that parsneps should be universally cultivated; because they afford an excellent and wholesome food for all kinds of cattle during the winter, and may be used to great advantage to fatten them. Our hogs have no other food in all that season, and our bullocks and oxen thrive well upon it. Our cows fed with parsneps, give more milk than with any other winter fodder, and that milk yields better butter than the milk of cows nourished with any other substance. Our horses fatten with this food: though some pretend that it renders them less mettlesome, and hurts their legs and eyes.

"Cattle eat these roots raw at first, sliced lengthwise; and when they begin not to relish them, they are cut in pieces, put in a large copper, pressed down there, and boiled with only so much water as fills up the chafins be-

tween them. They then eat them very greedily, and continue to like them."

PARTERRE, a level division of ground, which, for the most part, faces the south and best front of the house, and is generally furnished with greens, flowers, &c.

There are several sorts of parterres; as plain grass with borders, and parterres of embroidery, &c.

Plain parterres are more beautiful in England than in any other country, by reason of the excellency of our turf, and that decency and unaffected simplicity that it affords to the eye of the spectator. Other parterres are cut into shell and scroll work, with sand alleys between them; which sort of parterres are esteemed finest in France.

As to the general proportion of parterres, an oblong, or long-square, is esteemed the best: therefore, a parterre should not be less than twice as long as it is broad; twice and a half is accounted a very good proportion; and it is very rare that three times is exceeded. As to the breadth of a parterre, it is to take its dimensions from the breadth of the front of the house; if the front of the house is one hundred feet long, the breadth of the parterre should be one hundred and fifty feet; and if the front of the house be two hundred feet, the parterre should be fifty feet broader; but where the front exceeds the breadth of this parterre, it will be a good proportion to make the parterre of the same dimensions with the front.

There should be a terrace-walk on each side of the parterre, for an elevation proper for view; and therefore, there should never be the flat of a parterre between terrace-walk and terrace-walk, above three hundred feet; nor can it be well made less than one hundred and forty. As to the adorning and furnishing these parterres, whether it be plain or with embroidery, that depends much upon the form of them, and therefore must be left to the judgment and fancy of the designer.

PARTRIDGE, a timorous and simple bird, and is so valuable at the table, that there are a great many ways of taking it, invented by the sportsmen; all of which succeed, from the folly and fear of the animal.

The places that partridges most delight in, are cornfields, especially while the corn grows; for that is a safe retreat, where they remain undisturbed, and under which they usually breed. They frequent the same fields after the corn is cut down, and that with another intent; for they then feed on the corn that has fallen from the ears, and find a sufficient shelter for them under covert of the stalks, especially of those of wheat stubble. When the wheat stubble is much trodden by men or beast, they retire to the barley stubble, and will there hide themselves in coveys of twenty or thirty. When the winter comes on, and the stubble-fields are trodden down or ploughed up, they then retire to the upland meadows, where they lodge in the high grass, and among rushes; sometimes they resort to the low coppice woods, especially if there be corn-lands near them.

PASTERN *of a horse*, the distance between the joint of the mane and the coronet of the hoof.

This part should be short, especially in the middle-sized horses, because long pasterns are weak, and cannot so well endure travel: some have pasterns so long and flexible, that the horse in walking almost touches the ground with them, which is a great imperfection, and a sign of little or no strength, such horses not being fit for any kind of toil and fatigue.

PASTERN-JOINT, the joint next a horse's foot, which is said to be crowned, when, without being galled or hurt, there is a swelling round it beneath the skin, in form of a circle, about half the breadth of one's finger.

It proceeds from a humour gathered by much travel, and shews that the horse's legs have been too much used.

When the pastern-joint swells after travelling, chase it every morning and evening with a mixture of two parts of brandy and one of oil of nuts.

If the swelling be large, apply the red honey-charge with a convenient bath; and if it be hard, lay on a poultice of rue boiled in thick wine.

PASTURE, or **PASTURE LAND**, a general name for all sorts of land reserved for the purposes of feeding cattle.

Pasture ground is of two sorts: the one is low meadow land, which is often overflowed; and the other is upland, which lies high and dry. The first of these will produce a much greater quantity of hay than the latter, and will not require manuring or dressing so often: but then the hay produced on the upland is much preferable to the other;

other; as is also the meat which is fed in the upland more valued than that which is fattened in rich meadow: though the latter will make the fatter and larger cattle, as is seen by those which are brought from the low rich lands in Lincolnshire. But where the people are nice in their meat, they will give a much larger price for such as hath been fed on the downs, or in short upland pasture, than for the other, which is much larger. Besides this, dry pastures have an advantage over the meadows, that they may be fed all the winter, and are not so subject to poach in wet weather; nor will there be so many bad weeds produced; which are great advantages, and do, in a great measure, recompense for the smallness of the crop.

We have already mentioned the advantages of meadow land, or such as is capable of being overflowed with water, and given directions for draining and improving low pasture land, under the article LAND; therefore shall not repeat that here, but just mention some methods for improving of upland pasture.

The first improvement of upland pasture is, by fencing it, and dividing it into small fields of four, five, six, eight, or ten acres each, planting timber trees in the hedge-rows, which will screen the grass from the dry pinched winds of March, which will prevent the grass from growing in large open lands; so that, if April proves a dry month, the land produces very little hay; whereas in the sheltered fields the grass will begin to grow early in March, and will cover the ground, and prevent the sun from parching the roots of the grass, whereby it will keep growing, so as to afford a tolerable crop, if the spring should prove dry. But, in fencing of land, it must be observed, as was before directed, not to make the inclosures too small, especially where the hedge-rows are planted with trees; because, when the trees are advanced to a considerable height, they will spread over the land; and, where they are close, will render the grass sour; so that, instead of being of an advantage, it will greatly injure the pasture.

The next improvement of upland pasture is, to make the turf good, where, either from the badness of the soil, or for want of proper care, the grass hath been destroyed by rushes, bushes, or mole-hills. Where the surface of the land is clayey and cold, it may be improved by paring it off, and burning it in the manner before directed: but, if it is an hot sandy land, then chalk, lime, marle, or clay, are very proper manures to lay upon it: but this should be laid in pretty good quantities, otherwise it will be of little service to the land.

If the ground is over-run with bushes or rushes, it will be a great advantage to the land to grub them up towards the latter part of summer; and after they are dried to burn them, and spread the ashes over the ground just before the autumnal rains; at which time the surface of the land should be levelled, and sown with grass-seed, which will come up in a short time, and make good grass the following spring. So also, when the land is full of mole-hills, these should be pared off, and either burnt for the ashes, or spread immediately on the ground, when they are pared off, observing to sow the bare patches with grass seed, just as the autumnal rains begin.

Where the land has been thus managed, it will be of great service to roll the turf, in the months of February and March, with an heavy wood roller; always observing to do it in moist weather, that the roll may make an impression: this will render the surface level, and make it much easier to mow the grass, than when the ground lies in hills; and will also cause the turf to thicken, so as to have what the people usually term a good bottom. The grass, likewise, will be the sweeter for this husbandry, and it will be a great help to destroy bad weeds.

Another improvement of upland pastures is, the feeding of them: for where this is not practised, the land must be manured at least every third year: and where a farmer hath much arable land in his possession, he will not care to part with his manure to the pasture. Therefore every farmer should endeavour to proportion his pasture to his arable land, especially where manure is scarce, otherwise he will soon find his error; for the pasture is the foundation of all the profit which may arise from the arable land.

Whenever the upland pastures are mended by manure, there should be a regard had to the nature of the soil, and a proper sort of manure applied: as for instance, all hot sandy land should have a cold manure; neat's dung and swine's dung are very proper for such lands; but, for cold lands, horse-dung, ashes, and other warm manures,

are proper. And when these are applied, it should be done in autumn, before the rains have soaked the ground, and rendered it too soft to cart on; and it should be carefully spread, breaking all the clods as small as possible; and then harrowed with bushes, to let it down to the roots of the grass. When the manure is laid on at this season, the rains in winter will wash down the salts, so that the following spring the grass will receive the advantage of it.

There should also be great care had to the destroying of weeds in the pasture every spring and autumn; for, where this is not practised, the weeds will ripen their seeds, which will spread over the ground, and thereby fill it with such a crop of weeds as will soon overbear the grass, and destroy it; and it will be very difficult to root them out, after they have gotten such possession; especially ragwort, and such other weeds as have down adhering to their seeds.

These upland pastures seldom degenerate the grass which is sown on them, if the land is tolerably good whereas the low meadows, which are overflowed in winter, in a few years turn to an harsh rushy grass, though the upland will continue a fine sweet grass for many years without renewing.

There is no part of husbandry, of which the farmers are in general more ignorant than that of the pasture: most of them suppose, that when old pasture is ploughed up, it can never be brought to have a good sward again; so their common method of managing their land, after ploughing, is, to sow, with their crop of barley, some grass seeds, as they call them; that is, either the red clover, which they intend to stand two years after the corn is taken off the ground, or rye-grass, mixed with trefoil: but as all these are, at most, but biennial plants, whose roots decay soon after their seeds are perfected; so, the ground, having no crop upon it, is again ploughed for corn: and this is the constant round which the lands are employed in, by the better sort of farmers; for I never have met with one of them who had the least notion of laying down their land to grass for any longer continuance; therefore, the seeds which they usually sow, are the best adapted for this purpose.

But, whatever may have been the practice of these people, I hope to prove, that it is possible to lay down land, which has been in tillage, with grass, in such a manner, as that the sward shall be as good, if not better than any natural grass, and of as long duration. But this is never to be expected, in the common method of sowing a crop of corn with the grass seeds: for, wherever this has been practised, if the corn has succeeded well, the grass has been very poor, and weak; so that, if the land has not been very good, the grass has scarcely been worth saving: for the following year it has produced but little hay, and the year after the crop is worth little, either to mow or feed. Nor can it be expected to be otherwise; for the ground cannot nourish two crops: and, if there were no deficiency in the land, yet the corn, being the first, and most vigorous of growth, will keep the grass from making any considerable progress; so that the plants will be extremely weak, and but very thin, many of them which came up in the spring, being destroyed by the corn: for, whenever there are roots of corn, it cannot be expected there should be any grass. Therefore the grass must be thin, and, if the land is not in good heart, to supply the grass with nourishment, that the roots may branch out after the corn is gone, there cannot be any considerable crop of clover: and, as their roots are biennial, many of the strongest plants will perish soon after they are cut; and the weak plants, which had made but little progress before, will be the principal part of the crop for the succeeding year: which is many times not worth standing.

Therefore, when ground is laid down for grass, there should be no crop of any kind sown with the seeds; and the land should be well ploughed, and cleaned from weeds, otherwise the weeds will come up the first, and grow so strong, as to overbear the grass, and if they are not pulled up, will entirely spoil it. The best season to sow the grass seeds upon dry land is about the middle of September, or sooner, if there is an appearance of rain: for the ground being then warm, if there happen some good showers of rain after the seed is sown, the grass will soon make its appearance, and get sufficient rooting in the ground before winter, so will not be in danger of having the roots turned out of the ground by frost, especially if the ground is well rolled before the frost comes on, which will press it down, and fix the earth close to the roots. Where this hath not been practised, the frost has often loosened the ground so much, as to let in the air to the roots of the grass, and done it great damage; and this has been brought as an

objection to the autumnal sowing of grafs : but it will be found to have no weight, if the above direction is practised : nor is there any hazard of sowing the grafs at this season, but that of dry weather, after the seeds are sown ; for if the grafs comes up well, and the ground is well rolled in the end of October, or the beginning of November, and repeated again the beginning of March, the sward will be closely joined at bottom, and a good crop of hay may be expected the same summer. But, where the ground cannot be prepared for sowing at that season, it may be performed the middle or latter end of March, according to the season's being early or late ; for, in backward springs, and in cold land, we have often sowed the grafs in the middle of April, with success : but there is danger, in sowing late, if dry weather, and especially if the land is light and dry ; for we have seen, many times, the whole surface of the ground removed by strong winds at that season ; so that the seeds have been driven in heaps to one side of the field. Therefore, whenever the seeds are sown late in the spring, it will be proper to roll the ground well soon after the seeds are sown, to settle the surface, and prevent its being removed.

The sorts of seeds which are the best for this purpose, are, the best sort of upland hay-seeds, taken from the cleanest pastures, where there are no bad weeds : if this seed is sifted to clean it from rubbish, three bushels will be sufficient to sow an acre of land. The other sort is the *trifolium pratense album*, which is commonly known by the names white Dutch clover, or white honeyfuckle grafs. Eight pounds of this seed will be enough for one acre of land. The grafs seeds should be sown first, and then the Dutch clover-seed may be afterwards sown : but they should not be mixed together ; because the clover-seeds, being the heaviest, will fall to the bottom, and consequently the ground will be unequally sown.

When the seeds are come up, if the land should produce many weeds, these should be drawn out before they grow so tall as to overbear the grafs : for where this has been neglected, the weeds have taken such possession of the ground, as to keep down the grafs, and starve it ; and, when these weeds have been suffered to remain until they have shed their seeds, the land has been so plentifully stocked with them, as entirely to destroy the grafs : therefore it is one of the principal parts of husbandry, never to suffer weeds to grow on the land.

If the ground is rolled two or three times, at proper distances after the grafs is up, it will press down the grafs, and cause it to make a thicker bottom : for, as the Dutch clover will put out roots from every joint of the branches which are near the ground, so, by pressing down of the stalks, the roots will mat so closely together, as to form a sward so thick as to cover the whole surface of the ground, and form a green carpet ; and will better resist the drought. For, if we do but examine the common pastures in summer, in most of which there are patches of this white honeyfuckle grafs growing naturally, we shall find these patches to be the only verdure remaining in the fields. And this, the farmers in general acknowledge, is the sweetest feed for all sorts of cattle ; yet never had any notion of propagating it by seeds : nor has this been long practised in England ; for, till within a few years that some curious persons imported the seed from Brabant, where it had been long cultivated, there was not any of the seeds saved in England : though now there are several persons who save the seeds here, which succeed full as well as any of the foreign seeds which are imported.

As the white clover is an abiding plant, so it is certainly the very best sort to sow, where pastures are laid down to remain : for as the hay seeds which are taken from the best pastures, will be composed of various sorts of grafs, some of which may be but annual, and others biennial ; so, when those go off, there will be many large patches of ground left bare and naked, if there is not a sufficient quantity of the white clover, to spread over and cover the land. Therefore, a good sward can never be expected, where this is not sown : for in most of the natural pastures we find this plant makes no small share of the sward ; and it is equally good for wet and dry land, growing naturally upon gravel and clay, in most parts of England : which is a plain indication how easily this plant may be cultivated, to great advantage, in most sorts of land throughout the kingdom.

Therefore, the true cause why the land which has been in tillage, is not brought to a good turf again, in the usual method of husbandry, is, from the farmers not dis-

tinguishing which grasses are annual from those which are perennial : for, if annual or biennial grasses are sown, these will of course soon decay ; so that, unless where some of their seeds may have ripened and fallen, nothing can be expected on the land but what will naturally come up. Therefore this, with the covetous method of laying down the ground with a crop of corn, has occasioned the general failure of increasing the pasture in many parts of England, where it is now much more valuable than any arable land.

After the ground has been sown in the manner before directed, and brought to a good sward, the way to preserve it good is, by constantly rolling the ground with an heavy roller, every spring and autumn, as hath been before directed. This piece of husbandry is rarely practised by farmers : but those who do, find their account in it ; for it is of great benefit to the grafs. Another thing should also be carefully performed ; which is, to cut up docks, dandelion, knapweed, and all such bad weeds, by their roots every spring and autumn : this will increase the quantity of good grafs ; and preserve the pastures in beauty. Dressing of these pastures every third year is also a good piece of husbandry ; for otherwise it cannot be expected the ground should continue to produce good crops. Besides this, it will be necessary to change the seasons of mowing, and not to mow the same ground every year ; but to mow one season and feed the next ; for, where the ground is every year mown, it must be constantly dressed, as are most of the grafs grounds near London, otherwise the ground will be soon exhausted. *Miller's Gard. Dict.* See the article MEADOW.

The following Methods of improving wet Pastures, will, we doubt not, be very acceptable to our Readers, as they are founded on Experience, and consequently have no tendency to deceive the Husbandman.

" As I have, says our ingenious husbandman, within a few years, not only had some experience in my own farm, but observed the methods employed by many neighbouring gentlemen and farmers in mending their pastures, I shall communicate a few of my remarks to you on the improvement of wet pastures ; a subject which may prove, perhaps, of some little utility, as I shall speak of nothing but what I have either performed myself, or seen hereabouts.

" The particular lands of which I speak are loose, woodcock, brick-earth soils for about eighteen or twenty inches, and under that, clay to a great depth.

" Some that I have improved myself were exactly level, so as to be quite poisoned with the wet, which could not drain off.

" From the best observations I could make on many experiments, the following is the method which answers best to improve them. I shall also give you the expence with us.

" The first thing to be done is, to make large, deep ditches round every field, and if the fields are large, to divide them into smaller, of five, six, or seven acres each, by new ditches ; nothing is attended with a more sudden improvement of all the ground near the borders of the fields, than good ditches.

" I generally make mine six feet perpendicular deep, seven wide at top, and three at the bottom. I never pay for them by the rod (which is customary) but give twopence halfpenny per load, of thirty bushels, for all the clay, &c. that is thrown out of them, and two shillings and sixpence a score loads for filling and spreading it.

" These ditches should be made in such a manner that no water can remain in them, but a descent from one to another to carry it quickly off.

" It may be easily imagined how much these must drain the land, besides the quantity of excellent manure (clay) which arises out of them. Add to this the great convenience of having such fences about a farm, that the farmer is sure to find his cattle wherever he turns them, instead of their breaking perpetually into his corn or hay fields, which, in multitudes of farms, is so often the case : it is sometimes the work of a boy, only to be hunting after hogs or sheep that go astray for want of good fences.

" In the banks of new ditches we always lay white-thorn, fifty roots to a rod (the workmen are allowed sixpence per hundred for gathering them ;) but I always avoid intermixing any thing with it, especially hazel, for in the nut season fences are pulled in pieces for the fruit by all the boys and girls in the neighbourhood ; and oak, ash, &c. only give an opportunity to get over the hedges with greater ease.

ease. Sallow, willow, elder, &c. are to be avoided in the hedge, or by way of hedge-stake for the dead hedge, as they grow so fast as quite to overshadow the quick, and even destroy it. After frequent cuttings, to render the plants thick and strong, I keep the quick regularly clipped, which, in few years, render the fence impenetrable to man or beast, considering the largeness of the ditch.

" If an old fence is grown bad and thin, or composed of improper plants, I never yet observed it improved by planting quick in the gaps: the best way is, to reverse the bank, and plant fresh quick.

" One advantage arising from good fences is not apparent at first sight. To the disgrace be it spoken of most of the gentlemen of large fortunes round Bury, the game is wretchedly destroyed by poachers, who take it with night-nets. These vermin, who are generally labourers, swarm in every village round me. Their method is this: they take the farmer's horses out of his fields, and, after their doing a hard day's work, ride them all night, as fast as they can make them go, over the stubbles, to catch the partridges, blundering over every hedge (except such as I have described) in their way, oftentimes taking the horses (of which two instances have I seen this season) making gaps in the fences, riding over standing corn, clover for seed, or any thing that is a cover for birds, and after damaging the farmer in a most shameful manner, carry the produce of their infamous labour to many, who, to their great dishonour, encourage these rascals for their convenience. The money they get is spent at the next alehouse, and instead of doing the farmer a good day's work, they are drunk, asleep, or idle, the whole day.

" Now there are very few farmers horses that will leap a gate; but most will plunge through such hedges as are common hereabouts: none could pass such ditches as I always make and recommend. A farmer in this parish has so effectually fenced in his fields with prodigious ditches, that I have heard him declare, that not a single night-netter has been on his grounds on horse-back; and were they to attempt it, they would lose more time in passing one ditch than was necessary to drag some whole farms.

" The pernicious effects, to farmers, of this abominable practice, are notorious, and cry aloud for redress: if they would ease themselves, I know of no way but such ditches as I have described.

" But to return.

" When the ditching is done, the next work is to land-drain the whole fields in such a manner that every part of them may be laid dry. In a pasture of six acres I did two hundred rod. If there is the least fall in any part, or any place more wet than others, the drains should be cut through them. If the surface is exactly level, the depth of the drains should vary, so that the water may every where have a descent.

" These drains are made, in general, thirty-two inches deep, twenty inches wide at the top, and four wide at the bottom. They are filled eight inches deep with either stones or wood; but I should ever recommend the former, as the most effectual and lasting, to those who are not desirous of saving the difference of the expence. However, I know many fields in this parish and neighbourhood that are drained with wood, and which answer extremely well; and I have been assured that they will last twenty or thirty years. Nay, in some parts of Essex I hear they do it with straw alone: but this must be of service for only a few years: if stone be used, there can be no doubt of its lasting. The labour of the whole is three-pence per rod; sometimes it is done for two-pence half-penny,

" If with stone of the farmers, a load of thirty bushels will do three rods, which costs one shilling and a half-penny flubbing and picking; so the expence of a rod is seven-pence, besides carriage of the stone, which will not be much: but if he buys his stone, as is much the most probable in this country, we may suppose he must go two miles to fetch it, and give a shilling for eighteen bushels ready picked: the carriage is worth a shilling more, and reckoning the eighteen bushels to do a rod and half (which is near the matter) the stone of it will cost per rod one shilling and four pence.

" If bushes are used, a load of forty faggots will cost, if he buys them, or be worth if he has them, five shillings, and cost cutting one shilling. They will do ten rods; so that the whole expence of doing a rod with them will be ten-pence, and of stone one shilling and seven pence.

" The very first year the prodigious advantage of these

drains appears, especially if the season proves wet. The grafts (or corn if in ploughed fields, for it answers in all) will be fresh, vigorous, and sweet, wherever the pastures are drained.

" I have a field of six acres (mentioned above) which by land-draining, ditching, and manuring, is an exceeding good pasture, and has produced two tons and ten hundred weight of hay per acre, in a very good year, and generally thirty-five hundred weight per acre; whereas the pastures adjoining are scarce worth the farming, and let but at seven shillings per acre, producing scarce any thing but a little feed for lean cattle. The soil is the same in both; the six acres, about twelve years ago, being full as bad as the rest.

" These are the principal points to be observed in improving such wet, cold, loose pastures, as I have described: some that I have quite changed by these means were half over-run with moss and rushes; but draining them thoroughly, and claying them, kills all rubbish of this sort, and presents the farmer with so admirable a view of good pasture for dairy or grazing, where so lately nothing could live, as to be equalled in scarce any thing of the kind.

" But as all improvement ceases to be such when more money is spent in it than the advantages will repay, I shall in a few words display how far this is from being the case here. I will suppose two or three fields are improved by claying and draining, amounting in the whole to twenty acres.

	l. s. d.
" Sixty loads of clay per acre thrown out of the ditches, twelve hundred loads, at two pence halfpenny per load	12 0 0

" I will suppose sixty rod of new ditching done, which before clay is thrown out by the load, will cost one shilling per rod	3 0 0
--	-------

" Three thousand quicksets, at sixpence per hundred	0 15 0
---	--------

" Land-draining seven hundred rod with bushes (this is the quantity I have now marked out in a field of twenty acres) at ten-pence per rod	29 3 4
--	--------

" N. B. I had a great part of my last crop of barley killed in this field with the wet: I had therefore a fine opportunity of marking exactly where the drains should be made, which ought, on such occasions, never to be omitted, were it only for the common water-furrows which are made for every crop. In some fields, unless such a guide offers, it is very difficult to tell exactly where to make the land-drains.

" Turning and mixing one thousand six hundred load of manure	6 8 0
--	-------

" Filling and spreading one thousand six hundred loads, at two shillings and sixpence per score	10 0 0
---	--------

" I will suppose that the work may be done the sooner if the farmer brings one hundred loads of the four hundred of dung from the nearest town; and as I have not reckoned the horses and driver for the clay cart, I shall not in the bringing the dung: therefore the expences per waggon load will be, the cost three shillings, boy sixpence, and turnpike sixpence. A waggon load is two tumbrel loads (in this country) so fifty loads, at four shillings, are 10 0 0

Total 71 6 4

" This is three pounds eleven shillings and three-pence per acre: and supposing the profit to last but twenty years, although the draining and ditching part will last twice that time, and the clay five and twenty, as good as at first; and the farmers hereabouts seldom change their farms, if tolerable ones, living in them their lives and their sons after them, with leases of seventeen, twenty-one, and twenty-five years: supposing twenty years profit, I say, the expences will then be, per acre per annum, three shillings and six-pence halfpenny.

" So

"So small is the expence divided. But now let us consider the profit.

"Such land as I have described never lets here for more than ten shillings per acre, by far oftener for eight shillings, or eight and sixpence; and it is from my own experience, as well as various observations, that I assert the same land, after the improvements, will let to any tenant for seventeen, eighteen, and twenty shillings per acre.

"I will suppose it only sixteen shillings, though I am certain that is considerably under the mark: he then gains, in point of rent, six shillings per acre; and the whole calculation is absurd if we do not add his whole proportional profit on the acre: supposing his profit on it before improvement was a rent, ten shillings; afterwards, it will undoubtedly be the same at least; which adds six shillings per acre per annum, or eight shillings and sixpence clear, after the improvement is paid.

"Twelve shillings per acre is per annum, for	l.
twenty years	240
"Expences of improvement	71

"Clear profit	169
---------------	-----

"Or eight pounds nine shillings per annum: and if we reckon five per cent. interest for the seventy-one pounds, that is three pounds eleven shillings per annum absolute profit.

"Thus, I think, I have stated the case of this improvement clearly; and I must repeat it, that I speak from experience. The sum to be expended on twenty acres will appear large to most farmers, whose property is not considerable; but the proportion holds for a single acre, and those who cannot afford to improve twenty, may three, four, or five; and I make no doubt but such as attempt it will find their accounts in it greater than I have stated it.

"As I have mentioned a tumbrel-load to be thirty bushels, and a waggon-load to be but two tumbrels, I should observe that we carry away of muck fifty bushels at a time in our tumbrels, and so agree with our men in proportion to the thirty bushel loads.

"I have observed, that in making new ditches, or enlarging old ones, I never pay by the rod, but by the load: however, to those who chuse the former way, I would recommend that they have them worked by a frame of small slit deal, nailed into the exact size of the intended ditch, and agree with the workmen to do their work by it: this will prevent disputes which frequently arise."

PATE, a brock or badger.

PATH. A path across arable land is a great loss, as are crooked hedges. To remedy which, and forming a new straight ditch a quarter of a mile long, which was a nuisance, to a corner of a farm, Mr. Marshall, in his Minutes of Agriculture, has the following advantages stated thus:

	l.	s.	d.
Paid for breaking-up, deep enough for the plough, to pass safely, 86 rods in length, and about a rod in width, at 2s.	8	12	0
—clearing and stacking 28½ stack of wood cankered pollards, and the roots of timber trees taken down for buildings, at 5s.	7	1	3
—binding 320 bavins at 2s. 6d.	0	1	0
—making 79 rod of ditch, five feet wide at top, three feet deep, and ten inches wide at bottom, at 17d. though 16d. is a fair price	5	9	1
The new bank and ditch take up about 55 square rod, worth, during the remainder of a term of a lease, about	5	0	0
	26	10	4

"The wood is worth on the spot 15s. a stack, and the bavins, and spray bavins 10s. per hundred.

28½ stacks of wood is, at 15s. is worth	21	3	9
320 bavins at 10s.	1	12	0

The land reclaimed is about half an acre, which, on a par with the rest of the farm, during the remainder of the lease, 7l. 6s. 3d; but it is fresh virgin soil and will give three or four good crops without manure, and is worth at least	10	0	0
	32	15	9

Thus there is an apparent gain of 6l. 5s. 5d. besides the invaluable advantage of open fields and long ridges. But

the ditch is not a fence; the quick is to be planted, a temporary hedge to be made, and the quick to be weeded and defended; this took up sixteen days work, and cost, with collecting the plants at 8d. per hundred, 2l. 17s. 4d. The plants were placed four inches apart, each rod taking fifty. It was watered with the drainings of the dunghill, as they were planted in a trench, to a great advantage.

PEAR. Nature, as has already been said relative to apples, has furnished us with only one sort, namely the wild pear, from whence all the cultivated varieties are produced. See APPLE. The squash is in much the highest esteem. It is an early fruit; remarkable for the tenderness of its flesh. If it drops ripe from the tree, it bursts to pieces with the fall. The liquor made from this fruit is pale, sweet, yet remarkably clean, and of a strong body: a most excellent liquor, if duly manufactured from a soil which suits it. The Oldfield is a favourite old pear, remarkable for the elegant flavour of its liquor. The Barland pear is in great repute, as producing a perry which is esteemed singularly beneficial in nephritic complaints; as is the red pear for producing a liquor of singular strength. The huffcap and the sack are other pears which have been usually grafted: and besides these, and a variety of others, great numbers of kernel fruits are found among the pear-trees, as well as among the apple-trees, in Herefordshire. See PERRY and ORCHARDS, *Marshall's Rural Economy of Gloucestershire*.

PEARL; called also pin, and web, or any unnatural spot or thick film over an horse's eye, proceeding from some stroke or blow received, or from the fire or dam.

The pearl is known by a little round thick white spot, like a pearl, (from which it took its name) growing on the sight of the eye.

As for the cure, it is the same as for Blood-shot Eyes.

PEASE, a genus of plants cultivated in every part of England, both in the field and kitchen-garden. We shall here give the best instructions in our power for obtaining large crops in the field.

Mr. Lisle, for the greater ease and more certain guidance of country people, who are apt to be perplexed by a long list of particular names of different sorts of field-peas, and of their several numerous varieties, judiciously ranges them under two general heads, viz. the tender and the hardy small sort, and the tender and the hardy great sort: under the one or the other of which classes he thinks all kind of peas may properly be ranked, because they equally agree or disagree with the same soil. The tender pea, for example, is improper for a cold country, or which amounts to the same, for cold ground in a warm country; and the large pea, by reason of its great haulm, is not proper for strong rich land, because its haulm will there increase to so great a length, that it will not be able to bear pods. His own experience in the year 1704, satisfied him fully that the best way to make peas pod well, is to sow them on a mellow mould, rendered light by ploughing; and he thinks it right to roll the ground soon after they are sown.

Even the most general directions cannot but be of service to the husbandman: but more particular observations and actual experiments, properly diversified, are still much wanted in the culture of this, and indeed of all other podded grains and succulent plants, whose importance, as destroyers of weeds, improvers of land, and excellent preparers of it for other crops, is established beyond dispute. It is even a rule with farmers not to sow the same land a second time with peas, till six, or at least five years after the former crop of the same kind; because till then the ground on which they grew will continue so rich as to make them run luxuriantly to haulm, in a manner inconsistent with the bearing of much fruit.

The common white pea does best on light sandy land, or on a rich loose soil. It is generally sown with a broadcast, and only harrowed in. Three bushels of these peas are the usual allowance of seed for an acre of ground; and the common time for sowing them is about the latter end of March, or the beginning of April, on warm land; but a fortnight or three weeks later than this, will be early enough on cold ground. If sown in drills, which is by far the best way, a bushel and a half of seed will be full enough for an acre; and, when they are thus set regularly, the ground may be stirred with a hoe, to destroy the weeds, and earth up the plants, by which they will be greatly improved, and the peas will be much easier to cut in autumn, when they are ripe.

The green and the maple roundivals require a stronger soil

soil than the white, and should be sown a little later in the spring, also in drills, but farther asunder, that is to say, at the distance of at least two feet and a half, or three feet from each other, because they are apt to grow rank, especially in a wet season. The ground between these rows should be stirred two or three times with a hoe, which will not only destroy the weeds, but, by earthing up the peas, will greatly improve them, and also render the land fitter to receive whatever crop is put on it the following season.

The grey and other large winter pease, as they are called, are seldom cultivated in gardens, because they require a great deal of room. The best time for sowing of these is about the beginning of March, when the weather is pretty dry; for if they are sown in a very wet season, they are apt to rot, especially if the ground be cold. The distance between the rows should here be at least three feet, and these pease should be sown very thin in the rows: for if they are sown too thick, their haulm will spread so as to fill the ground, and they will ramble over each other; by which means many of the plants will be rotted, and hindered from bearing. The common allowance of these large pease, is two bushels to an acre: but that is certainly more than confists with the very thin sowing, which is best for them.

The grey peas, in particular, thrive best on a strong clayey land, in which they are commonly sown under furrow. But by this method of sowing, large pease, especially, are always planted too thick, and at unequal depths, which prevent their coming up regularly. For this reason, among many others, all rank-growing plants should undoubtedly be sown in drills, in which their seeds will be distributed much more equally in all respects.

If only a small spot of ground be planted with these pease, a channel about two inches deep may be made with a hoe, guided by a line; the seeds may be dropped therein, and the earth may be drawn over them with a rake. By this means they will be covered equally, and with tolerable dispatch, though not sufficient for large fields, where, for this reason, a shallow furrow is commonly made with the plough, the seeds are scattered in, and the earth is harrowed over them. The greatest trouble then remaining is to keep the plants clear from weeds, and lay the earth up to their roots, which, in countries where labour is dear, is very expensive to have done with the hand-hoe, but may be easily effected by drawing a horse-hoe between the rows. This will entirely eradicate the weeds, stir the soil, render it mellow, and greatly promote the proper growth of the plants.

Mr. Marshall, in his *Rural Economy of Gloucester*, says, "In the Cheltenham quarter of this district, I have observed a singular method of setting pease: not in continued lines, but in clumps; making the holes eight or ten inches from each other, putting a number of pease in each hole. This is called bunching them. The hoe has, undoubtedly, in this case, greater freedom: all the danger arising from the practice is, that the soil is not so evenly and fully occupied by the roots in this case, as they are when the plants are distributed in continued lines."

All sorts of pease love lined or marled land: but, when they are sown late in the season, the soil should be strong and moist; for they will then burn up and perish in hot light land, or at least not produce a crop worth taking off the ground. The authors of the *Maisons Rustiques* approve of steeping them twenty-four hours in water before they are sown, as well to separate the bad and faulty from the good, as to enable these last to rise the sooner by being thus moistened. In general, the larger the pea is, and consequently the later its usual time of ripening, the earlier it should be sown, as experience has directed, and as Mr. Lisle rightly infers from the following curious observation, which, if duly attended to, may be of service to husbandmen and gardeners, and perhaps productive of some improvements in the culture of this plant.

In 1708, when the field and garden pease were near a foot high, he observed on the very top of them a purse or nest of buds of blossoms, lying in a bag together; and perceiving at the same time that there was no show of blossoms putting forth at the lower joints, he concluded that the crops of pease would miscarry that year; that they would not only have some top-kid, and that it would be vain to expect any on the lower joints, because they are always forwarder in blossoming and kidding than the upper joints, and had not then the least appearance of doing either. This afforded him some amusements in reasoning: but,

not being satisfied, in a day or two after looked again into these upper pods or bags of these blossoms, and upon dissecting a number of them, found sometimes in a single one, near thirty buds of blossoms, two or three of which seemed usually to have got the start of the rest, and to be bigger in bulk, and taller; most of the rest seemed to lie in a huddle without making any gradations; but as he had never seen, excepting the crown pea (which carries all its blossoms in a tuft at top, like a nosegay), other pease put forth above two blossoms and kids at top, which seldom come to any good, he suspected that the many blossoms in this pod must form the successive gradations of blossoming joints, arising from that stock as from a common root, and that every blossom shot forth in order as it grew forwarder than the rest, while the main stem, advancing higher and higher, left behind the subaltern blossom of a lower joint. To be clear in this, he tied scarlet threads just under several of these pods, that he might know them again, and, as he expected, found in four or five days time a gradation of blossoms arising from joints with lobous leaves above his scarlet threads, and the pod of blossoms still advanced on to the end, leaving behind farther joints of blossoms, till the whole stock was spent.

From this observation Mr. Lisle infers, 1. That by looking into this pod, or purse of buds, while it is yet so much in its infancy as only to be viewed by a magnifying glass, we may judge what hopes there are of a future crop, provided the succeeding months prove favourable: and, 2. That we may learn from hence what sort of pease to adopt to every sort of ground: "but, continues he, before I enter on this part and use of the above-mentioned observation, I must, for the better understanding thereof, premise, that the farmers vary in their judgment in no one point so much as in the nature of the pea. Several sorts of pease are commonly sown within the limits of the same parish, and each of the persons who sow them generally has a great prejudice to any other sort than that which he sows, having perhaps been disappointed of his expected return from other pease, when he has sowed them, and being, for the same reason, equally disposed as readily to alter his opinion for his last favourite kind; for the produce of a crop of pease is always very uncertain. But if the farmer would consider, from the foregoing observation, how early or rath-ripe a pea is, or how late in ripening, in its nature; and that (as all its stock or power to put forth blossoms lies within the foliage of one pod) the art must result from thence, so to sow the pease, in such ground, and at such time, that each sort of pea, according to its nature, may, before autumn and cold weather come to check them, send forth all its gradations of joints or blossoms, so that none may become abortive for want of summer enough to enable nature to bring her embryos to maturity, and carry the bud-blossoms into kids; then it is apparent (as all large pease ripen late, and run to great haulm or stalks, and small pease have less haulm and ripen earlier) that the great or late ripe pease should be sowed as early as the climate will permit; for thereby such pea will get so forward as to have time to put forth all its gradations of blossoms and kids, and to perfect them before a rainy autumn comes, and puts a stop to farther vegetation. Again, great pease ought to be sowed on a white, or some mixed land, not too gross of juice; but not on a cold clay: for the moisture of this last will keep feeding the haulm, and be inconsistent with the main design of sowing them early, which is, that they may bring all their fruit to maturity in due time. The white or mixed mould must be in good heart; for otherwise it cannot maintain a great pea. On the other hand, it is evident from hence that a pea which ripens early should be sowed in a strong feeding land, because such land will nourish it more vigorously, without danger of too great an increase of its haulm, which is naturally short; and notwithstanding the coldness of the soil, there need be no doubt but that all the kids will ripen.

Moderate rains are of singular service to pease while they grow, and particularly at their time of blossoming and filling up their pods; but a continuance of cold rain for many days, is perhaps as prejudicial as too much heat or drought. The bluish bloom upon their leaves, and their expanding backward the two outermost and largest leaves of their blossoms, are undoubted signs of great health and vigour. Mr. Lisle is of opinion, that they neither ripen nor harden so well upon high grounds, as in the vallies, and consequently that the former are not so fit for keeping as the latter.

Among the very few experiments on the culture of pease in field, the following, which M. Duhamel has given, afford a pretty strong conviction of the benefits which arise from horse-hoeing between their rows.

In April 1753, M. de Villiers, one of that ingenious gentleman's correspondents, sowed a small field in Champagne, with pease in double rows. Not being provided with a proper instrument to hoe the intermediate spaces, he made use of a narrow angular kind of share, which stirred only three or four inches on the outside of the rows. Almost all the pease in his neighbourhood were destroyed that year by a kind of vermin called vine-fretters. His were hurt the least of any; which was probably owing to the greater vigour of the plants, or the insects being killed by the stirring of the ground. By a comparison which he made of the produce of this spot, he found that it yielded six times as much as the same extent of the best land in the same country. "In a good year, says M. Duhamel, the difference would not have been so great; but still this experiment shews, that plants cultivated in the new or horse-hoeing way, are better able to resist the inclemencies of the seasons, and other accidents, than those which are cultivated according to the old method."

The next year, M. de Villiers, being provided with M. Duhamel's drill and horse-hoe, sowed pease again in rows, in some places two feet, and in others two feet and a half asunder. But this distance was so narrow, that it rendered the horse-hoeing very difficult in many places, and quite impracticable in others. He was therefore obliged to contrive other means of stirring the ground, in which, notwithstanding this, his pease flourished extremely, and yielded more than any others on the very best land in the same district.

The same gentleman drilled pease again, in 1755, in a strong heavy soil, in which no one had ever ventured to sow any in the common husbandry. They grew as high as if the ground had been ever so fit for them, and yielded half as much again as any sown in the common way, besides the saving in the seed, which in pease thus drilled is about one half. They were sown in double rows, with a space about two feet and a half wide between the outmost rows of one range and the next outmost row of another, and this space was stirred with the horse-hoe.

When any particular sorts of pease are intended for feed, they should be carefully looked over whilst in flower, in order to draw out all such plants as are not of the right sort; for there will always be, in every sort, some rogues plants, as the gardeners term them, which, if left to mix, will degenerate the kind. As many rows as may be thought sufficient to furnish the desired quantity of seed should then be marked out, and left till their pods turn brown, and begin to split, when they should immediately be gathered up, with the haulm; and if the husbandman has not room to stack them till winter, they may be threshed out as soon as they are dry, and put up in sacks for use: but particular care should be taken not to let these remain too long abroad after they are ripe; because wet would rot them; and heat, after a shower of rain, would make their pods burst in such a manner that the greater part of their seeds would be lost.

When the pease are reaped, or hacked, as they call it in some parts of England, they are laid up in small wads, and left in the field till the haulm and pods are dry: but during this time they should be frequently turned, and raised as much as possible from the earth, that they may lie hollow for the wind to dry them, especially when any rain happens to wet and beat them down. In Leicestershire they set all their pease abroad in stacks, being persuaded that they thence acquire a much better colour than when housed in a barn.

An ingenious farmer has obliged the public with the following method of preparing pease for hog-meat; and which we shall here give in his own words:

"A few years ago, says he, I had a plentiful crop of pease on a ten acre piece, which lies near my house: when they were full podded and nearly ripe, I had them hooked in the usual manner; but before I could get them in, there came a heavy shower of rain, which wetted them through and through; and the dull heavy weather, with frequent showers which followed, prevented their drying for a considerable time.

"I caused the wads to be from time to time turned, to prevent the haulm from rotting; and at length a few days

sunshine dried them enough to be inned; for as they lay hollow, the wind was greatly assistant to the operation.

"Before I got them in, on examining some of the pods, I found that the pease were all sprouted to a considerable length: this was what I had expected, as I gave my crop over for lost, till after a little recollection, as the weather still continued fine, I determined to thresh them in the field.

"This was accordingly done; and the crop, after it was cast and riddled, to separate it from the rubbish, was dried on my malt-kiln.

"When this operation was over, I began to reflect in what manner I should dispose of my pease, being sensible that they could not be proper for seed, and standing no chance of disposing of them to any advantage in the market.

"At length, as it was then a time of war, and of course there was a great demand for pork for the use of the navy, I determined to buy a considerable number of lean hogs, that I might by their means consume this crop on my own premises, and in that manner make the most of it.

"My expectations were more than answered; for I found, by repeated experience, that three bushels of the pease I have mentioned went nearly as far in fattening the hogs I bought, as four bushels got in dry and hard in the manner usually practised.

"This discovery I made several years ago, and it has turned out to my advantage; for since that time I have been quite indifferent as to the weather in which my pease are hooked, being rather better pleased, as far as relates to them, with wet, than dry weather: but if the weather happens to be dry at the time they are ripe. I always use as many as I want for feeding my hogs, which are not a few in a year, to be regularly malted in the same manner, nearly as my barley: this management has of late succeeded very well with me, and I therefore intend to continue it.

"Besides feeding my hogs with these malted pease, I have besides often given them to my horses, with which they agree very well, and are heartening food.

"Turkeys will fatten apace on them also, and be fine meat.

"I have applied my malted pease to many other uses, which I have not, at present, time to enumerate: but were they only used for feeding hogs and horses, it is still worth while to prepare some in this manner every year. Pease should be never ground when given to fatten hogs."

Museum Rusticum, vol. I. page 109.

PEASE-BOLT, pease-haulm.

PEAT, a species of earth used in many countries for firing.

Under the article ASHES we have given some account of the uses of those made from peat; and shall here add the observations of a very intelligent husbandman, with regard to the value of those ashes, and the several crops to which they may be profitably employed as a manure.

"The more general, says he, a manure is in its uses, of so much the more value is it to the farmer; and, of all sorts of manures, perhaps ashes agree with the greatest variety of soils and crops: ashes, therefore, should, one would imagine, be had in universal request, for the purpose of dressing land; but the misfortune is, no great plenty can be procured, and the few that are to be got fetch a large price: this deters the farmer from making use of them often as manure.

"I must, however, except one sort of ashes which are on all accounts valuable; I mean peat, or turf-ashes: these are in most places easy to be procured, cost no great matter, and have a wonderful effect on almost every soil and crop. You may believe what I say, as I have had many years experience of their good qualities.

"The sulphureous and saline particles with which these ashes abound, have a most happy effect in promoting vegetation; and if used with discretion, the increase procured by them is truly wonderful.

"I suppose few of your readers will be at a loss to know what peat or turf is, most people having seen a kind of it burnt as fuel.

"The ordinary peat is dug from wet bogs and morasses; but that which is of much superior quality and virtue in its ashes, is dug from moory wetish lands, which will bear cattle: as to the peat that is pared from the surface of heaths and commons, for firing for the poor cottagers, the

ashes

ashes of it are of very little value, when compared with those above-mentioned.

"Peat is found in most low grounds that lie betwixt hills, especially if timber has formerly stood upon the spot. It lies in various depths, being often near the surface, and sometimes six, eight, or ten feet deep, having a stratum of black moory earth over it, such as the soil of many of our low meadows near the banks of rivers: it sometimes even lies under a bed of gravel.

"Peat may be burnt for the sake of procuring its ashes for manure, all the summer season: as soon as it is dug, some of it is mixed in a heap regularly disposed with faggot wood, or other ready burning fuel: after a layer or two of it is mixed in this manner, peat alone is piled up to complete the heap. A heap will consist of from four hundred to a thousand loads.

"After setting fire to it at a proper place, before on purpose prepared, it is watched in the burning, and the great art to is to keep in as much of the smoke as possible, provided that as much vent is left as will nourish and feed the fire.

"Whenever a crack appears, out of which the smoke escapes, the labourer in that place lays on more peat; and if the fire slackens too much within, which may easily be known by the heat on the outside, the workman must run a strong pole into the heap in as many places as is necessary to supply it with a quantity of fresh air. When managed in this manner, the work goes on as it should do. It is to be noticed, that when once the fire is well kindled, the heaviest rain does it no harm whilst it is burning.

"Having procured a sufficient quantity of ashes, the farmer's next care should be to apply them properly to use; and to do this, he must be well acquainted with the nature of the manure he is to lay on his land.

"All ashes are of a hot, fiery, caustic nature; they must therefore be used with caution. With respect to peat-ashes, almost the only danger proceeds from laying them on in too great quantities at improper seasons.

"Nothing can be better than peat-ashes for dressing low damp meadows, laying to the quantity of from fifteen to twenty Winchester bushels on an acre: it is best to sow them by hand, as they will then be more regularly spread.

"This work should be done in January or February at latest, that the ashes may be washed in towards the roots of the grass by the first rains that fall in the spring.

"If they were spread more forward in the year, and a speedy rain should not succeed, being hot in their nature, they would be apt to burn up the grass, instead of doing it any service.

"It is to be remembered, that the damper and stiffer the soil, the more peat-ashes should be laid on it; but in grass lands the quantity should never exceed thirty Winchester bushels, and on light warm lands less than half that quantity is fully sufficient.

"On wheat crops these ashes are of the greatest service, but they must be laid on with the utmost discretion. Were they to be spread in any quantity before the winter, after the sowing the corn, they would make the wheat too rank, and do more harm than good: was the spreading this manure, on the contrary, deferred till the spring, the corn could not possibly during the winter season be benefited by it. After due reflection and repeated experience, my method of management in this case is as follows:

"About the beginning of November, before the hard frosts set in, I sow on every acre of my heavy clayey wheat land about eight Winchester bushels of these ashes; on my lighter warmer lands in wheat, I sow only four bushels at this season.

"The winter dressing is, I imagine, of great service: trifling as the quantity may seem, it warms the roots of the plants, brings it moderately forward, preserves its verdure, and disposes it to get into a growing state the first fine weather after Christmas.

"About the latter end of February, or the beginning of March, on the above-mentioned heavy lands in wheat, I bestow another dressing of ashes, by sowing of them on every acre eight bushels more; on light lands, in this second dressing, I allow only six bushels.

"These ashes laid on in the spring are of the greatest service, without any probability of danger; if rain falls within a few days after the dressing is laid on, it is washed

in, and has a happy effect on the succeeding crop, co-operating with the manure that was laid on in November; if, on the contrary, dry weather for a long continuance succeeds, the first winter-dressing has its full effect, and the quantity laid on in the spring is in fact so small, that there is very little probability of its burning or hurting the crop.

"This method has succeeded very well with me, and I have no reason to think it can fail with any one else.

"This excellent manure is, I find, of great use in the turnep-husbandry on many accounts, particularly as it much contributes to preserve the young crop from being devoured by the fly.

"When I sow my turneps, before I harrow in the seed, I have eight bushels of these ashes strewed by hand on every acre; and when the plants shew their first leaves above ground, I sow on every acre four bushels more: by this management my crops seldom fail, when at the same time some of my neighbours sow their turnep-land three or four times over.

"But one of the principal advantages derived from these ashes I have not yet mentioned, which is the very great service they are of to every kind of artificial pasture.

"Saintfoine receives great benefit from this manure, and so does clover, ray-grass, and trefoil, provided it is laid on with discretion: the proper season is about the month of February: the quantity must be regulated by the nature of the crop and soil; but in my opinion, it ought scarcely in any instance to exceed thirty Winchester bushels. Clover, with the help of this manure, grows with great luxuriance, inasmuch that I have often had two large crops of hay from the same field in a year, and good autumn feed afterwards.

"But the effect of it is most seen in tares or vetches, and on them it is I bestow most of this manure, as they will bear it, being a very succulent plant. I had last summer a crop of tare-hay that was astonishing, by the help of these ashes, being above three large loads on an acre. The field contained six acres; it was a dryish loam, and not very rich. In the beginning of February I caused ten bushels, Winchester measure, to be strewed on each acre: immediately after the first rains had washed them in, the same quantity was in like manner spread, and about the middle of March I bestowed on each acre six bushels more for the last dressing. I am fond of dividing my entire quantities, thinking my crops are thereby less exposed to the danger of being burned, and the manure is besides more gradual and lasting in its effects.

"My tares came on amazingly; but they ran chiefly to haulm, which was what I wished, not having any desire of saving the seed, but intending to make the crop in hay: my only fear was, that it would rot on the ground before it was in a proper condition to cut; but this I luckily escaped, by the soil being tolerably dry, and by the fineness of the weather. It was so heavy in the swarth, that I was obliged to pay an extraordinary price for mowing it.

"I have observed above, that I was fearful my tares would have rotted on the ground before they were fit to cut; this was owing entirely to the invigorating quality of the ashes, which by their salts, &c. promoted the growth of the plants even to luxuriance.

"Before I well knew the great fertilizing quality of these ashes, I lost, by improper management, a fine three acre piece of hog-pease. I laid on this field, soon after the pease came up, threescore Winchester bushels of these ashes at one dressing: this brought them forward a great pace, but at harvest I found, to my grief, I had scarcely any corn, for I had overdone it in laying on so much, and the pease were run all to haulm.

"Ever since this accident I have declined using them as a common dressing for my pease; and this I have been the more induced to do, as, in several little experiments I have since made, I have found it extremely difficult to appportion the several quantities which ought to be laid on various soils when sown with pease; for the quantity that has one year succeeded very well with me, has, the next, owing to the difference of seasons, on the same soil, in another part of the same field, totally disappointed me; so that, for pease, I esteem it a very critical manure, therefore very cautiously to be used.

"The effects of this manure will be visible at least three

three years, and it does not, like some others, leave the land in an impoverished state, when its virtues are exhausted and spent.

"Peat-ashes are not so certain a manure for barley and oats as for the winter corn: for as these are quick growers, and occupy the land but a few months, this warm manure is often apt to push them forward too fast, and make them run too much to coarse straw, yielding only a lean immature grain. Oats, however, are not so apt to be damaged by it as barley.

"To get a good crop of barley, I often sow it after turneps, which have two light dressings of ashes, in the manner above described.

"When the turneps are fed off, or drawn, I give the field, if the season permits, a good ploughing; if they were fed off, the land will want no more ashes; but if they were drawn, and either carried into another ground to feed sheep, or given to my stall-fed oxen, I strew on each acre, after this ploughing, five Winchester bushels of ashes, leaving them to be washed in by the first rain. In this manner I let the land lie till I give it the second and last ploughing before it is sown. The manure has by this management the desired effect, and the barley generally produces full and heavy ears.

"When I sow my barley after turneps, I give the land only two ploughings, because the soil was before much loosened by the hoeings bestowed on the turneps; but in other cases I am fond of allowing three, and sometimes four ploughings, to my lands destined for barley; and I generally find it answer very well; for many years experience has convinced me, that upon a fine tilth barley always thrives best, and yields most: in fact, the crop is almost always governed by the condition of the land, and a well-tilled soil is less exposed to danger in an untoward season.

"Peat-ashes approach, in their effects on the several crops on which they are laid, to coal-foot; but two-thirds of the quantity that is used of foot, will be sufficient of the ashes, as they are, in a much stronger degree, impregnated with a vegetative power; and they are, besides, in most places easier procured in quantities, and at a cheaper rate.

"It may possibly be objected, that this manure requires great nicety in the application. I allow it does; yet every intelligent farmer, who knows the nature and qualities of the soils of his several fields, will soon be able, with great precision, to judge how much he ought to lay on each acre: his chief care at first should be not to overdo it; for therein consists the principal danger; though, after all, these ashes will, at the worst, unless laid on in very great excess indeed, only occasion the inexperienced farmer the perhaps partial loss of a single crop; for the succeeding year they will, in all probability, have a very salutary effect on the land, and sometimes even repay the preceding loss.

"When the error is in the excess, it is very easy for a farmer to avoid falling into it: for, independent of every other consideration, the sole view of lessening his expences will, it is imagined, sufficiently induce him to be attentive to this particular.

"When peat is burnt for the sake of its ashes in summer time, it is necessary that some care should be taken to defend them from the too powerful influence of the sun, air, dews, rains, &c. or great part of their virtue would be exhaled and exhausted. If the quantity of ashes procured is not very great, they may be easily put under cover in a barn, cart-lodge, or hovel; but large quantities must necessarily, to avoid expence, be kept abroad; and when this is the case, they should be ordered as follows:

"A dry spot of ground must be chosen; and on this the ashes are to be laid in a large heap, as near as possible in the form of a cone standing on its base, the top as sharp pointed as possible: when this is done, let the whole be covered thinly over with a coat of soil, to defend the heap from the weather: the circumjacent earth, provided it is not too light and crumbly, will always serve for this purpose.

"When thus guarded, the heap may very safely be left till January or February, when it is in general the season for spreading it: but, before it is used, it is always best to sift the ashes, that the cinders, stones, and half-burnt turf, may be separated from them.

"This may, perchance, by many be esteemed an un-

necessary trouble; but experience, which is the best guide, has convinced me, that by this means I can better ascertain the quantity that ought to be sown on the several sorts of land; for the small powdered ashes, being equal in quality, are of course equal in its effect: whereas, when there has been any other mixture with them, the effect has often been greater or less than I could have wished. Thus, when I mention the number of bushels I strew on an acre, it is always to be understood of sifted ashes: should any farmer be inclined to try them rough as they are first produced after burning, the quantity to be allowed for an acre must be more in proportion to the mixture of other matter that is in them.

"These peat-ashes are almost, as I have already observed, a general manure suited to every soil. On cold clay they warm the too compact particles, dispose it to ferment, crumble, and of course fertilize; and, in fine not only assist it in disclosing and dispensing its great vegetative powers, but also bring to its aid a considerable proportion of ready prepared aliment for plants.

"On light lands these ashes have a different effect: here the pores are too large to be affected, or farther separated by the salts or sulphur contained in them; but, being closely attached to the surfaces of the large particles, of which this earth is generally composed, this manure disposes them, by means of its salts, to attract the moisture contained in the air: by this operation, the plants which grow on these porous soils, are prevented from being scorched up and burnt; and if they want, which they generally do, more nourishment than the land is of itself capable of affording, this is readily and abundantly supplied by this useful manure.

"In large farms it is very usual to see all the home-fields rich and well mended by the yard-dung, &c. whereas the more distant lands are generally poor, impoverished, and out of heart, for want of proper manure being applied in time.

"Whilst the farmers depend almost entirely on their yard-dung, this cannot fail being the case; for dung is of very heavy carriage: they are willing, therefore, to drop it as near home as possible, being in this way able to do a great deal more work in the same space of time: but would they once try the virtue of peat-ashes, all their lands might be alike improved, though at a very considerable distance from the home-stall; for so few of them are required, and they are so light of carriage, that a single tumbrel will hold as many as ought, in most cases, to be laid on two acres of land; by which means, when these ashes are used as a dressing for the distant fields, it costs the farmer less in carriage than does that of the stable-dung for the home-fields." *Museum Rusticum*, vol. I. p. 222.

PENNY-earth, a term used by the farmers for a hard, loamy, or sandy earth, with a very large quantity of sea shells intermixed in it; some of which being round and flat, and in some measure resembling pieces of money, have occasioned the earth's being called by this name. It is an earth not easily dug, but is usually undermined with pick-axes, and then falls in large lumps; which, with the frosts, break to pieces, and leaves the shells loose. It is prepared by breaking and mixing well with water, and then makes very desirable floors. The Jersey combers comb-pots, are also made of it, and the sides and roofs of ovens are plastered with it; and being rightly managed, it combines into a floor almost as strong as plaster of Paris. *Moreton's Northamptonshire*

PEKRY, the name of a very pleasant and wholesome liquor extracted from pears, in the same manner as cyder is from apples. See the articles **CYDER**, **APPLE**, **PEAR**, and **ORCHARD**.

The best pears for perry, or at least the sorts which have been hitherto deemed the fittest for making this liquor, are so excessively tart and harsh, that no mortal can think of eating them as fruit: for even hungry swine will not eat them; nay, hardly so much as smell to them. Of these the Bosbury pear, the Bateland pear, and the horse pear, are the most esteemed for perry in Worcestershire, and the squash pear, as it is called, in Gloucestershire; in both which counties, as well as in some of the adjacent parts, they are planted in the hedge-rows and most common fields.

There is this advantage attending pear-trees, that they will thrive on land where apples will not so much as live, and that some of them grow to such a size, that a single pear-tree, particularly of the Bosbury and the squash kind, has frequently been known to yield, in one season, from one

to four hogheads of perry. The Bosbury pear is thought to yield the most lasting and most vinous liquor. The John pear, the Harpary pear, the Drake pear, the Mary pear, the Lullum pear, and several others of the hardest kinds, are esteemed the best for perry, but the redder or more tawney they are, the more they are preferred. Pears as well as apples, should be full ripe before they are ground.

Dr. Beale, in his general advertisements concerning cyder, subjoined to Mr. Evelyn's Pomona, disapproves of Palladius's saying, that perry will keep during the winter, but that it turns sour as soon as the weather begins to be warm; and gives, as his reasons for being of a contrary opinion, that he had himself tasted, at the end of summer, a very brisk, lively, and vinous liquor, made of horse-pears; that he had often tried the juice of the Bosbury pear, and found it both pleasanter and richer the second year, and still more so the third, though kept only in common hogheads, and in but indifferent cellars, without being bottled; and that a very honest, worthy, and ingenious gentleman in his neighbourhood assured him, as of his own experience, that it will keep a great while, and grow much the stronger for keeping, if put into a good cellar, and managed with due care. He imputes Palladius's error to his possibly speaking of common eatable pears, and to the perry's having been made in a very hot country: but he would have ascribed it to a more real cause, perhaps, had he pointed out the want of a thorough regular fermentation, to which it appears plainly that the ancients were entire strangers; for all their vinous liquors were medicated by boiling, before they were laid up in order to be kept. See the article CYDER.

PHEASANT, a bird so nearly allied to our common poultry, that it would naturally appear a very easy thing to breed them up from young; but the proper food of them is not sufficiently enquired into. Though they eat corn when full grown and in health, yet they have recourse in their young state, and when sick, to another sort of food, preying on several insects, and that in a very voracious manner.

The young pheasants and partridges prey upon ants; and they will never succeed with us, if they have not a proper quantity of ants to have recourse to, as soon as they leave their roost in a morning. When musty corn, or want of due care in cleaning their houses, has made them sick, a repast of ants will often recover them. When that fails, they may be offered millepedes or earwigs, or both together, which will always do much better than either singly. To this medicine must be added a proper care that their common food of corn be very sweet, their habitation kept nicely clean, and their water shifted twice a day. They must not be let out of the house in a morning till the dew is off the ground; and after the sun-set they must be immediately taken in again: in the heat of the day they must be allowed to bask in the sun in a dry sandy place. With these regulations the birds of this kind will succeed much better than they usually do. The pheasant is a bird of a fullen disposition, and, when the coupling time is over, there are seldom found more than one in a place. *Philos. Trans.* No 23.

PHYSIC for Horses. For a purging ball: Take Barbadoes aloes ten drachms and a half; diagyridium and ginger (in powder), each a drachm; jalap and Castile soap, of each a drachm and a half; syrup of blackthorn, sufficient to make a ball. These balls may be encreased or decreased in their purgative qualities, so as to be selected by the judgment of the reader. The ball being given early in the morning, let it be washed down with a quart of water slightly warm; give him a little sweet hay, and about three hours after give a warm mash of scalded bran, containing one fourth of oats, and let it be repeated twice in the course of the day, and on the following morning, about which time the physic may be expected to begin its operation. So soon as the physic begins to operate, assist the work by frequent applications of warm water, and do not omit letting him be walked out about half an hour at least (well clothed). Frequent supplies of warm water must be given, and two other mashes at their proper times, by no means omitting to take him out, and walk him gently twice or thrice in the course of the day.

Bartlet recommends a cooling purging drink, which is cooling, easy, and quick in its operation, and greatly preferable, in all inflammatory cases, to any other purge, as it passes into the blood, and operates also by urine.

"Take fenna, two ounces; infuse in a pint of boiling

water, two hours, with three drachms of salt of tartar; pour off and dissolve in it four ounces of Glauber salts, and two or three drachms of cream of tartar."

In inflammatory cases, or when the horse causes the ball to regurgitate, and it cannot be easily or properly passed, this drink may be admitted with propriety.

PIGEON. A domestic bird, very well known: I shall chiefly mention those that are bred in pigeon or dove-houses; some there are, for want of the conveniency of such houses, that are bred in coops and dove-cotes; in general we reckon but two sorts of pigeons, the wild and the tame; the tame rough-footed ones differ not much from the wild, only they are somewhat bigger, and more familiar: the wild usually perch upon trees, being seldom seen on the ground, and are very good food.

By wild pigeons, are meant those that breed in woods, sea-rocks, &c. and by the tame, such as are bred in dove-houses.

There are indeed many sorts of pigeons, such as carriers, croppers, powters, horsemen, runts, jacobins, turbits, helmets, nuns, tumblers, barbs, petits, owls, spots, trumpeters, shakers, turners, finikins, &c. from which proceed, when they are contrarily matched together, bastard-bred pigeons, such as are called from the cropper or powder, and the carrier, powting horsemen; from the tumbler and the horseman, dragoons: of the generality of these I shall say but little, they being only kept for fancy, and not for the profit of the table, though the same method is to be used in breeding them.

There are different sorts of runts, one called Spanish runts, generally of a blood-red or mottled colour: they are very loose feathered, and large bodied, but breed not so often as the smaller sorts.

Horsemen are excellent breeders, and are not easily took; the common English runt is a good sized pigeon, and breeds well.

The pigeon called the Leghorn, is a sort of runt, only distinguished by a little wattle over his nostril: he is a full bodied pigeon, whose feathers lie close to his body, and is an excellent breeder, and generally of a grizzled colour, ermined round the neck.

To those who keep pigeons for the sake of good breeding, I would recommend bastard-bred pigeons, such as powting-horsemen, powting dragoons, from a powder or cropper, and a Leghorn; the reason is, such pigeons will breed nine or ten pair of young ones in a year; for the little puff of wind thrown in from the powder, gives them a heat and mirth; they will continually be playing or courting, and when they have young ones, will feed them well, which a cropper, by reason of the bigness of his crop, seldom doth.

Carriers breed but slowly; three or four pair a year for them is much, by reason of their cold nature: they are constant lovers, and very rarely tread any but their own mate, and therefore hard to match when separate; they will often take three months time.

On the contrary, a powder will tread any hen that will let him, at any time; and take him from his own mate, and he will match to another in a day or two; for that reason bastard-bred pigeons are most serviceable for those who breed them to supply the table.

Great care must be taken to make convenient places to breed in; each pair of pigeons must be sure to have two nests, with baskets in them is best, for before one pair can go out of the nest, or feed themselves, the old ones will lay, and be sitting: nay, I have often seen a second pair. Be sure when you take the young ones, clean out the nest, or put in a clean basket, for cleanliness is a great help.

Never let them want meat; for if you do, they cannot be provided with soft meat in their crop when the young hatch, which if wanting, the young ones certainly die: or if you feed the old ones by hand, they will go feed their young immediately with what they get, which they not being able to digest, kills them; so that the best way is to let them have meat always by them in a box, with a hopper in it made for that purpose.

Breed young ones for stock in the spring, those bred in the winter being generally crampy, and never prove good breeders.

The reason why I recommend baskets to breed in, is, tame pigeons seldom build their nests, the want of which a basket supplies. Be sure take care no vermin come among them.

Of those bred in pigeon-houses, the grey pigeon, inclining to ash colour and black, is best; and she generally shows her fruitfulness by the redness of her eyes and feet, and by the ring of gold colour which is about her neck.

There are two seasons in the year wherein you may stock your pigeon-house; the first is May; for as these pigeons having much strengthened themselves during the winter, they are in a condition soon to yield profit to the buyer. Secondly, in August there are a great number of young pigeons that have been well fed with the corn which their dams, both cocks and hens, have plentifully supplied them with, from the harvest in that season.

You must take care to furnish your pigeon-house according to the bigness of it; if you put but a few in it, it will be a great while before you will have the pleasure of eating young pigeons, for you must take none out of the pigeon-house before it is well stocked.

Be sure to feed them in hard weather, and in bending time, which is when the corn is in the ear, and keep out the vermin, and you will never want stock.

It is good to give them loam, mixed with salt and cummin-seed, mixed well, made up in lumps and dried; it provokes lust, and helps them in breeding.

Be sure never to let them want fresh water. The mornings and evenings are proper times to give them their meat, and never at noon, for fear of breaking their rest, which they usually take at that hour, which roost is very necessary to make them thrive with the food which they eat.

To hinder pigeons from quitting the pigeon-house, take the head and feet of a goat, and boil them together till the flesh separates from the bone: take this flesh and boil it again in the same liquor, till the whole is consumed; bruise into this decoction, which is very thick, some potter's earth, (out of which you are to take all the stones,) vetch, dung, hemp, food, and corn; the whole must be kneaded together and reduced to a paste, or dough, which form into small loaves about the thickness of two fists, and dry them in the sun or oven, and take care it do not burn; when they are baked, lay them in several parts of the pigeon-house, and as soon as they are set there, the pigeons will amuse themselves with pecking them and finding some taste there which pleases them; they will keep so close to it that they will not afterwards leave it but with regret. Others take a handful of salt, which they candy, and afterwards put into the pigeon-house. Some take a goat's head and boil it in water with salt, cummin, hemp, and urine, and then expose it in the pigeon-house, with which they amuse the pigeons. Lastly, there are those who fry millet in honey, adding a little water to prevent it's burning; this preparation is a repast to them, and will cause them to have such an affection for their ordinary habitation, that so far from abandoning it themselves, they will draw strange pigeons to it.

Pigeons will live eight years, but they are only prolific for the first four years; afterwards they are worth nothing, for when they are once past that age, all they do is, to deprive you of the profit you might reap by others that are younger. It is something difficult to know how to distinguish their age.

If you would furnish your table with young ones in the winter, and feed daintily, you must not tarry for them till they can fly, but take them when they are grown pretty strong; pluck the largest quills out of their wings, which will confine them to their nests; others tie their feet, or else break the bones of their legs, by which means they will be fat in a very short time, because the substance of the nourishment they receive being then not so much dispersed, turns into fat.

There are several species of tame pigeons; viz.

Runts, the largest kind of pigeons, called by the Italians, *troufo*; but these may again be distinguished into greater or smaller: those which are commonly called the Spanish runts are much esteemed, being the largest sort of pigeon, but are sluggish, and more slow of flight than the smaller sort of runts: but the smaller runts are better breeders, and quicker of flight, for which they are esteemed. As for the colours of their feathers, they are uncertain, so that a judgment cannot be made of the sort by them.

The next which makes the largest figure, but is not in reality the largest bird, is the cropper, so called, because they usually do, by attracting the air, blow up their crops to an extraordinary bigness, even so as to be sometimes as large as their bodies. This sort is the most valued, according as it can swell up its crop to the larger size.

The bodies of this sort are about the bigness of the smaller runt, but are somewhat more slender; this sort also is of various colours in the feathers.

The shakers; these are of two sorts, viz. the broad-tailed shaker, and the narrow-tailed shaker: these are so called, because they are almost constantly wagging their heads and necks up and down; the broad are distinguished from the narrow in that the broad-tailed sort abounds with tail feathers about twenty-six in number; but the narrow-tailed shakers have not so many.

These, when they walk, carry their tail-feathers and crest spread abroad like a turkey-cock: they have likewise a diversity of feathers.

The jacobines, or cappers, which are so called on account of certain feathers which turn up about the back part of the head: some of this sort are rough footed; they are short billed, the iris of their eye of a pearl colour, and the head is commonly white.

The turbit, which some suppose to be a corruption of the word *corbeck*, or *curtbeke*, as they are called by the Dutch, which seems to be derived of the French, *court-beck*, and signifies a short bill, for which this pigeon is remarkable; for the head is flat, and the feathers on the breast spread both ways; these are much of the same size with the jacobines.

The carriers are pigeons so called from the use which is sometimes made of them in carrying of letters to and fro: certain it is that they are very nimble messengers, for some authors affirm that it has been found by experience, that one of these pigeons will fly three miles a minute, or from St. Alban's to London in seven minutes; this has been tried by experiments.

We have an account of their passing and repassing with advices between Hirtius and Brutus, at the siege of Modena, who had, by laying meat for them in some high places, used their pigeons to fly from place to place for their meat, they having before kept them hungry, and in a dark place.

These pigeons are about the size of common pigeons, and of a dark blue, or blackish colour, which is one way of distinguishing them from other sorts: they are also remarkable for having their eyes compassed about with a broad circle of naked spongy skin, and for having the upper chap of their beak covered more than half from the head, with a double crust of the like naked fungous body. The bill or beak is moderately long, and black.

These birds have this quality, that if they are carried many miles from the place where they are bred and brought up, or have themselves hatched or bred up any young ones, they will immediately return home as soon as they are let to fly.

When persons would use them for carriers, they must order them in the following manner:

Two friends must agree to keep them, the one at London, and the other at Windsor, or any other place; he that liveth at Windsor must take two or three cocks or hens which were bred at his friend's at London, and the other two or three that were bred at Windsor: when the person at London has occasion to send any advice to his friend at Windsor, he must roll up a piece of paper, and tie it gently, with a small string passed through it, about the pigeon's neck.

But here you must remember, that the pigeons you design to send with a letter, must be kept pretty much in the dark, and without meat for eight or ten hours before they are turned out, and then they will rise and turn round till they have found their way, and continue their flight till they have got home.

With two or three of these pigeons on each side, a correspondence might be carried on in a very expeditious manner, especially in matters of curiosity, &c.

The Barbary pigeon, or barb, is another sort, whose bill is like that of the turbit, short and thick, having a broad and naked circle of a spongy white substance round about the eye, like that of the carrier pigeon; the iris of the eye is white, if the feathers of the pinion are inclinable to a darker colour, but is red if the feathers are white, as is observed in other birds.

Smiters are supposed to be the same that the Dutch call *dragers*; this sort shake their wings as they fly, and rise commonly in a circular manner in their flight, the males, for the most part, rising higher than the females, and frequently falling and flapping with their wings, which makes a noise that may be heard a great way off, which often

is the cause of their breaking or shattering their quill-feathers.

These very much resemble the tumbler pigeon; the difference chiefly is, that the tumbler is somewhat smaller, and in its flight will tumble itself backward over its head; the diversity of colours in the feathers makes no difference.

The Helmet pigeon is distinguished from the others, because it has the head, the quill-feathers, and the tail-feathers, always of one colour, sometimes black, sometimes white, or red, or blue, or yellow; but the other feathers of the body are of a different colour.

The light horseman; this is supposed to be a cross strain, between a cock cropper and a hen of the carrier breed, because they seem to partake of both, as appears from the excrescence of flesh upon their bills, and the swellings of their crops; these are not inclined to leave the place of their birth, or the house that they have been used to.

The bastard-bill pigeon is something bigger than the Barbary pigeon; they have short bills, and are generally said to have red eyes, though probably those coloured eyes belong only to those that have white feathers.

There is a pigeon called the turner, which is said to have a tuft of feathers hanging backwards on the head, which parts like a horse's mane.

There is also a pigeon of the smaller sort, called the finikin, but in other respects like the former.

There is another pigeon called the spot, supposed (and with judgment), to take its name from a spot on the forehead, just above the bill, and the feather of its tail always of the same colour with the spots, and all the other feathers are white.

The Mahomet, or mawmet pigeon, supposed to be brought from Turkey, which is singular for its large black eyes, but the other parts are like those of the Barbary pigeon.

To distinguish which are the males and females among pigeons, it is chiefly known by the voice and cooing; the females having a small weak voice, and the male a loud and deep voice.

The food which is generally given to pigeons is tares, but if spurry seeds were mixed with them, or buck-wheat, those grains would forward their breeding; however, with only tares, they may be expected to breed eight or nine times a year; but perhaps they seldom hatch above one at a time, though, if they be in full vigour, they will breed a pair at one sitting.

In the feeding of pigeons, it is advisable not to let them have more meat at one time than they can eat, because they are apt to toss it about and lose a great deal of it; so that the contrivance of filling a stone bottle with their meat, and placing the mouth downwards, so that it may come within an inch of a plane or table, will give a supply as they feed.

And something of the same method should be used about their water, by the bottle being reversed with the mouth into a narrow shallow cistern; but they must by no means be without water, they being of themselves a dry bird, and subject to contract dirt and fleas.

To take Pigeons, upon new-ploughed or sown Ground.

Take a good number of small twigs, of strong wheaten straw, of a good length, bird-line them well, lay them on the ground where pigeons, &c. frequent, and they will soon be entangled with them; and in order to allure to your twigs or straws, you may tie two or three pigeons to the ground, among the twigs.

Another Way.

Cut some sheets of thick brown paper, each into about eight parts, making them up in the shape of a sugar-loaf, and line the inside of them three or four days before you intend to use them; put into each paper, near the bottom, three or four grains of corn, and lay these papers up and down the ground, as much as you can, under clods of earth, early in the morning, before the pigeons, &c. come to feed. The more papers you lay, the greater you may expect your sport. When the pigeons come to feed they will see the corn, and by thrusting in their heads to reach it, will get hood-winked by the paper sticking to their heads, which will occasion them to take wing, and fly bolt upright till they have spent themselves, when they will come tumbling down and may be easily taken.

PIGEON-HOUSE, a house erected full of holes within, for the keeping, breeding, &c. of pigeons, otherwise called a dove-cote.

Any lord of a manor may build a pigeon-house on his land, but a tenant cannot do it without the lord's licence. When persons shoot at or kill pigeons within a certain distance of the pigeon-house, they are liable to pay a forfeiture.

In order to erect a pigeon-house to advantage, it will be necessary, in the first place, to pitch upon a convenient situation, of which none is more proper than the middle of a spacious court-yard, because pigeons are naturally of a timorous disposition, and the least noise they hear frightens them. With regard to the size of the pigeon-house, it must depend entirely upon the number of birds intended to be kept; but it is better to have too large than too little: and as to its form, the round should be preferred to the square ones; because rats cannot so easily come at them in the former as in the latter. It is also much more commodious; because you may, by means of a ladder turning upon an axis, easily visit all the nests in the house, without the least difficulty: which cannot so easily be done in a square house.

In order to hinder rats from climbing up the outside of the pigeon-house, the wall should be covered with tin plates to a certain height, about a foot and a half will be sufficient; but they should project out three or four inches at the top, to prevent their clambering any higher.

The pigeon-house should be placed at no great distance from water, that the pigeons may carry it to their young ones; and their carrying it in their bill will warm it, and render it more wholesome in cold weather.

The boards that cover the pigeon-house should be well joined together, so that no rain may penetrate through it. And the whole building should be covered with hard plaister; and white-washed within and without, white being the most pleasing colour to pigeons. There must be no window, or other opening, in the pigeon house, to the eastward; these should always face the south; for pigeons are very fond of the sun, especially in winter.

The nests or covers in a pigeon-house, should consist of square holes made in the walls of a size sufficient to admit the cock and hen to stand in them. The first range of these nests should not be less than four feet from the ground, that the wall underneath being smooth, the rats may not be able to reach them. These nests should be placed in quincunx order, and not directly over one another. Nor must they be continued any higher than within three feet of the top of the wall: and the upper row should be covered with a board projecting a considerable distance from the wall, for fear the rats should find means to climb the outside of the house.

M. Duhamel thinks that pigeons neither feed upon the green corn, nor have bills strong enough to search for its seeds in the earth; but only pick up the grains that are not covered, which would infallibly become the prey of other animals, or be dried up by the sun. "From the time of the sprouting of the corn, says he, pigeons live chiefly upon the seeds of wild uncultivated plants, and therefore lessen considerably the quantity of weeds that would otherwise spring up; as will appear from a just estimate of the quantity of grain necessary to feed all the pigeons of a well-stocked dove-house." But Mr. Worlidge and Mr. Lill alledge facts in support of the contrary opinion. The latter relates, that a farmer in his neighbourhood assured him he had known an acre sowed with pease, and rain coming on so that they could not be harrowed in, every pea was fetched away in half a day's time by pigeons: and the former says, "It is to be observed, that where the flight of pigeons falls, there they fill themselves and away, and return again where they first rose, and so proceed over a whole piece of ground, if they like it. Although you cannot perceive any grain above the ground, they know how to find it. I have seen them lie so much upon a piece of about two or three acres sown with peas, that they devoured at least three parts in four, of the seed, which, I am sure, could not be all above the surface of the ground. That their smelling is their principal director, I have observed; having sown a small plat of peas in my garden, near a pigeon-house, and covered them so well that not a pea appeared above ground. In a few days, a parcel of pigeons were hard at work in discovering this hidden treasure; and in a few days more, I had not above two or three peas left out of about two quarts that were planted; for what they could not find before, they found when the birds

buds appeared, notwithstanding they were hoed in, and well covered. Their smelling alone directed them, as I supposed, because they followed the ranges exactly. The injury they do at harvest on the peas, vetches, &c. is such that we may rank them among the greatest enemies the poor husbandman meets withal; and the greater, because he may not erect a pigeon-house, whereby to have a share of his own spoils; none but the rich being allowed this privilege; and so severe a law being also made to protect these winged thieves, that a man cannot encounter them, even in defence of his own property. You have therefore no remedy against them, but to affright them away by noises, or such like. You may, indeed, shoot at them; but you must not kill them; or you may, if you can, take them in a net, cut off their tails, and let them go, by which means you will impound them: for when they are in their houses, they cannot bolt or fly out of the tops of them, but by the strength of their tails: after they are thus weakened they remain prisoners at home."

Mr. Worlidge's impounding the pigeons reminds me of a humorous story of a gentleman, who, upon a neighbouring farmer's complaining to him, that his pigeons were a great nuisance to his land, and did sad mischief to his corn, replied jokingly, Pound them, if you catch them trespassing. The farmer, improving the hint, steeped a parcel of peas in an infusion of *coccus Indicus*, or some other intoxicating drug, and strewed them upon his grounds. The pigeons swallowed them, and soon remained motionless on the field: upon which the farmer threw a net over them, inclosed them in it, and carried them to an empty barn, from whence he sent the gentleman word that he had followed his directions with regard to the pounding of his pigeons, and desired him to come and release them.

PIGGIN, a little pail or tub, with an erect handle.

PIKE, a name given in some counties to what is generally called a fork, used for carrying straw, &c. from the barn, cocking of barley, &c.

PINE, the name of a forest tree, of which there are various species, but two only that deserve cultivating; namely, the Scotch-pine, and the white pine, commonly called in England lord Weymouth's, or New England pine.

The Scotch pine, so called from its growing naturally on the mountains of Scotland, is the tree that affords the red or yellow deal, which is the most durable of any of the kind yet known. The leaves of this tree are pretty broad and short, of a greyish colour, growing two out of each sheath; the cones are small, pyramidal, and end in narrow points; they are of a light colour, and the seeds are small.

This sort grows well upon almost every soil; I have planted numbers of the trees upon peat-bogs, where they have made great progress. I have also planted them in clay, where they have succeeded far beyond expectation; and upon sand, gravel, and chalk, they likewise thrive as well; but as they do not grow near so fast upon gravel and sand, as upon moist ground, so the wood is much preferable; for those trees which have been cut down upon moist soils, where they have made the greatest progress, when they have been sawn out into boards, have not been valuable; the wood has been white, and of a loose texture; whereas, those which have grown upon dry gravelly ground, have proved nearly equal to the best foreign deals; and I doubt not but those plantations, which of late years have been made of these trees, will in the next age, not only turn greatly to the advantage of their possessors, but also become a national benefit.

The white pine is one of the tallest trees of all the species, often growing a hundred feet high, as I have been credibly informed. The bark of this tree is very smooth and delicate, especially when young; the leaves are long and slender five growing out of each sheath; the branches are pretty close, garnished with them, so make a fine appearance; the cones are long, slender, and very loose, opening with the first warmth of the spring: so that if they are not gathered in winter, the scales open and let out the seeds. The wood of this sort is esteemed for making of masts for ships; it is in England called lord Weymouth's, or New England pine, as hath been already observed. As the wood of this tree was generally thought of great service to the navy, there was a law made in the ninth year of queen Anne, for the preservation of the trees, and to encourage their growth in America: and it is within forty years past these trees began to be propagated in England in any

plenty, though there were some large trees of this sort growing in two or three places long before, particularly at the marquis's of Bath at Longleet; and Sir Wyndham Knatchbull's, in Kent; and it hath been chiefly from the seeds of the latter that the much greater number of these trees now in England have been raised; for although there has annually been some of the seeds brought from America, yet those have been few in comparison to the produce of the trees in Kent: many of the trees, which have been raised from the seeds of those trees, now produce plenty of the seeds, particularly those in the gardens of the late duke of Argyle, at Whitton, which annually produce large quantities of cones, which his grace, when living, most generously distributed to all the curious.

All the sorts of pines are propagated by seeds, which are produced in hard woody cones; the way to get the seeds out of these cones, which are close, is to lay them before a gentle fire, which will cause the cells to open, and then the seeds may be easily taken out. If the cones are kept entire, the seeds will remain good some years, so that the surest way to preserve them, is to let them remain in the cones, until the time for sowing the seeds: if the cones are kept in a warm place in summer, they will open, and emit the seeds; but if they are not exposed too much to heat, many of the sorts will remain entire some years, especially those which are close and compact; and the seeds, which have been taken out of cones of seven years old, have grown very well, so that these may be transported to any distance, provided the cones are well ripened, and properly put up.

The best time for sowing the seeds of pines, is about the end of March; when the seeds are sown, the place should be covered with nets to keep off birds; otherwise, when the plants begin to appear with the husk of the seed on their tops, the birds will pick off the heads of the plants and destroy them.

Where the quantity of seeds to be sown is not great, it will be a good way to sow them either in boxes or pots, filled with light loamy earth, which may be removed from one situation to another, according to the season of the year; but if there is a large quantity of the seeds, so as to require a good space to receive them, they should be sown on an east or north-east border, where they may be screened from the sun, whose heat is very injurious to these plants at their first appearance above ground. Those seeds which are sown in pots or boxes, should also be placed in a shady situation, but not under trees: and if they are screened from the sun with mats, at the time when the plants first come up, it will be a good method to preserve them.

When the plants appear, they must be constantly kept clean from weeds, and, in very dry seasons, if they are now and then gently refreshed with water, it will forward their growth; but this must be done with great care and caution, for if they are hastily watered it will wash the tender plants out of the ground, or lay them down flat, which often rots their shanks: and when this is too often repeated, it will have the same effect; so that unless it is judiciously performed, it will be the best way to give them none, but only screen them from the sun.

If the plants come up too close, it will be a good method to thin them gently about the beginning of July. The plants, which are drawn up, may then be planted on other beds, which should be prepared ready to receive them, for they should be immediately planted as they are drawn up, because their tender roots are soon dried and spoiled at this season of the year. This work should be done, if possible, in cloudy or rainy weather, and then the plants will draw out with better roots, and will soon put out new fibres again; but if the weather should prove clean and dry, the plants should be shaded every day from the sun with mats and now and then gently refreshed with water. In drawing up of the plants, there should be great care taken not to disturb the roots of the plants left remaining in the seed-beds, &c. so that if the ground be hard, the beds should be well watered some time before the plants are thinned, to soften and loosen the earth; and if, after the plants are drawn out, the beds are again gently watered to settle the earth to the roots of the remaining plants, it will be of great service to them; but it must be done with great care, so as not to wash out their roots, or lay down the plants. The distance which should be allowed these plants, is four or five inches row from row, and three inches in the row.

In these beds the plants may remain till the spring twelve-months after, by which time they will be fit to transplant, where

where they are to remain for good; for the younger plants are, when planted out, the better they will succeed; for although some sorts will bear transplanting at a much greater age, yet young plants planted at the same time will in a few years overtake the large ones, and soon outstrip them in their growth; and there is an advantage in planting young, by saving the expence of staking, and much watering, which large plants require. I have several times seen plantations of several sorts of pines, which were made of plants six or seven feet high, and at the same time others of one foot high planted between them, which in ten years were better trees than the old ones, and much more vigorous in their growth; but if the ground, where they are designed to remain, cannot be prepared by the time before mentioned, the plants should be planted out of the beds into a nursery, where they may remain two years, but not longer; for it will be very hazardous in removing these trees at a greater age.

The best season to transplant these pines, is about the latter end of March, or the beginning of April, just before they begin to shoot; for although the Scotch pine, and some of the most hardy sorts may be transplanted in winter, especially when they are growing in strong land, where they may be taken up with balls of earth to their roots; yet this is what I would not advise for common practice, having frequently seen it attended with bad consequences; but those which are removed in the spring rarely fail.

Where these trees are planted in exposed situations, they should be put pretty close together, that they may shelter each other, and, when they have grown a few years, part of the plants may be cut down to give room for the others to grow; but this must be gradually performed, lest by too much opening the plantation at once, the air should be let in among the remaining trees with too great violence, which will stop their growth.

Wherever large plantations are designed to be made, the best method will be to raise the plants either upon a part of the same land, or as near to the place as possible, and also upon the same sort of soil; a small piece of ground will be sufficient to raise plants enough for many acres; but, as the plants require some care in their first raising, if the neighbouring cottagers, who have many of them small inclosures adjoining to their cottages; or, where this is wanting, a small inclosure should be made them for the purpose of raising the plants, and they be furnished with the seeds, and directions for sowing them, and managing the young plants till they are fit for transplanting, the women and children may be usefully employed in this work, and the proprietors of land agreeing with them to take their plants, when raised at a certain price, it would be a great benefit to the poor, and hereby they would be engaged to have a regard for the plantations when made, and prevent their being destroyed.

The Scotch pines, as was before observed, being the hardiest of all the kinds, and the wood of it the most useful, is the sort which best deserves care. These will thrive upon the most barren sands, where scarce any thing else except heath and furze will grow; so that there are many thousand acres of such land lying convenient for water carriage, which at present is of little benefit to any body, that might, by plantations of these trees, become good estates to their proprietors, and also a national benefit; and as the legislators have taken this into their consideration, and already passed some laws for the encouraging these plantations, as also for their preservation and security, so it may be hoped that this will be undertaken by the gentlemen who are possessed of such land in all the different parts of the kingdom, with proper spirit; for although they may not expect to receive much profit from these plantations in their own time, yet their successors may, with large interest, and the pleasure which these growing trees will afford them, by beautifying the present dreary parts of the country, will in some measure recompense them for their trouble and expence, and by creating employment for the poor, lessen those rates which are now, in many parts of England, very heavy.

The expence of making these plantations is what most people are afraid of, so would not engage in it; but the greatest of the expence is that of fencing them from the cattle, &c. for the other is trifling, as there will be no necessity of preparing the ground to receive the plants and the charge of planting an acre of land with these plants, will not be more than thirty shillings where labour is dear,

exclusive of the plants, which may be valued at forty shillings more. I have planted many acres of land with these trees, which were covered with heath and furze, and have only dug holes between to put in the plants, and afterwards laid the heath or furze, which was cut upon the surface of the ground about their roots, to prevent the ground drying, and few of the plants have failed. These plants were most of them four years old from seed, nor was there any care taken to clear the ground afterwards, but the whole left to shift, and in five or six years the pines have grown so well as to overpower the heath and furze, and destroy it.

The distance which I have generally planted these plants in all large open situations, was about four feet, but always regular, avoiding planting in rows as much as possible; and in the planting great care is, not to take up the plants faster than they can be planted, so that some men have been employed in digging up the plants, while others were planting. Those who take up the plants must be looked after to see they do not tear off their roots, or wound their bark; and as fast as they are taken up, their roots should be covered to prevent their drying, and put into their new quarters as soon as possible. In planting them, care should be had to make the holes large enough for their roots, as also to loosen and break the clods of earth, and put the finest immediately about their roots, then to settle the earth gently with the foot to the roots of the plant. If these things are duly observed, and a proper season chosen for performing it, there will be very little hazard of their succeeding; but I have seen some plantations made with plants, which were brought from a great distance, and had been so closely packed up, as to cause a heat, whereby most of the plants within had their leaves changed yellow, and few of them have grown, which has discouraged others from planting, not knowing the true cause of their failure.

After the plantations are made, the only care they require for five or six years, will be to secure the plants from cattle, hares, and rabbits; for if these are admitted to them, they will make great destruction in a short time; for if the branches are gnawed by hares or rabbits, it will greatly retard the growth of the plants, if not destroy them.

In about five or six years after planting, the branches of the young trees will have met, and begin to interfere with each other, therefore they will require a little pruning; but this must be done with great caution. The lower tier of branches only should be cut off; this should be performed in September, at which time there will be no danger of the wounds bleeding too much, and the turpentine will harden over the wounds as the season grows cold, so will prevent the wet from penetrating of them. These branches should be cut off close to the stem of the plants, and care should be taken in the doing of this, not to break any of the remaining branches of the young trees. This work should be repeated every other year, at each time taking off only the lower tier of branches: for if the plants are much trimmed, it will greatly retard their growth, as it does in general that of all trees; but as these trees never put out any shoots where they are pruned, so they suffer more from amputation than those which do.

In about twelve or fourteen years these will require no more pruning, for their upper branches will kill those below, where they have not air; but soon after this, if the plants have made good progress, it may be necessary to thin them; but this should be gradually performed, beginning in the middle of the plantation first, leaving the outside close to screen those within from the cold, so by degrees coming to them at last, whereby those, which were first thinned, will have had time to get strength, so will not be in danger of suffering from the admission of cold air. When these plantations are thinned, the trees should not be dug up; but their stems cut off close to the ground, for their roots never shoot again, but decay in the earth, so there can no harm arise by leaving them, and hereby the roots of the remaining plants are not injured. The trees which are now cut, will be fit for many purposes; those which are straight, will make good putlocks for the bricklayers, and serve for scaffolding poles, so that there may be as much made by the sale of these as will defray the whole expence of the planting, and probably interest for the money into the bargain.

As the upright growth of these trees renders their wood the more valuable, they should be left pretty close together, whereby they will draw each other up, and grow very tall.

I have seen some of these trees growing, whose naked stems have been more than seventy feet high, and as straight as a walking-cane, and from one of these trees there was as many boards sawed, as laid the floor of a room near twenty feet square. If these trees are left eight feet asunder each way, it will be sufficient room for their growth; therefore, if at first thinning a fourth part of the trees are taken away, the others may stand twelve or fourteen years longer, by which time they will be of a size for making ladders, and standards for scaffolding, and many other purposes: so that from this sale, as much may be made, as to not only pay the remaining part of the expence of planting, if any should be wanting in the first, but rent for the land with interest, and the standing trees for fortunes of younger children. This may be demonstrated by figures, and there has been several examples of late years, where the profits have greatly exceeded what is here mentioned. *Miller's Gard. Dict.*

Pitch, tar, rosin, and turpentine, are all made from these trees by a very familiar process. In the spring time, when the sap is most free in running, they pare off the bark of the pine-tree, to make the sap run down into a hole which they cut at the bottom to receive it: in the way, as it runs down, it leaves a white matter like cream, but a little thicker: this is very different from all the kinds of resin and turpentine in use, and it is generally said to be used in the making of flambeaux, instead of white bees wax. The matter that is received in the hole at the bottom, is taken up with ladles, and put in a large basket; a great part of this immediately runs through, and this is the common turpentine. This is received into stone or earthen pots, and ready for sale. The thicker matter, which remains in the basket, they put into a common alembic, adding a large quantity of water; they distil this as long as any oil is seen swimming upon the water; this oil they separate from the surface in large quantities, and this is the common oil or spirit of turpentine; the remaining matter at the bottom of the still, is common yellow resin. When they have thus obtained all that they can from the sap of the tree, they cut it down, and, hewing the wood into billets, they fill a pit dug in the earth with these billets, and, setting them on fire, there runs from them, while they are burning, a black thick matter; this naturally falls to the bottom of the pit, and this is the tar. The top of the pit is covered with tiles, to keep in the heat; and there is at the bottom a little hole, at which the tar runs like oil; if this hole be made too large, it sets the whole quantity of the tar on fire; but, if small enough, runs quietly out.

The tar being thus made, is put up in barrels, and, if it be to be made into pitch, they put it into large boiling vessels, without adding any thing to it: it is then suffered to boil a while, and, being then let out, is found, when cold, to be what we call pitch. *Phil. Transf. Numb. 243.*

PIP, or PER, a disease among poultry, consisting of a white thin skin, or film, which growing under the tip of the tongue, hinders their feeding. It usually arises from their drinking puddle-water, or eating filthy meat; and is cured by pulling off the film with the fingers and rubbing the tongue with salt.

PIPE-DRAINS. See DRAINING and UNDER-DRAINING.

PISMIRE, or ANTS, are destroyed by laying human ordure on their hills, as that will drive them away or kill them if done in frosty weather. Some destroy them by firing their nests. Another manner of driving them away is by the root of wild cucumber, muske-shells burnt with storax, and beat to powder strewed over the gardens where they are, will compel them to quit their holes and prove their destruction.

Origanum, powdered, and spread among them, kills them; or cirenicum, melted in oil, will answer the same purpose: or, make a roll of wool, newly plucked from the sheep's belly, and encompass your flower-stem, five fingers in breadth.

Smear the bottom of the trees all round with tar, which will prevent their climbing; or put human ordure round the root or stem of the tree.

Mix some powder of arsenic with honey; put it into a box made of cards or pasteboards, pricked full of holes with a bodkin. Hang these boxes on the trees, and it will kill the vermin. Be careful not to make the holes too large, lest bees should likewise get in, and be poisoned.

Some persons hang a glass bottle on the tree, with a

little honey, or other sweet liquor in it, and it will draw the ants into it. If you do this you must often wash the bottle and place it there again; they are also killed by frequent watering the walks or paths.

In winter the ant-hills should be dug up, and the core taken out, that when you lay your turf down, it may lie lower than the ground. This prevents ants returning, and the rain and frost will destroy those that remain.

The dregs of oil, mixed with lupins, and rubbed over the bottom of your plants, will preserve them from pismires. To keep your sugar or spice-box from these insects you must cover it with white wool. Brimstone powdered, and steeped in water, till the water is become coloured, will drive them away.

PISSING of Blood [in horses] may proceed from divers causes, sometimes by being ridden over-hard, or laboured beyond his strength, and by carrying too heavy burdens on his body; at other times it may be by some vein broken in his body, on which blood will frequently issue out of his body; or it may proceed from some stone fretting upon his kidneys, and from several other causes.

For the cure:

Take knot-grass, shepherd's purse, bloodwort of the hedge, polypody of the wall, comfrey, and garden bloodwort, of each an handful, shred them small, and boil them in a quart of beer, to which add a little salt-leaven and foot, and give the horse.

PLANET-STRUCK, or SHREW-RUNNING, as it is called by some, is a distemper in horses, being a deprivation of feeling or motion, not stirring any of the members, but that they remain in the same form as when the beast was first seized with it.

It proceeds sometimes from choler and phlegm, superabundantly mixed together: sometimes from melancholy, blood, being a cold and dry humour which affects the hinder part of the brain; sometimes from extreme heat and cold, or raw digestion, striking into the veins suddenly; or lastly, from extreme hunger, occasioned by long fasting.

If the disease proceed from heat, it may be known by the hotness of the horse's breath, and the free fetching of his wind; but if from cold, by a stuffing and poze in his head. For the cure,

Some prescribe to hang a flint-stone over his head, or some cold iron, as an old scythe, &c. others, to give him fifteen seeds of single piony; others prescribe exercise before and after water, to mix hemp-seed in his provender, and to cause him to sweat, by giving him mistletoe of the oak, mustard-seed, seed of black poplar, cinquefoil, germander, hyssop, and St. John's wort.

PLANTATION. Mr. Marshall, in his Rural Economy of Gloucester, says, "that the plantations of the Vale consist wholly of fruit-trees. Forest-trees may be said to be here in total neglect; excepting some few ash coppices for cyder-cask hoops; a species of plantation common on the Herefordshire side of the county.

"If, however, we may judge from the coppice which has been spoken of above, and the hedge noticed aforegoing, it is highly probable, that many of the cold swells, which occur in different parts of the Vale, might be planted with great profit.

"The timber-oak is, at present, almost entirely banished from this side of the Severn; and although the opposite banks are yet sufficiently wooded, the present woods will, in all probability, be fallen, long before such as may be now raised from the acorn, will be ready for the axe.

"Unfortunately for the Cotswold hills, a spirit of planting has never been generally diffused among them. Something has been done about Guiting and Dowdeswell; and an ancestor of the marquis of Lansdown laid out and planted a new park, near his residence at Sherborne. And lord Bathurst's grounds near Cirencester are well known. But these have all been done with a view to ornament, merely. The propagation of wood for the use of estates appears not to have taken place; excepting some small ash coppices, which have been made, and still I see continue to be made, in the vallies, for hurdle stuff. Farms, in general, may be said to be totally destitute of wood. Coals are fetched 20 to 30 miles by land carriage; and faggot wood perhaps eight or ten

ten miles. Not a pole upon the farm to assist in making a handful of brushwood to kindle the fire. Straw, I am afraid, is here considered as an article of fuel: a circumstance which reflects no credit on the owners of landed estates.

"It strikes me forcibly that the corners and asperities of every estate ought to be cut off, and the angles filled up with coppice-wood: and that the more central farms ought each of them to have its skreen coppices, sufficiently extensive to admit of a plot being filled every year, for the use of the farm, and the cottagers of the township it lies in.

"In winter, the poor, on these shelterless hills, must be in a wretched state as to fuel. There are few hill countries which do not afford either wood, coals, peat, or at least turf; but here straw may be said to be the only fuel the country at present produces. Fortunately for the farmers stone walls will not readily burn.

"Few countries are so well adapted to the propagation of woodland as this. Wall is of all other the best plantation-fence; and here it is raised at an easy expence. Mark out the intended site; cleanse it by a turnep or a whole summer fallow; wall it round; dibble in acorns, beech masts, ash keys, hazlenuts, or other seeds of wood best adapted to the purpose intended; cleanse during the first three of four years, and fell at the age best suited to the ware required." See OAK, NURSERY, and ORCHARD.

PLAT-VEIN in a horse, is a vein on the inside of each fore-thigh, a little below the elbow, so called among common farriers; some call it the basilic vein.

PLEURISY, an inflammation of the lungs, &c. are disorders in horses, though they have scarce been mentioned by any writer in farriery before Mr. Gibson; who, by frequently examining the carcases of dead horses, has found them subject to the different kinds of inflammations here described.

He has often discovered matter on the pleura (or membrane which lines the chest internally) making its way into the chest; he has found in some horses the whole substance of the lungs black, and full of gangrened water; and in others abscesses of various sizes; and, in short, inflammations in every bowel. He has frequently seen the blood vessels so overloaded, that the blood has burst out of the smaller vessels, and run over their carcases in many places, while the collar-maker was fleaing off their hides, and on cutting open the larger vessels, the blood has gushed out as from a fountain, filling all the cavity of the body; an evident proof, that plentiful evacuations had been neglected. In order to distinguish these disorders from others, we shall describe the symptoms, in Mr. Gibson's own words.

"A pleurisy then, which is an inflammation of the pleura, and a peripneumony, which is an inflammation of the lungs, have symptoms very much alike; with this difference only, that in a pleurisy a horse shews great uneasiness, and shifts about from place to place; the fever, which at first is moderate, rises suddenly very high; in the beginning he often strives to lie down, but starts up again immediately, and frequently turns his head towards the affected side, which has caused many to mistake a pleuritic disorder for the gripes, this sign being common to both, though with this difference:

"In the gripes a horse frequently lies down, and rolls, and when they are violent, he will also have convulsive twitches, his eyes being turned up, and his limbs stretched out, as if he was dying; his ears and feet sometimes occasionally hot, and sometimes as cold as ice; he falls into profuse sweats, and then into cold damps, strives often to stale and dung, but with great pain and difficulty: which symptoms generally continue, till he has some relief: but in a pleurisy, a horse's ears and feet are always burning-hot, his mouth parched and dry, his pulse hard and quick; even sometimes when he is nigh dying, his fever is continued and increasing, and though in the beginning he makes many motions to lie down, yet afterwards he reins back as far as his collar will permit, and makes not the least offer to change his posture, but stands panting with short stops, and a disposition to cough, till he has relief, or drops down.

"In an inflammation of the lungs, several of the symptoms are the same, only in the beginning he is less active, and never offers to lie down during the whole time of his sickness; his fever is strong, breathing difficult, and attended with a short cough; and whereas in a pleurisy, a horse's mouth is generally parched and dry, in an inflammation of the lungs, when a horse's

mouth is open, a roapy slime will run out in abundance; he gleans also at the nose a reddish or yellowish water; which sticks like glue to the inside of his nostrils.

"In a pleurisy, a horse heaves and works violently at his flanks, with great restlessness, and for the most part his belly tucked up; but in an inflammation of the lungs, he always shews fullness, and the working of his flanks is regular, except after drinking and shifting his posture; and his ears and feet are for the most part cold, and often in damp sweats.

"The cure of both these disorders is the same. In the beginning a strong horse may lose three quarts of blood; the next day two quarts more; and if symptoms do not abate, the bleedings must be repeated, a quart at a time: for it is speedy, large, and quick repeated bleedings that are in these cases chiefly to be depended on. But if a horse has had any previous weakness, or is old, you must bleed him in less quantities, and oftener. Mr. Gibson recommends rowels, on each side the breast, and one on the belly; and a blistering ointment to be rubbed all over his brisket upon the foremost ribs.

"The diet and medicines should be both cooling, attenuating, relaxing, and diluting; and the horse should have warm mashes, and plenty of water or gruel. The following balls may be given thrice a day:

"Take of spermaceti and nitre, of each one ounce: oil of aniseed thirty drops: honey enough to make a ball.

"A pint of barley-water, in which figs and liquorice-root have been boiled, should be given after each ball; to which the juice of lemons may be added; and if the lungs are greatly oppressed with a dry short cough, two or three horns full of the decoction may be given three or four times a day, with four spoonfuls of honey and linseed oil. A strong decoction of the rattle-snake root is also much recommended in pleuritic disorders, and may be given to the quantity of two quarts a day, sweetened with honey. It remarkably attenuates the blood, and disperses the inflammation, and in some parts is deemed a specific for this complaint.

"An emollient clyster should be injected once a day, to which may be added two ounces of nitre, or cream of tartar.

"In two or three days he will probably run at the nose, and begin to feed; but should he not, and continue hot and short breathed, you must bleed him again, and give the following clyster:

"Take fenna and marshmallows, of each two ounces: fennel and bay-berries, each one ounce: boil them in five pints of water to two quarts, pour off the clear, and add four ounces of purging salts, two or three of syrup of buckthorn, and half a pint of linseed, or any common oil.

"If by these means he grows cooler, and his pain moderates, repeat the clyster the next day, unless it worked too much; then intermit a day; and when he comes to eat scalded bran and picked hay, leave off the balls, and continue only the decoction, with now and then a clyster.

"But let it be observed, that a horse seldom gets the better of these disorders, unless he has relief in a few days; for if the inflammation is not checked in that time, it usually terminates in a gangrene, or collection of matter, which for want of expectoration, soon suffocates him.

"But as pleuritic disorders are apt to leave a taint on the lungs, great care should be taken of the horse's exercise and feeding, which should be light and open for two or three weeks. Thus a quartern of bran scalded, with a spoonful of honey and flour of brimstone, may be given every day, with two or three small seeds of oats, sprinkled with chamberlye. Instead of the bran, for a change, give about a quart of barley scalded in a double infusion of hot water, that it may be softened, and the water given to drink. His exercise should be gradual, in an open air and fair weather: and when his strength is recovered, a gentle purge or two should be given; that of rhubarb, when it can be afforded, is best, or the purging drink already recommended for this purpose.

"There is also an external pleurisy, or inflammation of the

the muscles between the ribs, which when not properly treated, proves the foundation of that disorder, called the chest-founder; for if the inflammation is not dispersed in time, and the viscid blood and juices so attenuated by internal medicines, that a free circulation is obtained; such a stiffness and inactivity will remain on these parts, as will not easily be removed, and which is generally known by the name of chest-founder.

"The signs of this inflammation, or external pleurisy, are a stiffness of the body, shoulders, and fore-legs; attended sometimes with a short dry cough, and a shrinking when handled in those parts.

"Bleeding, soft pectorals, attenuants, and gentle purges, are the best internal remedies; and externally, the parts affected may be bathed with equal parts of spirit of sal ammoniac, and ointment of marshmallows, or oil of chamomile.

"These outward inflammations frequently fall into the inside of the fore-leg, and sometimes near the shoulder; forming abscesses, which terminate the disorder.

"The membrane which separates the lungs, and more particularly the diaphragm, or midriff, is often also inflamed; which is scarce to be distinguished from the pleurisy, only in this, that when the midriff is greatly inflamed, the horse will sometimes be jaw-set, and his mouth so much closed, that nothing can be got in: but the method of cure is the same." *Bartlett's Farriery* p. 51.

PLOUGH, a well-known machine for breaking up the ground.

The advantage of digging with the spade, or such other instrument, very naturally led men to the invention of the plough, a much more expeditious way of doing the same thing; that is, cutting and breaking the earth into small pieces; but in this the spade has the advantage of the common plough, as it goes deeper, and divides the earth more minutely; but the improvement of the common plough into the four-coultered one, shews that it is easy to make the plough perform this office as much better, as it usually does it worse than the spade.

The plough described by Virgil had no coulter; and at this time, the ploughs of Italy and the south of France, have none; and the ploughs in Greece, and in the eastern nations in general, are of the same kind. Neither is it indeed possible to use a coulter in such a plough; because the share does not cut the bottom of the furrow horizontally, but obliquely: in going one way it turns off the furrow to the right-hand, but in coming back it turns it off to the left; therefore if it had a coulter, it must be on the wrong side every other furrow.

It is a great mistake in those who say that Virgil's plough had two earth-boards, for it really had none at all; but the share itself always going obliquely, served instead of an earth-board; and two ears, which were the corners of a piece of wood lying under the shares, did the office of ground-wrists. This fashion of the plough continues to this day in those countries; and in Languedoc this sort of plough performs tolerably well when the ground is fine, and makes a shift to break up light land. This is the sort of land that is common in the East, and the arable land, about Rome, being never suffered to be fallow so long as to come to turf: this plough succeeds very well in such places, but it would be wholly impossible to turn up what in England we call strong land, with it.

The English ploughs are therefore different from these, as the soil is different. Our ploughs, where well made, cut off the furrow at the bottom horizontally; and therefore, it being as thick on the land side as on the furrow side, the ploughs cannot break it off, from the whole land at such a thickness, being six times greater than what the eastern ploughs have to break off, and for this purpose it must have, of necessity, a coulter to cut it off: by this means the furrow is turned perfectly whole, and no part of the turf of it is broken; and if it lie long without new turning, the grass from the edges will spread, and form a new turf on the other side, which was the bottom of the furrow before the turning, but is now become the surface of the earth, and will soon become greener with grass than it was before ploughing.

Mr. Marshall says, that the Yorkshire, the Rotherham, and the Whip-rein ploughs are totally unfit for a stiff soil:

in loose mould they make very good work; but thinks them too short and stubbed for any soil. Their shortness makes them unsteady, as they are one moment buried, and the next above ground.

If whole, strong, turfy furrows are ploughed cross ways, as is too commonly practised, the coulter cannot easily cut them; because, being loose underneath, they do not make a proper resistance or pressure against its edge, but are apt to be drawn on heaps, and turned in all directions, but without cutting.

Some of our heavy drags have long iron tines in them; and though these broken pieces of furrows, being now looser than before, require keener edges to cut them, these tines have no edges at all. Thus the clods of earth are tossed into heaps again, and the surface left bare between them, and great labour and expence is used to very little purpose: all this is owing to the one coulter.

If the soil be shallow, it may be broken up with a narrow furrow, which will the sooner be brought into tilth; but if it be a deep soil, the furrows must be proportionally enlarged, or else a great part of the good mould will be left unmoved, and so be lost. The deeper the land is, the worse it is broke by one coulter; that is, it is broke into larger furrows, and it requires such repeated labour to conquer this, that often the best land will scarcely pay the tillage.

This gives an opportunity to servants to cheat their masters. They plough such deep land with a small furrow, and shallow, to the end, that the turf and furrows may be broken the sooner, and the superficial part made fine. They pretend the plough will go deeper the next time; but this is never the case.

This sort of land must not be ploughed the second time in wet weather; for this will cause the weeds to multiply, and the earth will be formed into thick and heavy clods where trodden: and in dry weather, the resistance of the untouched earth below, and the slight pressure of the plough above, will always be reasons why the plough will enter no deeper the second time than it did the first.

Another way to conquer strong turf, is to plough it up first with a breast-plough, very thin: and when the sward is rotten, then it is to be ploughed to the proper depth; but this method is liable to great objections; it is very troublesome and expensive, and if the turf be pared off in the winter, or early in the spring, it is a chance but the rains come on, and set it to growing faster than before: if, on the other hand, it be pared later in the year, though the turf be thoroughly killed by the succeeding dry weather, yet the time is lost, and the farmer loses the sowing season for wheat, which is the proper corn for such strong land.

Mr. Marshall, in his Minutes of Agriculture, says, that "he observed, after the fall of a great quantity of rain, that though the roads were sheets of puddle, yet in riding over some fallow grounds, which is as flat as a bowling-green, he found them still firm; which on examination he found had been plowed remarkably deep, and their firmness was owing entirely to the quantity of cultivated mould, by the deep ploughing. For had it been but half the depth of porous soil, its absorption would have been satiated, and the mould reduced to mud. This he imputes as a strong evidence in favour of deep plowing of neat soils. For though the roots of corn may strike two or three feet deep, this is no reason why six inches is insufficient to bring even wheat to perfection. He concludes with recommending deep-ploughing as universal good management."

In his Rural Economy of Yorkshire he, says, "the plough at present in universal estimation in the Vale is of the little, short, winding, mouldboard sort, which in different parts of the kingdom goes under the name of the Dutch plough, or the Yorkshire plough.

"On the construction of a ship volumes have been written, without any universally received principles being yet established. The Bermudians, who build by the eye alone, without either drawing or gauge to assist them, excel all other nations in the construction of small vessels (the almost only produce of their islands); which are remarkable as fast sailers, and notorious for lying nearer the wind than any other vessels.

"Different as the ship and the plough may be in magnitude and general appearance, there is some similarity in the principles of their construction; and the difficulty of fixing those

Scale of 6 Feet.

those principles, and of reducing them to a regular theory, is nearly the same in both. The art of construction in either case is principally attained by practice.

"In this district, the species of plough under notice is in general constructed better than it is perhaps in any other; yet even here, the ploughs of different makers pass through the soil with various degrees of facility and execution: nevertheless, though I have paid some attention to the different makes, I find myself entirely incapable of laying down such particular rules of construction as would do my country any service, or my work any credit. Even the general principles of construction I must mention with diffidence.

"The great difficulty, in the construction of a plough, is that of adapting it to all soils, in all seasons, and to all depths.

"If the soil break up in whole furrow, every inch of depth requires, in strictness, a separate plough, or a separate regulation. Here rests the main objection to the winding mouldboard, which admits of no regulation in respect of depth.

"If the semi-arch or hollow of the hindpart of the mouldboard be raised sufficiently high to turn a thick furrow completely, it is of no use in turning a thin one. On the contrary, if it be brought down sufficiently low to turn a shallow furrow properly, it is impossible to turn a deep one with it in a workman-like manner. There is not room for it within the hollow or semi-archway of the mouldboard. The inevitable effect of this is, either the furrow is forced away wholly by the upper edge of the mouldboard and set on edge; or the mouldboard rides upon the furrow, raising the heel of the plough from the ground; the evil effects of which need not be explained.

"An upright stern, with a moveable heelplate to turn the furrow at any given depth, is in this point of view much preferable to a hollow mouldboard; and if its use in raising a crest of mould for the purpose of covering the seed be added, its preference is still more conspicuous; and I see no reason why the Yorkshire plough should not receive so valuable an improvement.

"The foreparts of a Yorkshire plough of the best construction are admirably adapted to insinuate themselves beneath the soil and raise the furrow: a better form, perhaps cannot be conceived.

"The form of the Yorkshire plough is not its only excellency; the ordinary price of the woodwork complete, is not more than seven shillings and sixpence; the iron work about twenty shillings, including plates for the landside and mouldboard. Cast iron plates, somewhat resembling those of the Norfolk plough, are now coming into use instead of wooden mouldboards. These will reduce the general price still lower."

In his discourse about implements, he says as follows:

"The common sledge. This petty implement will be considered as unworthy of notice by those who are unacquainted with the uses of it. Nevertheless, here, where it is in common use, it is in universal estimation.

"For carrying harrows and other implements, thorns and other rough wood, turneps when the ground is tender, &c. &c. a sledge is frequently much preferable to a cart or a waggon. Some are made small and light for one horse; others strong and large, to be drawn by a team of oxen or horses.

"The principal singularity of construction consists in a valuable addition to the common harrow-sledge of other countries. This addition is made with two cross-pieces (like the cross-pieces of a cart or waggon), one fixed upon each end of the body of the sledge, projecting without the side-pieces about ten or twelve inches at each end. Upon the extremities of these cross-pieces are fixed two rails, provincially, stelvings, one on each side; thus increasing the width and hollowness of the bed of the sledge, and thereby rendering it capable of carrying a larger load with greater steadiness.

"The moulding sledge. This implement, I apprehend, is peculiar to Yorkshire.

"Its use is that of smoothing the surface of meadows; at the same time spreading the dung and molehills.

"The construction is that of the body of the common sledge, without its side-rails and cross-pieces; the upper edge of the side-pieces (of the body of the sledge) being for this purpose made perfectly straight.

"In use, it is drawn with the face downward, and the side foremost, across the ridges.

"Its effect is different from that of the landplane described in his Minutes of Agriculture, which having a middle bar, levels the surface; whereas this, having no middle bar, only smooths it.

"The front bar (namely, the side which is drawn foremost) forces off worm-casts, the rudiments of anthills, and other loose incumbrances which lie in its way.

"This collection of materials being driven before the implement, grind each other down fine enough to lodge in the dimples and fissures of the sward, thus smoothing the surface in a two-fold way; at the same time mixing, reducing, and distributing the meliorating ingredients in the most effectual manner.

"The front bar is sometimes shod with iron, projecting with a hoe-like edge before the woodwork. But this is unnecessary; and is frequently injurious in defacing the sward. The woodwork itself, while the acting angle in front remains sharp, is perhaps the best: but the angle soon wears off; by which means the implement loses its effect in removing the more stubborn protuberances. An iron bar fixed, not beneath, but in the front of the woodwork, the lower edge being set flush with the face of the implement, acts in a similar way to the wood itself, without being so liable to be worn away."

Paring PLOUGH, an instrument used in several parts of England, for paring off the surface of the ground, in order to its being burnt. See the article BURN-BAKING.

One of the best and simplest instruments of this kind is that which Mr. Bradley gives, with the following description.

From A to A, fig. 1. Plate XXI. is the plough-beam, about seven feet long, mortised and pinioned into the block B; which is of clean timber, without knots. C C are the sheaths or standards, made flat on the inside, to close equally with the paring-plate, and be fastened to it with a bolt and key on each side, as is marked at D.

E is the paring plate of iron laid with steel, about four inches wide, and from twelve to eighteen inches long, as the business may require. This plate must be made to cut on the sides, which are bolted to the standards, as well as at the bottom part.

FF are two iron braces, to keep the standards from giving way. These standards must be mortised near their out-sides, and through the block,

GG are the plough handles, which must be fixed slope-wise between the beam and the standards.

The pin-holes in the beam, the use of which is to make this plough cut more or less deep, by fixing the wheels nearer to or farther from the paring plate, should not be above two inches asunder.

Rotheram, or *Patent* PLOUGH, the name of a plough very simple in its construction, easily worked, and therefore deserves the husbandman's particular attention.

Fig. 2. Plate XXI. represents the left or land side of this plough, of which A B is the beam, CD the sheath, EBD the main handle, FR the smaller handle, GH the coulter, KI the sock or share, NP the bridle, S the flyband, ML a piece of wood in place of a head. The forms of all these different parts, as they appear on this side of the plough, are here represented, and their sizes and distances may be measured by the annexed scale of feet and inches.

Fig. 3. represents the right hand side of this plough, with all the parts that can be seen on that side, in which TV is the mould-board, &c.

Fig. 4. shews the under part of this plough turned up, in which may be seen the shape and size of the share, and the manner in which it is fixed on the sheath, mould-board, and ground-rest, with the angle which they make.

Fig. 5. represents the hind-part of the plough, in which are seen the two handles EF, with the hinder-part of the mould-board, VT, and a piece of wood in the place of the head LM, in their proper shapes and sizes by the scale.

Fig. 6. represents an upper view of this plough, as it appears while it works, with the bridle NP extended, the mould-board TV, fixed in its proper position, and all the other parts as they appear in this situation, and in their several shapes and sizes according to the scale.

Fig. 7. is the upper part of the sock or share.

Fig. 8. shews the opening of the share, as it is fixed on the end of the sheath and mould-board.

Fig. 9. is a perspective view of the bridle.

The whole of this plough should be made of ash or elm;

the irons should be steeled and well tempered; and that part of the plough which is under ground in tilling, should be covered with plates of iron.

The difference betwixt this and the common ploughs, seems to consist in the bridle at the end of the beam, by which the ploughman can give the plough more or less land by the notches at N in fig. 4, and 6, or make it cut deeper or shallower by the holes at P, in fig. 2, and 3, in the coulter and share, which are made and set so as to cut off the new furrow without tearing; and in the mould-board, which is so shaped at first to raise a little, and then gradually turn over the new cut furrow with very little resistance. But the greatest advantage of all is, it being so easy of draught, that it will do double the work of any common plough, as experience has proved; and, with only one man and two horses, will perform, even in stiff land, as much as two men and six horses can do in a moderately light soil with any of the wheeled ploughs generally used, or indeed known in this country, where their great defect is, that they are too complex, and weigh too much upon the fore-carriage, so that the friction of their wheels becomes a considerable addition to the draught: for the best plough certainly is that which is the most simple in its make and tackle; which requires the least strength to draw it, in proportion to the stiffness of the soil; which can be made always to cut to a proper depth; and which, by the shape of its mould-board, is best adapted to turn the furrow upside down. The principle of the Kentish plough, with the shifting mould-board, is very good, where the land is dry, and will admit of it.

Messieurs de Chateauxvieux and Duhamel, ever studious to promote the welfare of mankind, have endeavoured to remedy these inconveniencies in wheeled ploughs, by the following improvements, which, with their usual spirit of universal benevolence, they have most obligingly communicated to the world. We shall begin with the invention of the former of these gentlemen, because it was rather prior, in point of time, to that of M. Duhamel.

The fore-part of M. de Chateauxvieux's plough is composed of a wheel thirty-two inches, in diameter, which may be extended to thirty-four inches, or reduced to thirty: but to fall short of, or to exceed these measures, would be attended with inconveniences. This wheel may be made very light, especially if it be encircled with a thin hoop of iron. The plough itself is represented in Plate XXII. fig. 1, 2, and 3, where fig. 2. is the plan, and fig. 1. the profile.

The frame in which the wheel is placed, is formed by two shafts AB CD, fig. 2. distant from each other eighteen inches, from inside to inside; which fixes the length of the nave of the wheel. These shafts are four feet eight inches long, and may be reduced to four feet four inches, by shortening them at the ends C and A. They are about two inches and a quarter square: but the edges should be rounded off. These two pieces are fastened together by the two cross staves EF, GH, which are two inches and a half wide, and about an inch thick. They are riveted to one of the shafts, at E and G, where they are not to be loosened at all; and at their other ends F and H, the shaft must be moveable, so as to be taken off, to let the two cross staves through two mortises in the beam IK of the plough after which the shaft CD is put in its place, and fixed with two iron pins, *a*, *b*. Between the two shafts is placed the wheel LM, the nave of which is pierced through its center, with a hole proportioned to the thickness of the iron pin or spindle NO, which serves for an axle-tree, and is represented by the two pricked lines. This spindle, or axle-tree, the diameter of which is about three quarters of an inch, ought not to project beyond the outside of the shafts, lest it should lay hold of or hurt the stalks of the corn, when this plough is used for stirring the earth between the rows in the New Husbandry, as will hereafter be more particularly mentioned. To fix it at N, that end is flattened, and bent over the shaft to the middle of its upper side, where it is fastened at *d*, by a small pin driven through it and the shaft.

On the upper surface of each of the shafts, at the ends A and C, are the hooks A C, to which the harness is fastened: and at the other ends B and D, are two rings, the use of which will be explained hereafter.

The shafts AB, CD, should be pierced with four or five holes, to set the wheel more or less forward or backward, in order to make the plough strike more or less deep into the earth, as may be seen in fig. 1. at *a*, *b*, *c*, and *d*. The same holes are indicated by the pricked lines on the two shafts of fig. 2. from A to N, and from C to O.

The hind part of of this plough consists of the beam IK, fig. 1, and 2. the ground-rest CD, fig. 1. which is covered by the share LD; the handles KP, KQ, fig. 2. and KP, fig. 1. the sheat EF, fig. 1. of which part is pricked in fig. 1. and the end appears at X in fig. 2. the mould-board RS, fig. 2. part of which is seen at N in fig. 1, the coulter GH, fig. 1. and TV, fig. 2. and the share LD, fig. 1. part of which is seen at Y, in fig. 2.

The beam is four feet eight inches long, exclusive of the tenon which traverses the handles. Three inches and a quarter square are very sufficient in its thickest part, which is from X to V, fig. 2. The mortises in the beam, which are under *g*, *h*, and through which the two cross-staves EF, GH, are slipt, should be so fitted, that the cross-staves may not shake or be loose in them, at the same time that the beam should, by their help, slip with ease over the cross-staves, either to the right towards EG, or to the left towards FH, according as the intended ploughing may require. The beam should be fastened, either by two nuts screwed on at *m*, *n*, which will fix it tight to the cross-staves EF, GH; or by two iron pins stuck through the holes P and Q, in the cross-staves, one to the right in the cross-staff EF, and the other to the left in the cross staff GH. These pins will keep the beam steady in its place.

The lower part of the ground-rest should be somewhat concave, as is represented at CD, fig. 4. in order to lessen its friction against the earth.

The beam IK, fig. 1. and the ground-rest CD, are fastened together by the sheat FE, and the handles PK, both of which last are riveted to the ground-rest by two strong iron pins, the heads of which are seen at *g* and *h*; and to the beam, as also to the tenon of the beam which traverses the handles at *m*, *n*; and by the two wedges, *p*, *q*, and *r*, another use of which will be explained hereafter.

Wood naturally crooked is best to make the handles of, that they may be all of one piece, which should be so disposed, that one third of the space between the two handles, should be left on the left side, and the two other thirds on the right side, in order to facilitate the ploughman's walking in the furrow. This disposition is shewed in fig. 2. in which a line *e f*, drawn from the middle of the beam, between the two handles, gives to the left side a third P *f*, of the distance PQ between the two handles, and the two other thirds *f*Q to the other side.

For want of wood naturally bent to a proper shape, these handles may be made of two pieces firmly riveted and fastened together; and if it should be more convenient to the ploughman, the whole space between the handles may be on the right-side, as in fig. 6.

The sheat EF, fig. 1. should be very strongly and closely fastened by its tenon to the ground-rest at *g*. An intelligent workman will easily make it of a proper size, which is about two inches and a half wide, and a full inch thick. The inclining of this piece with the ground-rest gives it greater strength to resist, than if it was fastened to its right angles.

The mould-board, represented by RS, fig. 2. and AB, fig. 7, is from thirty to thirty-one inches long, and ten inches high or deep. It ought to be placed as in fig. 8, where its end A forms an acute angle, terminating at the junction of the fin of the share: its other end B extends beyond the length of the ground-rest, against which it should incline; in such a manner that, supposing the ground-rest to be lengthened out as far as C, the line CB would be twelve or thirteen inches long, reckoning from the farthest lateral surface of the ground-rest to the farthest lateral surface of the mould-board, which, being thus placed, will form the width of a furrow.

The lower part of this mould-board is sloped a little inward, as is expressed by the shade in fig. 7: and the part *b*, fig. 7, should jut out at least two inches beyond the part *a*. To this end, the mould-board should be made of a plank about three inches thick, which will bear being scooped on one side and rounded off on the other, in order to give it the concavity without, and the convexity within, represented in fig. 3, and 7.

The mould-board should be well fastened, to prevent its being displaced by the resistance of the earth. The upright piece CD fig. 7, which joins to the handles at its end D, and to the mould-board at its other end C, supports it strongly. It is highly necessary to cover the part of the mould-board which bears upon the earth, with a thin plate of iron, in order to preserve it; for otherwise it would soon be worn out.

The

The coulter GH, fig. 1. should be made of good iron well steeled. A notch is cut in the beam to receive it, as in fig. 9 and 10; and as the corners of the notch, C and B, against which the coulter bears hardest when the plough works, would soon be worn away if the wood was left bare, it is proper to secure them with two small pieces of iron AB, CD, about the sixth part of an inch in thickness, screwed on with flat-headed screws. These pieces of iron will keep the coulter steady in its place.

The coulter should be pierced with several holes from E to F, fig. 10, to take it higher up, or let it lower down, as occasion may require. It is fastened to the beam, which is pierced at E, fig. 9, by a strong iron pin with a square flat head, which is let into the beam and lies even with it, as in fig. 10. The other end of this pin, E, fig. 10, is a screw, fitted with its nut, by which the coulter is fastened tight to the beam. Upon this screw, hangs the handle A, fig. 1. which serves to turn it, and at the end of which is the key that fastens on the nuts of the iron pins which secure the share. By this means, the key to turn the screws is always carried with the plough.

M. de Chateaufieux's coulters weigh but five or six pounds a-piece at most, and frequently not more than three pounds.

He places his coulter so that its point G, fig. 1, projects about an inch beyond the outside of the share L C.

Fig. 12 represents the shape of the share, with its dimensions, as do also fig. 13 and 14. The point of this should be made of good steel, and the rest of good iron, neither too soft, nor too high tempered, that it may not be subject to break or bend. The tail of the share, AB, fig. 12, should be thickest from A to C, because that is the part which bears the greatest stress. Its thickness diminishes gradually to B, where the share is fastened to the ground-rest. This tail is pierced with two round holes at A and B, fig. 13, through which are put the iron pins DE, FG, fig. 12, which have square flat heads, lying even with the tail of the share. These pins pass through the ground-rest, where they are fastened on the other side by the nuts EG. A third round hole may be added at x, fig. 13, in order to fasten the share still more firmly to the ground-rest, with a short flat headed screw.

M. de Chateaufieux has likewise made some ploughs with the round holes *a b*, fig. 13, near A and B; that the iron pins DE, FG, fig. 12, might not traverse the tenons of the sheat and handles; and instead of those iron pins, he has riveted them with wooden pins, and found them keep the whole tighter than the iron ones.

To the left of the plough should be fastened the thin board N, fig. 1 and 7, the use of which is to prevent the earth from tumbling over between the share and the mould-board. As ploughing wears the point of the share, though it will not hurt this so much as it does that of the common plough, it must be new pointed from time to time, always observing to make the point incline a little towards the earth, as is represented by the pricked line DL, fig. 1, that the share may scarcely touch the ground at any other part than D and L, in order to lessen the friction.

The hind part of the plough, thus formed, is joined to the fore carriage, by running the cross staves EF, GH, fig. 2, through the mortises of the beams, *g h*; and is fixed there, either by the screws *m n*, or the pins *p, q*. The traces of the first and second horse are fastened to the hooks AC: and if a third horse be used, the traces of that third horse are fastened to those of the second. Horses will do better for this plough than oxen, unless these last have been used to be harnessed one before the other.

The plough thus equipped, may easily be carried to the field, if its hind part is laid upon the little carriage AEW, fig. 2, consisting of an iron axle-tree AEW, two small wheels *h i*, *h'*, and the two pieces B₁, D₁, at the end of which are the hooks B and D. These wheels are about twenty-one inches, or two feet in diameter; and three feet six inches, or even four feet asunder. They are very light, having but a small weight to bear. The hooks of these two pieces B₁, D₁, are inserted in the rings B and D at the end of the shafts; and by this means the plough will be carried upon three wheels, of which fig. 1 and 2 shew sufficiently the arrangement and use. Fig. 5. shews the slope that should be given to the upper surface of the middle of the axle-tree of this small carriage, on which the rest of the plough is to be loaded in order to remove it from one place to another, that the ground-rest and other pieces may lie flat and steady upon it.

To open the first furrow with this plough, the wheel must be placed at the last hole, towards the extremity of the shafts. This makes the share incline the more and consequently cut the deeper. But as it would be somewhat troublesome to change the position of the wheel, at every first cut of the plough, a very little attention will remedy that inconvenience. It is only inclining the handles of the plough to the right or left, instead of holding them even. The whole plough will incline with the handles, and the share will then enter into the ground with ease, and open the first furrow. The other furrows are ploughed without any sort of difficulty; and for them the plough is to be held even, or inclined but very little, either to the right-hand or the left, as the situation of the land may require.

M. de Chateaufieux generally rests the beam on the left-hand side of the fore-carriage. It is easy to place it so as to leave whatever distance is thought proper between the outmost row of corn and the furrow that is actually ploughing.

The forwarder the wheel is set, the deeper the plough cuts; and so on the contrary. But if one would have it cut still deeper, or shallower, than it can be made to do by altering the position of the wheel, that too may easily be effected. By loosening a little the wedge above the beam *p, o*, fig. 1, and driving farther in the wedge *q*, the plough will cut less deep: as, on the other hand, the share will be more inclined, and therefore cut deeper, if the wedge *q* under the beam is loosened, and the wedge *p, o*, over it is driven in tighter.

The chief differences between M. de Chateaufieux's plough, and that of M. Duhamel, are as follow.

1. The beam of this last, ABC, fig. 1. Plate XXIII, bends from C to B; whereas that of M. de Chateaufieux's is nearly straight all along.

2. In consequence of this bending, the hindermost extremity of M. Duhamel's beam is joined at B to the hindermost part of the ground-rest E, after passing through a mortise F, in the lower part of the handles; so that this beam is joined to the ground-rest by its extremity B, the bottoms of the handles F, and the sheat G; whilst that of M. de Chateaufieux's plough is joined to the ground-rest by this sheat, another which this plough has not, and the lower part of the handles: for the beam does not answer to the ground rest.

3. The mould board HI, fig. 2, of this plough, is lighter than that of M. de Chateaufieux's, and differently shaped.

4. The two handles KK, are at equal distances from the beam, and are joined together by a cross staff M.

5. The share N, fig. 3. is pretty much like that of M. de Chateaufieux's plough, but shorter and narrower; so that it cuts less wide furrows; which M. Duhamel rightly thinks the best way of ploughing.

6. The coulter O of this plough passes through a mortise in the beam, which is there strengthened by hoops of iron, to prevent the beam's being split by driving in of the wedges PP, which fix the coulter.

M. Duhamel thinks this hind part of his plough preferable to that of M. de Chateaufieux's, for light lands: but it would not do so well in stiff soils, because the earth would be apt to clog about the sheat at Q; whereas it is thrown off by M. de Chateaufieux's plough. M. Duhamel likewise approves of making the beam straight as M. de Chateaufieux's, instead of giving it the bending from C to B, especially for stiff lands.

7. The beam CA, is fixed to the cross staves RR of the fore-carriage of this plough, by the screws and nuts SS.

8. The shafts TT, are fastened before by a cross-staff V, which gives great solidity to the fore-carriage, and cannot be added to M. de Chateaufieux's plough; not only because the wheel is too large, but likewise because it must be set forwarder or backwarder, in order to make the share cut more or less.

The wheel of this plough is not so large as that of M. de Chateaufieux's, because the axle-tree, instead of being inserted in the shafts 'T T', is let into the side pieces X, fig. 4, which are fastened to the shafts by the screws and nuts Y Y.

The advantages of having the wheel smaller, are, 1. That the plough is less apt to lean too much on its side, and is more easily held upright; 2. That the cross-staff V may be added to the fore-carriage, by which it is rendered

ed more solid ; and 3. That the fore-carriage may be made shorter than it otherwise could be.

The bare inspection of the draught of this plough shews that it is made to cut more or less deep, by screwing the nuts Y more or less tight, and putting a thicker or thinner wedge between the side piece X and the shaft, which is an easier and quicker way, than changing the situation of the wheel. But still, a readier method is, to have under the shafts T T, a false shaft ZZ, fig. 5, fixed with hinges, &c. for then, by only sticking the peg a, into one of the holes b, the beam is raised or lowered, in a moment, to whatever degree is thought proper, without altering the position of the wheel.

It is likewise evident, that in order to give the share a greater or less degree of entrance into the earth, nothing more is requisite than to place the beam nearer to, or farther from, the right-hand shaft : for the horses, which are harnessed one before another, go, as does also the wheel, in the last made furrow, and the ploughman goes in the furrow actually making.

dd. Are hooks to fasten on the harness of the horses.

ee. Cramps to fasten the fore-carriage.

ff. Pins to fix the beams to the sheat.

gg. Pegs to fasten the cross staves.

h. A strong pin which goes through the hole i, to keep the mould-board steady.

Four-coultered PLOUGH, an instrument invented by Mr. Tull, being an improvement on the common plough, that makes it cut the pieces of earth into four ; that is, it thus divides the earth, four times as small as the common plough.

The common two-wheeled plough has of late years become universally used in many countries, and is found greatly preferable to the ploughs they used before ; there is an objection to it, indeed, in regard to some stiff and miry lands, in which the wheels become clogged up, and cannot turn. This, however, is easily remedied by twisting thumb ropes of straw about the iron circle and spokes of the wheels ; these spreading as they turn, and, as the circle twist bears upon the ground, throw off the dirt, and never clog. The two principal parts of this plough are the head and the tail : the plough-head contains the two wheels, and their axis, or spindle, passing through a box, and turning round both in it and in the wheels.

There are fixed perpendicularly in this box two crow-staves, as they are called, which are flat and narrow boards, each having on it two rows of holes, whereby to raise or sink the beam of the plough, by pinning up or down the pillow, to increase and diminish the depth of the furrow. Behind are a pair of gallows, through which the crow-staves pass at the top by mortises, into which they are pinned ; and to these are fastened what are called the wilds, which are rings and crooks of iron, by which the whole plough is drawn in the working. From the box to the center of the beam there is carried an iron chain, consisting of four, five, or more long links, and called the tow-chain : this fastens the plough-tail to the plough-head. It is fixed to an iron collar, fastened in the beam at one end, and at the other passes through a hole in the middle of the box, and is pinned in with a wooden pin.

From the same iron collar to which the tow-chain is fixed, there is also another chain fastened, called the bridle-chain : this runs above the beam, as the tow-chain does below it, and is composed of smaller and more numerous links. At the upper end, as the tow-chain enters to the box of the plough, this bridle-chain is fixed to the top of what is called the stake of the plough : this is a perpendicular stick, carried up parallel with the left crow-staff, and pretty near it, and fastened to it by a wyth or rope, or by the end of the bridle-chain itself, when that is long enough. This stake is also fastened in its lower part, under the gallows, to the same crow-staff, by another wyth or piece of rope.

These are the parts of which the head-part of the plough is composed. The plough tail consists of the beam carried from the head to the very extremity, and serving as the support and base of all the rest. A little below the collar to which the tow-chain and bridle-chain are fastened, this beam is pierced with a large hole, which lets through the coulter : this is a long narrow piece, terminating in an edge, and reaching just to the share ; and it is fixed immovably in its place by means of a wedge which is driven into the whole of the beam with it : the office of this coulter is to cut the earth as it is thrown up by the share. Behind these, the same beam is pierced with two more

holes, one very near its end : these give passage to two oblong pieces, called the fore-sheat and hinder-sheat, by which the plough-share is supported in its place. To the top of the hinder-sheat there is fastened a short handle by a wooden pin. Parallel to the hinder-sheat there runs up a piece of wood of much the same form, called the drock ; and to this is fastened another horizontal piece, called the ground-wrist ; these are all on the right-hand side of the plough, and parallel with the fore-sheat. There runs another piece of much the same form with it, on the right hand : and the bottom of this is the earth-board. The long handle of this, which reaches as far as that of the sheat, is fastened to the drock by a pin, the other end of which goes into the beam. Near the lower end of the fore-sheat, there are two flat pieces of iron, which pass from the two sides of it up to the beam ; and being let through it, are fastened to the upper part by screws and pins. These keep the sheat in its place.

The structure of the four-coultered plough is different, in some respects, from this, though in general founded on it. Its beam is ten feet long, whereas that of the common plough is but eight. The beam is straight in the common plough, but in this it is arched in one fourth part of its length, near the plough-head. At the distance of three feet two inches from the end of the beam at the plough-tail, the first coulter, or that next the share, is let through ; and at thirteen inches from this, a second coulter is let through ; a third at the same distance from that ; and, finally, the fourth at the same distance from the third, that is, thirteen inches.

The crookedness of the upper part of the beam in this plough is contrived to avoid the too great length of the three foremost coulters, which would be too much, if the beam was straight all the way ; and they would be apt to bend and be displaced, unless they were vastly heavy and clumsy. Ash is the best wood to make the beam of, it being sufficiently strong, and yet light.

The sheat in this plough is to be seven inches broad. The fixing of the share in this, as well as in the common plough, is the nicest part, and requires the utmost art of the maker ; for the well-going of the plough wholly depends upon the placing of this. Supposing the axis of the beam, and the left side of the share, to be both horizontal, they must never be set parallel to each other ; for, if they are, the tail of the share, bearing against the trench as much as the point, would cause the point to incline to the right hand, and it would be carried out of the ground into the furrow. If the point of the share should be set so, that its side should make an angle on the right side of the axis of the beam, this inconvenience would be much greater ; and if its points should incline much to the left, and make too large an angle on that side with the axis of the beam, the plough would run quite to the left hand ; and, if the holder, to prevent its running quite out of the ground, turns the upper part of his plough toward the left hand, the pin of the share will rise up, and cut the furrow diagonally, leaving it half unploughed. To avoid this and several other inconveniences, the straight side of the share must make an angle upon the left side of the beam ; but that must be so very acute a one, that the tail of the share may only press less against the side of the trench than the point does.

The great thing to be taken care of, is the placing the four coulters ; for on this the success of the whole depends. These must be so set, that the four imaginary planes described by their four edges, as the plough moves forward, may be all parallel to each other, or very nearly so ; for if any one of them should be very much inclined to, or should recede much from either, of the other, then they would not enter the ground together. In order to the placing them thus, the beam must be carefully pierced in a proper manner. The second coulter-hole must be two inches and an half more on the right hand than the first : the third must be as much more to the right of the second, and the fourth the same measure to the right hand of the third : and these two inches and an half must be carefully measured from the center of one hole to the center of the other. Each of these holes is a mortise of an inch and a quarter wide, and is three inches and an half long at the top, and three inches at the bottom. The two opposite sides of this hole are parallel to the top and bottom, but the back is oblique, and determines the obliquity of the standing of the coulter, which is wedged tight

tight up to the poll. A perspective view of this curious plough the reader will find in Plate XXI. fig. 9.

The coulter is two feet eight inches long, before it is worn; the handle takes up sixteen inches of this length, and is hallowed thus long, that the coulter may be driven down as the point wears away. *Tull's Horse-hoeing Husbandry.*

The four-coultered plough being heavy, difficult to manage, and fit only to break up meadow ground, or ground where there are very few or no stones, is now in disuse. The scaricator may be substituted to break the turf, and the land ploughed deeper afterwards. But it is still a better way of breaking up land, to trench-plough it; first paring the surface with a paring-plough, about two inches deep, turning the grass side downwards, upon which, with a common plough immediately following, in the same furrow, turn a deeper furrow upon the turf, going in all as deep as the staple will admit. This should be done in autumn; and if it is good meadow land, wheat may be sown upon it; if not, let it remain a winter fallow, and sow oats upon it in the spring. In either case the turf will be rotten by the time the wheat or oats are cut and carried off, and the land will be ready for other crops to follow in the common course, if to be continued in tillage; but if intended to be laid down again to grass, a crop of turneps is a good preparative; and at any rate lay it down in good heart. The scaricator will answer the purpose cheaper, without breaking up the land. See the article MEADOW.

Double PLOUGH, an instrument invented by Mr. Randal, which, by putting the share point to the middle of the interval left by the horse-hoe, throws the mould on each side of it, at the same time, towards the rows, and earths them up to what degree the ploughman pleases, in order to nourish them on to perfection. If a common plough, instead of the single hoe, was used, the furrows would be turned into the middle of the interval, and appear in the form of a single ridge: and if the plough went twice in a place, to deepen the soil, the ridge in the middle would be proportionably higher, and the ground strangely improved by such operations, and the vegetables surprisingly promoted in their growth. In either of these cases, of the plough's going once or twice in a place, the double plough, by taking fast hold of the mould, throws all back again; and if the vegetables are not effectually earthed up, which may be the case after double spitting the intervals, then running the double plough over again, completes the business, and strangely tosses about and mellows the ground. This, in general, is the use of this plough in earthing up vegetables, that have three feet intervals.

These whose mould-boards move on hinges, and may be set wide or narrow at pleasure, are the most convenient.

But under the name of this double plough, we are to understand another of the same form, much narrower in the tail, to perform what they called ridge-work, which is either single or double: if single, this double plough works alone, throws up the ridges, and, at a proper time, splits them, and throws them back into the trenches; and this tosses the mould backwards and forwards, which, by these agitations, and other operations, is made ready for cropping, as is particularly mentioned in my Treatise. If these ridges are to be double, that is, if there is to be double spitting, then the double plough performs as before, and goes as deep as is consistent with the interest of the man's arms, and the horse's ease. Here the worthy ploughman is requested to keep his hands even, that the plough may run flat upon its sole, and clear the trench of mould, as far as necessary, which it is made to do in that posture: to make way for the lifting-plough, of the same breadth in the tail. See Plate XXI. fig. 10.

Double lifting PLOUGH. My earnest desire, says Mr. Randal, is to imitate gardeners, in preparing the soil, by their always going a good depth, and which to be sure is the true bias of nature, in regard that vegetables in general, require a looser habitation, beneath the soil, to greater depth than farmers will allow them: this desire produced the lifting-plough, to raise the generous mould that lies far beneath the reach of common ploughing, into general use. This I have practised to very great effect, and never failed doing it, in all the going ground of the tenures of near a thousand acres, where the stratum, below the usual soil, would give me this desirable and encouraging advantage. Hence it was, that I was always extremely fond of this lifting-plough, which never fails

of success in the hands of an honest, worthy ploughman; and, no doubt, there are many such to be found. I was very imprudent, in my first construction of this plough, in having it made too large, in order, through a covetous disposition, to have much work done in a day. The draught was so fatiguing to the horses and men, that the invention was under a good deal of disrepute, and I was in danger of having all the servants leave the service, and of killing the horses: for these reasons, I was obliged to sit down with that loss, great as it was, in the purchase of this plough, and contract all the proportions of it, to make the draught quite easy to the team and men; and then there was not the least complaint heard, but only a backwardness to proceed, which use effectually removed.

Here, then, this lifting plough is to go into all the trenches made by the double plough, as mentioned before; and as the ploughman deepens the trenches as far down as is consistent with his own and horses ease, the irons, running up on each side of the plough, will lift up the mould, which will be thrown, by the motion, upon the old ridges. The ground now lies in deep trenches, and high ridges; and this is what is called, in my Treatise, double ridges; and how the soil is to be afterwards reduced to a level, and receive farther management, is therein particularly mentioned. Now, from the construction of these two ploughs, the soil beneath will, if the ploughman keeps his hands even, be cut level, instead of leaving these hills and dales, but two often practised, to the discouragement of the growth of the vegetables. See Plate XXI. fig. 11. *Randal's Semi-Virgilian Husbandry.*

Mr. Marshall, in his Minutes of Agriculture, says, that in his opinion the *Swing-PLOUGH* is the only plough of general use, especially for stiff land; it will plough it round or flat, clean or balky; wet or dry; foul or clear.

PLOUGHING, the action of breaking up, and loosening the soil.

"The principle, says M. de Chateauvieux, of thoroughly dividing and loosening the soil, is so generally received, that there is not a farmer who does not know, that one ploughing more than ordinary is of as much service to the ground, as dunging it would be. Experience must have shewn them, that his crops are increased by this extraordinary ploughing: but he is not sufficiently sensible, that of all the ways of improving his land, no one is more effectual, or less expensive than this. Were its full value known, it would be more generally practised, and every husbandman would give all his lands at least one ploughing extraordinary.

"To satisfy myself of what might be done with the plough alone, I resolved to make a trial on a spot, of ground which I knew to be incapable of naturally producing any thing. Some years before, I had dug away the earth, three feet deep, from a space of sixty square perches. Nothing remained in it but a white clay, like that which potters use. This spot, thus circumstanced, seemed to me a proper one for my experiment. As the space was too small for a plough to work in, I had recourse to the spade and hoe. The ground was laid out in beds, which were afterwards sowed with wheat, and the spaces between them were frequently stirred. The first year my plants were very poor, and branched into only two, three, or four stalks apiece. In the second year, they did much better; and in the third, they were as large and fine as any my garden could have produced. This spot still continues to produce equally well; the soil is now like fine mould; and, which is very remarkable, it has lost its former white colour, and is become black. We have here a strong instance of what may be done by pulverizing the earth. Let us but do the same with any of our bad lands, and persevere in ploughing and stirring them a sufficient time; the success will not be doubtful.

"To be still farther convinced of the truth of this important maxim in husbandry, that the earth should be thoroughly loosened by deep and frequent ploughings, I examined very carefully, whether my lands which had been prepared by repeated ploughings only, without the assistance of any dung or manure, were much loosened and rendered lighter than those which were under the common management. All my observations proved that they were. The first glance of my eye shewed me, that their surface was smoother; on sounding the furrows, I found them deeper; and much less strength was required to plough them; two horses, or sometimes only one, or a

single ox, doing here with ease, what would otherwise have employed double that number of cattle: a manifest proof that my grounds were in excellent tilth: whereas the common fields offered nothing pleasing or satisfactory to the eye; the earth there was extremely hard, close, and compact, and its surface almost as firm as that of a beaten road. The ground which had been well and often ploughed remained so light and soft, after its crop of wheat was taken off, that I thrust a stick of green willow eight or ten inches deep into it without the least difficulty, though I could not by any means push it at all into the land cultivated in the common way."

Camillo Tarello, a native of Lonato, in the Venetian territories, concerned to see the neglected and dreadful mismanaged state of husbandry, in his country wrote his small but highly valuable Treatise of Agriculture, and presented it to the senate of Venice under the title of *Ricordo d'Agricoltura*. The senate, in justice to the excellency of this work, and the patriotic intentions of its author, granted him, on the 29th of September 1566, not only the sole right of vending his book, but also ordered at the same time that all such as have adopted his new method of husbandry, should pay to him, and afterwards to his descendants, four marchetti (about three half-pence of our money), for every acre of corn land, and two marchetti for every acre of other land, planted according to his direction. The Berne society have favoured the public with the first part of Tarello's excellent treatise; and we shall take from thence the following extract, as a farther proof of the necessity of thorough ploughing.

"When we consider, says that good patriot and intelligent husbandman, Camillo Tarello, that every ear of wheat yields fifty grains (we will suppose that to be the medium number), we may infer, that if all these were sowed and grew, we should reap fifty times as much as was sown: but our crops are far from being so abundant. This failure cannot proceed from any other cause than that all these grains do not rise and prosper; nor can any but one, or all, of the seven following reasons be assigned for it, if we except bad seasons and extraordinary accidents.

"The deficiency arises either 1. from the seed; or 2. from rain, when the corn is in bloom: 3. from winds, when its stalks are large; 4. from birds which eat up the grains that have been sown; 5. from worms and insects; 6. from the earth; or, 7. from the cultivator himself.

"The cause of this defect is not in the seed: for, either the seed is good, or it is not: if it be not good, the grains will not rise at all: but if it be good, as we suppose it to be, each grain may, and should produce at least one ear. Another proof is, that if a parcel of seeds are planted at a proper depth, one by one, in holes made on purpose for them, and an equal number of the same kind of seeds are sowed at random in the same sort of ground, all the former will rise, but not all the latter.

"Neither ought it to be ascribed either to rain or winds, at the time of the blossoming of the corn: because we do not reap fifty for one, even when the weather is very fine; and even when each ear bears fifty grains, we do not reap fifty times the seed.

"Nor ought we to accuse the birds of the air: it being well known that lupins, which they never touch on account of their bitterness, do not all rise; for if they did, the crop would still be more considerable, as each of these plants bears from fifty to sixty-seeds. Besides, what the birds eat is not considerable.

"Worms and insects are not the cause, for three reasons, first, our crops are very little better even when neither worms nor insects are to be seen; secondly, the case here is the same as that of the lupins; and, thirdly, the worms would ravage whole fields (as they sometimes do) in so visible a manner, that it would be easy to distinguish the cause of the mischief. However, this is an extraordinary and pretty rare event.

"The same may be said of fogs, cold, bad weather, reptiles, and other mischievous creatures. Though these enemies do not injure our fields every year, we nevertheless constantly reap less corn than they might be made to produce.

"Lastly, the earth is not in itself the cause of this scantiness of increase: for the Creator has endowed it with perpetual youth and fruitfulness, as Columella justly and prettily observes in the first chapters of his first and second books. The earth and nature are always the same.

"Now, if the usual cause why we do not reap fifty for one, cannot be imputed to either of the things above-mentioned, it must of necessity be sought for in the ignorance, negligence, and indolence of the husbandman: for our practice is diametrically contrary to that of the ancient Romans. They ploughed often, and sowed little: yet every family lived upon the produce of its small farm: but we who plough little and sow a great deal, are always disappointed."

The Romans were not only extremely attentive to the thorough culture of their land, but also, even in the latter time of the republic, laid it down as a maxim to be followed by all good husbandmen, "to sow but little and plough much." This is strictly enjoined by Virgil; and Pliny, who instances the husbandry of Ctesimus, as an example of the good effects of this practice, laments the deplorable condition of Italy, when rich men, with the help of their numerous slaves farmed large districts of land; because it diminished the number of Roman citizens, and rendered the country less fruitful: for, as both he and Columella observe, the Romans then became dependant on other nations for the means of subsistence.

May not this naturally lead us to cast an eye upon our own country, where, of late years, gentlemen throw their estates, as much as possible, into large farms, which, in the language of Mago the Carthaginian, must, in general, render the farm stronger than the farmer, whereby it necessarily become less fruitful; this practice is attended with another most fatal consequence to a manufacturing and trading people: it lessens the number of inhabitants in the country from whence only the supply of population arises; for cities and large towns are always an expence of men.

Whilst we bestow this due commendation on ploughing, we do not mean to recommend it on Mr. Tull's principles, "that dividing and pulverizing the earth is all in all." When the earth is in fine tilth, so that the roots of plants can easily extend themselves every way, an advantage arises, which is thus described by the ingenious M. J. J. Biberg, in his Economy of Nature.

"Plants, as well as living creatures, must submit to death. They spring up, they grow, they flourish, they ripen their fruit, they wither, and at last, having finished their course, they die, and return again to the dust, from whence they first took their rise. Thus the black mould which we see upon the surface of the earth, is chiefly owing to dead vegetables. For all roots descend into the earth by their branches, and after a plant has lost its stem, the root remains; but this too rots at last, and changes into mould. By this means, this kind of mould is mixed with the earth, by the contrivance of nature: nearly in the same way as dung thrown upon fields is wrought into the earth by the industry of the husbandman.

"The earth thus prepared offers again to plants from its bosom, what it had received from them. For when seeds are committed to the earth, they draw to themselves, accommodate to their nature, and turn into plants the more subtle parts of this mould, by the co-operation of the sun, air, and moisture; so that the tallest tree is, properly speaking, nothing but mould wonderfully compounded and modified by a virtue communicated to a small seed by the Creator. From these plants, when they die, just the same mould is formed, as gave birth to them originally; but in such a manner, that it is in greater quantity than before, if the earth be kept loose to admit of the free extension of the roots. Vegetables therefore increase the black mould; whence fertility remains continually uninterrupted: whereas the earth would not make good its annual consumption, if it were not constantly recruited by new supplies."

The illustrious M. Lullin de Chateaufieux, to whom the world in general is infinitely indebted for some of the most judicious and best executed experiments ever made in agriculture, as is his native country in particular for his excellent administration in the high office of chief magistrate of the republic of Geneva, is the first writer who has attended to the advantages of stubble as a manure.

Towards the latter end of the year 1753, walking over his grounds after harvest, he was struck with the difference which he found in the stubble of his own experiments, and that of the corn which had been raised in the common way. This last was so poor and weak, that it scarcely opposed the motion of his feet, while the other resisted greatly. "I often felt it break, says he, under my feet, and frequently

quently met with tufts of twenty, thirty, forty, and sometimes more stalks, which stooped me short, like so many little bushes. I am the more particular in my account of this stubble, because it shews the great strength of the plants, which they would not have had if the earth had not been well prepared. Besides, it has its real use: for thorough ploughing supplies the want of dung, not only by keeping the earth constantly in a loose state, but likewise by the quantity of strong stubble which it produces, and which affords a most excellent manure, attended with no expence. It lies ready upon the spot; the ploughing of the earth buries it; and as it is a long time in rotting, it helps to keep the soil loose and light, and is repeated every year. I have found stubble almost whole at a year's end, and have seen some not quite consumed at the end of two years. From what I have seen of its effects, I will venture to say, that it contributes greatly to increase the productions of the earth. I have very often plucked up plants remarkable for their beauty, and have frequently found their roots interwoven with tufts of stubble, which shewed me the cause of their extraordinary growth."

"It is often, says Mr. Duhamel, more advantageous to increase the fertility of land by ploughing, than by dung: 1. Because in general, only a certain quantity of dung can be had, the product of twenty acres being scarcely sufficient to produce enough for four or five; whereas, the particles of the earth may be divided and subdivided almost to infinity. The help derived from dung is therefore limited: whilst no bounds can be set to the benefits that may accrue from ploughing.

"2. Few plants raised in dung ever have the fine flavour of those which grow in a good soil moderately dunged. Our kitchen gardens, and our other grounds afford daily instances of this truth. Pulse, pot-herbs, and fruit, are seldom so good in the neighbourhood of great cities, where dung abounds, as in country gardens, where but little of it is used. The corn raised in those excessively dunged lands, yields a great deal of bran, and not much fine flour, and is difficult to keep. Nice horses will not eat oats of the growth of fields manured with human ordure. But nothing is so striking as the difference between the wine of an undunged vineyard, and that of vines which have been greatly dunged.

"3. Dung, which is supposed to act by fermentation, causes indeed an inward division of the particles of the earth, which must be very useful, as well as the food which it furnishes to plants: but the plough, besides dividing those particles, changes their situation and turns the ground upside down, so that the part which was exposed to the influences of the air and dews, takes the place of another which is brought from within the earth up to its surface. The consequence of this is, that well ploughed land is not exhausted by weeds, and that it admits the moisture of rains and dews, together with the rays of the sun, all of which contribute greatly to render it fertile, as has been proved by very many experiments.

"4. Dung attracts insects, and those insects gnaw plants. It is well known that the roots of trees planted in dunged ground, are very liable to be damaged by insects; and this is one of the chief reasons why florists banish dung from gardens. Worms, grubs, and other such like vermin, make dreadful havock in their beds of flowers; and I have seen meadows where the grass has been entirely destroyed, by their eating its roots.

"I must add, that most sorts of dung contain a great many seeds, which fill the land with weeds.

"5. It is true that dung is equally serviceable to light lands, and to strong; but the same may be said of ploughing.

"Land is too strong when its particles lie so close together, that the roots of plants cannot extend between them, without great difficulty, in quest of their necessary food, for want of which they will remain poor and sickly. But when the ground has been well loosened by repeated ploughings, and its particles are set at greater distances from each other, those roots will be able to spread freely on all sides, to pervade every minute chasm, and to collect such quantities of food as will make the plants grow strong and vigorous. The friendly influences of the atmosphere will then penetrate to them. What plainly proves the good effects of loosening such soils, is, that their fertility is sometimes increased by a mixture of sand, instead of dung. Now sand does not afford any nutritive substance; but only hinders the particles of the earth from re-uniting too closely.

"Ploughing is equally beneficial to light lands, for the very contrary reason; though these do not require so much of it as the other. There is no danger of their being exhausted by any exposure to the sun: but, on the contrary, they acquire an additional degree of fertility by the stirring and grinding of their particles, and are thereby the better fitted to receive the moisture of rains and dews, and the salutary influences of the air and sun; whilst their inward pores are at the same time better adapted to the proper extensions of the roots of plants, by their being lessened.

"But, let the benefits arising from dung be ever so great, let the means of obtaining enough of it ever so easy, and let even its defects be corrected as much as can be; still it will not be the less true, that frequent ploughing is of infinite service to land.

"For this reason it is, that land intended for wheat is ploughed three or four times before the grain is sowed. Some farmers, who could not dung all their lands, ploughed part of them double the usual number of times, and reaped greater crops from these, than from those which were dunged. The expence of three ploughings extraordinary will be much less than the price of the dung necessary for the land, if the farmer is obliged to purchase it.

"In 1759, M. Delu gave three ploughings to some of his fields intended for oats; and though that year was very dry and unfavourable to spring-corn, his oats kept up well till they were perfectly ripe, and yielded a full crop of excellent grain.

"He gave five ploughings to a piece of wheat-land, which had not been dunged, and, at harvest, had taller and finer corn there, than in the neighbouring grounds which had been dunged and cultivated in the usual way.

"In short, the advantage of thorough tillage, while the plants are growing, is so great, that in many places it has been found amply to repay even the expence of digging between the rows of corn."

PLOUGH-WRIGHT, a person whose business it is to make ploughs, and other implements of husbandry.

POA, meadow grass, or that common species of grass, that principally forms the green covering of our fields.

POCKET, a large sort of bag in which wool or hops is packed up, in order to be sent from one part of the kingdom to the other.

POD, a term used to express a pericarpium, consisting of two valves, which open from the base to the point, and are separated by a membranaceous partition, from which the seeds hang by a kind of minute stalk.

POKE, a sack, or bag.

Hop-POLES, the upright poles, or pieces of wood, round which they bind, twist, and support themselves. See the article **HOP**.

POLLARD, or **POLLANGER**, a tree that has been frequently polled or lopped, and its top taken off.

POLE-EVIL, an abscess near the poll of a horse, formed in the sinuses between the noll-bone, and the uppermost vertebrae of the neck.

If it proceeds from blows, bruises, or any external violence, at first bathe the swelling often with hot vinegar; and if the hair be fretted off with an oozing through the skin, make use of two parts of vinegar, and one of spirit of wine; but if there be an itching with heat and inflammation, the safest way is to bleed, and apply poultices with bread, milk, and elder-flowers: this method, with the assistance of physic, will frequently disperse the swelling, and prevent this evil.

But when the tumor is critical, and has all the signs of matter, the best method then is to forward it, by applying the ripening poultices already taken notice of, till it comes to maturity and bursts of itself; or, if opened with a knife, great care should be taken to avoid the tendinous ligament that runs along the neck under the mane: when matter is on both sides, the opening must be made on each side, and the ligament remain undivided.

If the matter flows in great quantities, resembles melted glue, and is of an oily consistence, it will require a second incision, especially if any cavities are discovered by the finger or probe; these should be opened by the knife, the orifices made depending, and the wound dressed with the common digestive of turpentine, honey, and tincture of myrrh, and after digestion with the precipitate ointment; or wash the sore with the following, made hot, and fill up the cavity with tow soaked in it:

Take vinegar or spirit of wine, half a pint ; white vitriol dissolved in spring water, half an ounce ; tincture of myrrh, four ounces.

This may be made sharper, by adding more vitriol ; but if the flesh is very luxuriant, it should be first pared down with a knife before the application. With this wash alone, Mr. Gibson has cured this disorder without any other formality of dressing, washing with it twice a day, and laying over the part a quantity of tow soaked in vinegar and the white of eggs beat together. This last application will serve instead of a bandage, as it will adhere close to the poll, and come off easily when there is occasion to dress. Some wash with the phagedenic water, and then fill up the abscess with loose dossils of tow soaked in *Ægyptiacum* and oil of turpentine made hot, and continue this method till the cure is effected.

But the most compendious method of cure, is found by observation to be by scalding, as the farriers term it, and is thus prosecuted when the sore is foul, of a bad disposition, and attended with a profusion of matter.

Take corrosive sublimate, verdegriſe in fine powder, and Roman vitriol, of each two drachms ; green copperas half an ounce ; honey or *Ægyptiacum* two ounces ; oil of turpentine and train oil, of each eight ounces ; rectified spirit of wine, four ounces : mix together in a bottle.

Some make their scalding mixture milder, using red precipitate instead of the sublimate ; and white vitriol instead of the blue ; the following has been successfully used for this purpose, viz. half an ounce of verdegriſe, half a pint of train-oil, four ounces of oil of turpentine, and two of oil of vitriol.

The manner of scalding is, first to clean the abscess well with a piece of sponge dipped in vinegar ; then put a sufficient quantity of the mixture in a ladle with a spout, and when it is made scalding hot, pour it into the abscess, and close the lips together with one or more stitches. This is to remain in several days ; and if good matter appears, and not in an over great quantity, it will do well without any other dressing, but bathing with spirit of wine ; if the matter flows in great abundance, and of a thin consistence, it must be scalded again, and repeated till the matter lessens and thickens.

These liquid corrosive dressings agree well with horses, whose fibres are stiff and rigid, and whose juices are oily and viscid ; in this case they contract the vessels of the tendons on the hind part of the head and upper part of the neck, which are continually spewing out a matter or ichor that can hardly be digested, or the profusion abated without such applications as these.

POND, a reservoir or receptacle for collecting and preserving water.

The necessity of water, in all pastures, is self-evident ; as cattle cannot live without it, and the driving of them far for it, is known to be prejudicial to their health, in hot weather, besides being attended with great trouble, and a considerable loss of time. This is so sensibly felt in many parts of England, that people are obliged to dig wells, even to such a depth as frequently to require the assistance of a horse to draw up the water. The means of rendering it easily come at, must therefore enhance the value of the land where it can be procured, and are of very essential consequence to the husbandman.

Where the surface of the ground is sand or gravel, there seldom is occasion to dig deep for water ; because such soils generally lie upon marl, or some other rich earth, through which the water cannot descend. Beds of clay are most commonly thicker than those of sand or gravel ; and chalk is, too often, the thickest of all. But wherever water is wanting, the farmer should bore through the incumbent earth, if he intends to fit his land for pasture ; and if he finds the expence of obtaining it too great, his best way will be to convert the ground so circumstanced into arable, or to plant it with timber-trees suited to the nature of the soil.

Wherever water stagnates in a sandy or gravelly soil, the husbandman sees at once at what depth is the surface of the earth which retains it. But in other soils, and when this does not happen, Palladius, and the authors of the *Maſon Ruſtique*, give the following directions how to seek for water, with the greatest probability of success.

Where rushes, reeds, flags, willows, and other aquatic

plants grow spontaneously, or where frogs are observed to lie squatted down close to the ground, in order to receive its moisture, there generally is water underneath. Persons who make it their business to find out springs for fountains, cascades, &c. look upon it as an infallible sign of subterranean water, when they see a vapour arise frequently from the same spot of ground. Others assure, that wherever swarms of little flies are seen constantly flying in the same place, and near to the ground, in the morning, after sun-rise, there certainly is water under that spot. Again, where water is wanted on land apparently dry, let a man before sun-rise, lie down flat upon his belly, resting his chin upon his fist, placed close to the ground, that his view may be directed quite horizontally, and not rise too high, and in that situation let him look steadfastly toward the east. If he then sees a tremulous vapour arise from any particular spot, let him mark the place, by noticing some neighbouring tree, shrub, or other indication, and he will find water underneath it. But this experiment is to be made only on ground whose surface is dry ; because other exhalations, from a damp surface, would be apt in this case, to mislead the inquirer.

Another way is this. Dig a hole three feet wide, and at least five feet deep, and place at the bottom of it, when the sun is about to set, a pan, or basin, rubbed with oil on the inside : let the bottom of this vessel be uppermost ; cover it with dry hay, fern, or rushes, and over that with earth, and if any drops of water are found standing on its inside the next day, a spring is probably not far off. Or, put a new, unbaked, but well dried, earthen vessel into such a hole, and cover it as before ; and if there be water in that place, this vessel will be found soft and wet the next day. Likewise if wool be left all night in a trench of this kind, and water can be squeezed out of it the next day, little doubt remains but that plenty of water may be met with there.

The month of August is generally looked upon as the most proper time to search for water ; because we apprehend, as the heat of the preceding summer will have warmed the earth to a considerable depth, any steam arising from water resting on an impervious soil underneath, and particularly in hollows on the surface of that impervious soil, will then be most exhaled by this warmth. Now it is this steam, or vapour, which produces the before-mentioned signs.

By whatever method water is found, the means of coming easily at it are the next consideration. If it be on a plain, there is no other way than digging a well. In doing this, the substance under the sand or light soil must be dug into, to form a reservoir of water for occasional wants ; and this reservoir should be made deep and large, in proportion to the quantity wanted. If there were no such reservoir, the water, after having risen a little above the impervious body underneath, would glide along its surface, as usual, and very little of it could then be obtained, either by pumps, buckets, or any other way employed to raise it. If the well is made in a sloping ground, and the declivity is sufficient to give it an horizontal vent, it will be worth the husbandman's while to dig such a passage, and by means of pipes, or any other conveyance, to carry the water across the light soil, through which it would otherwise sink. The greatest quantity of water will be obtained in this manner, because there will then be a continual stream.

If the soil is very deep, and its surface has inequalities in which rain water runs in any quantity ; this may be collected in ponds made in the lowest parts of such grounds.

If a body of clay is found near the surface, it is worth the farmer's while to bore, that he may know at what depth a bed of sand or gravel may be met with : for he will be sure to find plenty of water in this last. If this be in a declivity, he need only cut an horizontal passage, and the water will flow so freely, as even to double the value of his land.

Here again the farmer needs not ever to be at a loss, because it cannot be very difficult to make a pond in a clayey soil, which is, of itself, retentive of water. But it may, perhaps, be advisable, even in this, to cover the bottom of the pond with a coat of gravel, in order to prevent its being poached by cattle, whose feet would otherwise be apt to sink deep into the clay. Some farmers judiciously pave the declivity by which the cattle enter into the pond, and this renders it much more lasting than it would otherwise be, and preserves the water clean.

When ponds are made in a loose soil, much more care is necessary. The bottom and sides there must be covered with a thick coat of the toughest clay, from a foot to two feet thick, well rammed down. Some have added hair and

and loam to the outer part of this covering, with a view of rendering it less liable to chap: but a thick coat of gravel is more necessary here, that the feet of the cattle may not pierce through the clay. Perhaps the expence of paving the whole inside of a pond, might, in the end, be money well laid out.

The greatest difficulty of finding water is in chalky soils, because these are not, of themselves, very retentive of it, and generally lie in such thick beds, that it is expensive to dig through them. However, it should be tried; and if sand or gravel be found underneath, water may be depended on. Even here, ponds are easily made, by digging into the chalk, and lining them with a coat of clay, as before directed. If there is a supply of proper manure, such as clay, or marle, this situation is well adapted to grain, which loves to stand dry; and as this kind of ground produces more forward crops than clayey or strong soils, it may be sowed early with corn, which will not, in that case, be so apt to be parched up as grass is, by the summer's drought. If a good soil can be made here, a foot deep, it will yield plenty of various sorts of pasture, either roots or grasses, as the farmer shall judge most proper: or it may be planted with different kinds of timber-trees. For the method of making ponds in gardens, see the art *de* DRINKING-POOLS.

Mr. Young, in his *Annals of Agriculture*, vol. VI. inserts the following method of constructing ponds. See PLATE XXIII*.

"As you are not unacquainted with that part of the East-Riding of Yorkshire, called the Wolds, the value of any discovery, by which so dry a tract of country can, at all times, and in all situations, can be supplied with water sufficient in quantity for the numerous flocks of sheep, and other cattle, kept upon it, and sufficiently good in quality for domestic purposes, cannot be doubted by you; if therefore you think ponds of the kind I am about to describe, may be of use to countries in similar circumstances, (and such there are in various parts of England), or where the water is brackish or otherwise of an unwholesome quality, you are at liberty to insert this account of the method of making them in any future volume of your *Annals of Agriculture*.

"About twelve or fifteen years ago, a man, by profession a well-sinker, first discovered the method of making these ponds; within this period the number of them has been so increased, that scarce a sheep-walk, or even field is now without one; and the use of them is creeping into the neighbouring country, in situations where otherwise water could not be had; so sudden and general an adoption is sufficient proof of their utility; before this period many sheep-walks were entirely destitute of water; it is, however, worthy of remark, that most of those sheep which have now a constant supply of water, are by many intelligent persons, thought, from circumstance only, to be considerably improved; whether, however, this opinion is well founded, I cannot, from my own experience, assert, not having had opportunity to make the necessary observations; but it does not admit of a doubt, that in very dry weather, much fewer sheep die than formerly: this in several instances was fully proved during the uncommon drought of a late summer, where the loss among sheep which had not this resource, was very great, while that among others of the same kind, and in similar situations, which did not labour under that want, was very trifling; perhaps not greater than would have taken place in any other equal space of time.

"The line A marks a circular hole dry in the ground of the size required, upon which a layer of clay B, sufficiently moistened, is to be carefully beaten and trod down into a compact and solid body of about the thickness of a foot.

"Upon this C is a layer of quick lime finely and uniformly spread over the whole, of one inch or upwards in thickness.

"D is another layer of clay of about one foot in thickness, which is to be trod and rammed down as the former; upon this are spread stones or coarse gravel E of such thickness as may prevent the pond receiving any injury from the treading of cattle, who would otherwise break through the body of the clay and lime, and by so doing let out the water; after this, according to the section, the pond will remain five feet deep and 45 feet diameter; the size they are usually made, D being the line of the water and of the ground.

"Brick-clay is by no means required for the ponds; any earth sufficiently tenacious to bear beating into a solid compact body, though not approaching to a pure clay, will very well answer the purpose.

"It is usual, where there is an opportunity, to make the

pond in a little valley, or at the bottom of a declivity, or near an high road, in which situations a stream of water may be brought into it after sudden showers or thaws, the object being to get it filled as soon as possible after it is made, that the sun and winds may not crack the clay; if it is not likely to be filled soon, some straw or litter must be spread over it; but in general after it is once filled the rains that fall in the course of the year will keep it full, no water being lost otherwise than by evaporation and the consumption of cattle.

"A pond of this size is usually made for from 4l. to 6l. exclusive of the time, and expence of carriage of clay, when that is necessary; the first varies in price in different countries, the last will depend upon the distance.

"It is to be remembered that the whole excellence of the pond depends upon the lime; care must be taken to spread it regularly and uniformly over the surface of the lower bed of clay; it is well known that ponds made with clay alone, however good its quality, and whatever care may be exerted in the execution, will frequently not hold water; these with the above precautions rarely fail. Never having seen a pond dug up after it had been made some time, I cannot say by what means the lime prevents the loss of water; one of these two is probably the cause; either the lime sets like terrace into a body impervious to water; or what I should rather think, the causticity of the lime prevents the worms in dry weather from penetrating through the clay in search of the water; certain, however, it is, that with lime, thus applied, ponds may be made in sand, however porous, or on rocks however open, in neither of which situations are they to be depended upon, when made with clay alone."

POOL. See DRINKING POOL and RILLS artificial.

POPLAR, a genus of trees, of which botanists enumerate four species; viz. the common white poplar, with large leaves: the common white poplar with smaller leaves: the common black poplar, and the poplar with trembling leaves, called the aspen tree. The poplar, whether black or white, may be easily propagated, either by layers, cuttings, or suckers, of which the white kind always produces a great many from the roots. The best season for the transplanting these suckers is in October, when the leaves begin to decay; and they should be removed into a nursery for two or three years, at the end of which time they will have got strength enough to be transplanted into the places where they are to remain.

When they are to be propagated by cuttings, it is best to do that in February, cutting off large truncheons of eight or ten feet long; which, being thrust down a foot deep in the ground, will take roots very quickly, and, if the soil be moist, will grow to a considerable size in a few years.

The black poplar is not so easily raised from these large truncheons, but should be planted in cuttings, of about a foot and a half long, planting them a foot deep in the ground. This will grow on almost any soil, but does much better on a moist one than on any other. They are the fittest of all trees for raising a shade quickly, as they will grow fourteen feet in height sometimes in one season, and in four or five years will be large trees.

A considerable advantage may be obtained by planting these trees upon moist boggy soils, where few other trees will thrive: many such places there are in England, which do not, at present, bring in much money to their owners; whereas, if they were planted with these trees, they would, in a very few years, over-purchase the ground, clear of all expence: but there are many persons in England, who think nothing, except corn, worth cultivating: or, if they plant timber, it must be oak, ash, or elm; and, if their land be not proper for either of these, it is deemed little worth; whereas, if the nature of the soil was examined, and proper sorts of plants adapted to it, there might be a very great advantage made of several large tracts of lands, which at this time lie neglected.

The wood of these trees, especially of the white, is very good to lay for floors, where it will last many years; and, for its exceeding whiteness, is, by many persons, preferred to oak; but being of a soft texture, is very subject to take the impression of nails, &c. which renders it less proper for this purpose: it is also very proper for wainscoting of rooms, being less subject to swell or shrink than most other sorts of wood; but for turnery ware, there is no wood equal to this for its exceeding whiteness, so that trays, bowls, and many other utensils, are made of it; and the bellows-makers prefer it for their use; as do also the shoemakers, not only for heels, but also for the soles of shoes:

it is also very good to make light carts ; the poles are very proper to support vines, hops, &c. and the lopping will afford good fuel, which in many countries is much wanted.

Miller's Gard. Dict.

Red POPPY, or RED-WEED. The common wild red poppy is one of the most mischievous weeds the farmers are plagued with among their corn, and it is the most difficult to thoroughly destroy of almost any other. Its seed will lie a long time in land unploughed, without ever shooting ; but they will be sure to grow with every crop of corn. Mr. Tull gives an instance of the seeds of this plant being buried four and twenty years in a field of saintfoin, and at the end of that time, the land being ploughed for wheat, they all grew up among the corn, though they had lain dormant so long before. *Tull's Horse-hoeing Husbandry.*

POTATOE, or POTATO, the name of a well known plant, the roots of which make a very nourishing food.

Mr. Houghton describes the potatoes to be a bacciferous herb, with esculent roots, bearing winged leaves and a belled flower ; and says, that according to his information, which is allowed to be very right in this respect, it was first brought from Virginia, by Sir Walter Raleigh, who, stopping at Ireland, about the year 1623, gave away a number of these roots, which were planted there, and multiplied so exceedingly, that, in the wars which happened afterwards in that country, when all the corn above ground was destroyed, potatoes became the chief support of the people : for the soldiers, unless they had dug up all the ground where they grew, and almost sifted it, could not have extirpated them. The Philosophical Transactions observe likewise, that the Irish were relieved from their last severe famine, which lasted two years during which all their corn failed, merely by the help of this root. From Ireland it was brought to Lancashire, now famous for its potatoes : and the culture of this plant has, within these last thirty years, been extended to almost every part of England. The rich, who, at first, deemed them fit for none but the meaner sort of people, now esteem them so much, that Mr. Miller thinks the quantity of them which is cultivated around London only, exceeds that of any other parts of Europe.

The red-rooted potatoes have purplish flowers, and the white-rooted (for Mr. Miller distinguishes only these two general varieties) bear white flowers.

The potatoe seldom perfects its seeds in England ; and if it did, the raising of it from them would be much more tedious and uncertain than propagating it by its roots, as is the general and right method : for these multiply exceedingly, and may be made to yield vast crops, with little cost or labour.

“ The Irish husbandman, says Mr. Switzer, after blaming the English for planting this root uncut, because it often contains five or six eyes, or perhaps more, from which the produce of the ensuing year is to spring ; and also for not allowing that bulb, or rather the great number of shoots and bulbs that proceed from it, a space of earth sufficient for their nourishment, which is the reason why so many poor, stunted, unserviceable potatoes are dug up in the autumn, relates the practice of his country, which is to chuse middle sized roots, for the largest are generally eaten, to single out the eyes, that seem strongest and most vigorous, and to cut them out in squares of at least half an inch every way : so that one root will sometimes furnish three or four good pieces to set.

“ The ground, prepared for planting, is marked out for beds four or five feet wide, with intermediate alleys of two or three feet. It is then trenched, only a single spit deep, and the bottom of this trench, made as in common garden-trenching, is covered with dung, long and short, taken out of a wheel-barrow which stands at the labourer's elbow. The potatoe-eyes cut as before directed, are placed upon this dung, at about five or six inches asunder ; and this trench is filled up with the mould taken out of the next, which is marked by a line at the distance of two or three feet. This trench is again filled with the mould of the next, and so on to the last, which is filled from the alley.

“ The use of the dung thus laid at the bottom of the trenches, is not only to make the roots grow single, for not above one root, or at most two, will in this case be produced by each eye, and these will be large and well fed ; but it is attended with the farther advantage of making the potatoes run, and spread themselves to a certain determinate depth, which is no small help to their growing large.

“ The last thing to be done to them is, in April or May (for they are planted in February or March) as soon as they begin to rise, to dig the earth out of the alleys, as is done for asparagus, and to cover the potatoe bed with it,

about five or six inches thick. This will give new life and vigour to the roots, will keep the green from running too much to haulm, and will make the bulbs grow much the larger. By this means the crop of fine large potatoes will be almost the double of what is obtained when they are planted promiscuously in the common way : nor will any farther culture be requisite till they are fit to be dug up, except the pulling out some of the largest weeds.”

Mr. Miller's reasons for disapproving of the planting either of the small offsets entire, or the eyes cut out of larger roots, are, that though the former generally produce a greater number of roots, these roots are always small ; and that the cuttings of the larger roots are apt to rot, especially if wet weather happens soon after they are planted. He therefore recommends, to make choice of the fairest roots for setting, and to allow them a larger space of ground, both between the rows, and between the plants in the rows ; and he assures us that he has observed, when this method has been followed, that the roots in general have been large the following autumn. M. Duhamel, in his Elements of Agriculture, does not object at all to the planting of the cuttings.

The soil in which this plant thrives best, is a light sandy loam, neither too dry nor over moist, but brought to a fine tilth, and ploughed very deep : for the deeper the earth is loosened, the finer and larger the roots will grow. In the spring, just before the last ploughing (according to Mr. Miller's method) a good quantity of rotten dung should be spread on the ground, and this should be ploughed in early in March, if the season be mild : otherwise it had better be deferred until the middle or latter end of that month ; for if a hard frost should come on soon after the roots are planted, they may be greatly injured, if not destroyed, thereby ; but if they can be planted in the spring, without that danger, the better it will be.

The last ploughing should lay the ground even, and then furrows should be drawn three feet asunder, and seven or eight inches deep. The roots should be laid at the bottom of these furrows, about a foot and a half asunder, and they should then be covered in with earth.

After all the ground intended for potatoes is planted in this manner, it must remain in the same state till near the time when the shoots are expected to appear ; then it should be well harrowed both ways, as well to loosen the surface and render it smooth, as to tear up the young weeds which will have begun to grow by that time. If much wet has fallen after the planting, it may have caked the surface of the earth, so as to retard the sprouting of the plants ; and this harrowing will, in such case, almost answer the intent of a first hoeing.

I have placed the rows of potatoes at three feet distance, continues Mr. Miller, in order to introduce the hoe-plough between them ; because that will greatly improve their roots : for by twice stirring and breaking of the ground between these plants, not only weeds will be destroyed, but the soil will be so loosened, that every shower of rain will penetrate to the roots, and greatly quicken their growth. But these operations should be performed early in the season, before the stems or branches of the plants begin to fall and trial upon the ground : for after that, it cannot be done without injuring the shoots.

If these hoe-ploughings are carefully performed, they will prevent the growth of weeds, till the haulm of the plants cover the ground ; and after that there will be little danger of their growing so as to injure the crop ; for the haulm will keep them under : but as the horse-hoe can only go between the rows, it will be necessary to make use of a hand-hoe to stir the ground, and destroy the weeds in the rows, between the plants. If this is well done, in dry weather, immediately after each of the two horse-hoeings, it will be sufficient to keep the ground clean until the potatoes are fit to be taken up ; which will be, very soon after the first frost in the autumn has killed the haulm. They should not remain much longer in the earth, lest the roots themselves be frost-bitten, which spoils them. A four or five pronged fork is better to dig them up with, than a spade, because it is less apt to cut them : but a principal thing to be considered here, is the clearing of the ground thoroughly of them : for if any are left, they will shoot up among the next crop, whatever it be, and do considerable damage, especially if it be wheat, as is generally the case, sown in the common broad-cast way.

The best way of keeping these roots during the winter, is to lay them up in a dry place in very dry sand, or in fine and perfectly dry earth.

The method of laying dung only at the bottom of the furrows in which the roots are planted, "is a very poor one, says Mr. Miller; because, where the potatoes begin to push out their roots, they are soon extended beyond the width of these furrows, and the new roots are commonly formed at a distance from the old, so will be out of the reach of this dung, and consequently will receive little benefit from it." But rather the contrary would seem to be the case, according to the Irish husbandman, who seems to speak from experience, when he says, he had intended expressly to answer this very objection, that "the dung is placed at the bottom of the furrows on purpose to make the roots grow single; and that its being so placed is attended with the farther convenience of making the potatoes run and spread themselves at a certain determinate depth, which is no small help to their growing large." Facts must here determine which is right: as they also must in regard to some parts of what Mr. Miller adds in the following words. "As most farmers covet to have a crop of wheat after the potatoes are taken off the ground, so the land will not be so thoroughly dressed in every part, nor so proper for this crop, as when the dung is equally spread and ploughed in all over the land, nor will the crops of potatoes be so good. I have always observed, where this method of planting the potatoes has been practised, the land has produced a fine crop of wheat afterward, and there has scarce one shoot of the potatoe appeared among the wheat, which I attribute to the farmers planting only the largest roots: for when they have forked them out of the ground the following autumn, there have been six, eight, or ten large roots produced from each, and often many more, and scarce any very small roots; whereas in such places where the small roots have been planted, there has been a vast number of very small roots produced, many of which were so small, as not to be discovered when the roots were taken up; so have grown the following season, and have greatly injured whatever crop was on the ground."

Will not a thorough ploughing and good harrowing, after the crop of potatoes has been taken off the ground, intermix the dung laid in the furrows, and the contiguous earth most impregnated thereby, with the rest of the soil, perhaps almost as well as if the dung had been spread equally over the whole field, at the very first? If it will, the presumption seems strong in the favour of the Irish method. For certain it is, that the land ought to be well ploughed and harrowed after the potatoes are removed, before it is sown with any other crop; unless the seed for that crop, which generally is wheat, be sprinkled by hand between the rows, as they are dug up, and there covered with the earth then turned over. This is practised in some parts of France; but, as M. Duhamel observes, the grain is so apt to be distributed unequally in this method, that it is better to plough the ground, and sow it in the regular way.

If the farmer apprehends that his land has not been thoroughly cleared of the potatoes, and is therefore afraid of their damaging his ensuing crop, his best way will be to lay it up very rough against winter; because the frosts of that season are known to kill and rot all potatoes in the ground exposed to them, and it will at the same time be thereby finely prepared for spring corn; especially as it will have been well enriched by the haulm of the potatoes lying upon it.

Though potatoes delight most in a light sandy loam, neither too dry, nor over moist, as was observed before; yet Mr. Maxwell says he has seen them thrive well on ground that seemed to be very bad; even in deep moss, which could not bear horses to plow it, but which is considerably bettered by them; and on coarse heath, where they were succeeded by grain, without more dung than was laid on at first. Of so improving a nature are they, and so much is the land enriched by the rotting of their stalks among it, and the digging it gets in raising them.

Several experiments communicated to M. Duhamel concur to prove the extraordinary increase of potatoes cultivated with the horse-hoe; but as this will always be the consequence of the New Husbandry, whenever it is properly used, I shall only borrow from him, on this occasion, M. de Viller's account of his method of practice, because it is the clearest and most concise.

"There are, says he, several sorts of potatoes. That which I cultivate is the middle sized. It is planted about the end of April, or the beginning of May, and it ripens

in October. My beds are five feet wide. I give them two ploughings in the spring; at the second of which I half-fill the main furrow. Before I plant, I cut a small furrow with the single cultivator, which likewise loosens the earth; but if it be moist, I put a double spring-tree bar to the cultivator, to avoid the poaching of the horses. I then plant the potatoes a foot asunder in the row, choosing for this purpose such as are about the size of a walnut. They are thrust in by hand, two or three inches deep; and if the mould does not then cover them sufficiently of its own accord, a little more is pushed down upon them.

"A slight hand-hoeing can hardly be avoided afterwards, to destroy the weeds which spring up at the same time as the potatoes: but this hoeing need not extend farther than three or four inches on each side of the row, because the plow will do the rest.

"I give the first hoe-plowing in the spring, as for wheat; but earlier or later, according to the condition of the ground.

"My second hoe-plowing is given as soon as the plants are tall enough to be earthed up; that is to say, when they are eight or ten inches high. I then turn the earth up towards them as much as possible.

"As this plant spreads greatly, and shoots out very fast, it would be impossible to give more than two of these hoeings, if one should neglect to take advantage of the time when its leaves and branches do not entirely cover the bed.

"The roots are dug up in October, or perhaps somewhat earlier or later, according to the season, with a strong iron prong; shaking and clearing them well from the mould. They are then left to dry for some hours, and are afterwards laid up in a place where the frost cannot reach them.

"This fruit, which yields surprisingly, is of great service to feed and fatten cattle, especially when it has been boiled a little. They like it very well raw, after it has been kept a few months above ground: but it is best for them after it has been boiled."

The reader is obliged to the ingenious Mr. Irwin for the following account of cultivating potatoes in Ireland, and which we shall give in his own words:-

"The potatoe, says he, is become a root of such immense utility, especially to the poorer sort, within this century, that too much, methinks, cannot be said towards improving, and extending the culture of it.

"In Provence, Dauphiny, Switzerland, and several other parts of Europe, and even in America, it yields commodious, abundant relief to the more indigent, as being easily and plentifully propagated in almost every kind of soil.

"In Ireland particularly it is the principal food of the poor during the greater part of the year, without which, since the late unproportionable rise of land in that kingdom, to the trade of it, they could not well subsist. And, indeed, it seems a particular favour of Providence sent to them on this account.

"In times, not very remote, lands were cheap there, and the peasantry, consequently, then lived on nourishment somewhat more luxurious, diversified: their labour also was less burthensome. But now, being obliged to work hard at four-pence and sixpence a day, and their rents considerably augmented, it will not seem surprising that this root alone has become the staple of their support, and that they have been the first people in Europe, or, perhaps in the world, that have led the example in an extensive improvement of it. This may naturally be supposed to arise from close-pressing necessity, the most cogent and inspiring of all motives.

"In truth, with much reason; for a poor labourer, in that ill-fated country, is driven to seek his sole refuge for subsistence in this root, for the inexorable imposition of a hard-hearted landlord, (sorry I am to have it to say, too many of them grind the poor; but hope it will not be long the case) who thinks he cannot get too much for his land out of the persons, or purses, of his independants, and who hath so inverted the old customs, that a hewer of wood, and drawer of water, (and many of these perhaps descendants of former proprietors) can afford himself but a miserable scanty platter of potatoes, seasoned with a palatable grain of salt, and washed down with a draught from the next rivulet, to support the fatigue of thirteen hours (statute quantity) of unceasing labour, about his ancient mansion.

mansion-house, or in his elegant gardens, well-laid out closes, or refreshing bog-holes.

"The potatoe is a root, a little of which is very filling, quickly appeasing hunger; but by no means a lasting solid nourishment for a labourer, as evidently testify the squalid looks of numbers of the poorer Irish; though at the same time it is in general wholesome, agreeing with most stomachs, that can vary their food; but like other productions of the earth, forbid in many cases by the medicinal tribe.

"There are several ways of breeding potatoes in Ireland, which partly arises from the difference in soil, and kinds of seed. The different soils for this purpose in use in my neighbourhood, for about twenty years past, and which, I believe, are pretty general, are the following, wherein they are abundantly propagated, viz.

"First, On rich clay land without any manure, vulgarly called *grafs* potatoes.

"When a lease is near being expired, that is, during the last seven years of it, if there be no covenants grounded on the statute against waste, &c. the tenant, finding no hopes of a renewal, sets considerable tracts in this way, where the soil will admit of it.

"Secondly, On good ley land well gravelled, (otherwise sanded) which ought to be done a year before planting. But the poorer sort, who are the chief cultivators of this root, are obliged to sand and plant at the same time, or nearly thereabouts; which is very destructive to themselves, their potatoes not having the proper benefit of the manure; at least one part in three of the return are on this account exceeding small, and are from hence called *poreens* by them, being a diminutive expression. Whole fields are set in this way, commonly called *spaddane*, in which a considerable trade is driven; especially in the provinces of Munster and Connaught.

"Had it been properly and moderately done, it would be a fine preparation for the increase of corn, and the laying down and bringing in, or, in other terms, the reclaiming of land; but the poor do it so negligently, and mangle it so intolerably, having but a short temporary use it in, besides paying near double the worth of it, that this manufacture, which might otherwise be of considerable benefit to Ireland, is, as now carried on, rather the contrary.

"Thirdly, On ground previously gravelled (that is perhaps six months before) and dunged at setting-time. There is but little done in this way, except by the gentry and renters of land, for their own private use; it being as yet out of reach of the peasantry, unless in a few instances.

"Fourthly, On the ley with dung alone. Marle is not in use in my neighbourhood, though there is plenty of it in several parts of it; therefore cannot yet inform you how it would do for the potatoes in that district. As to potatoes set in the ley with dung alone, this manufacture also is done, as you may judge, mostly by the more opulent. I have, however, often seen large fields set in this way to the public: but it is not of late years so much the custom, this sort of land being commonly kept for grazing: this hurts the land; and any preparation out of the ley for potatoes will, if not previously gravelled.

"Fifthly, In arable or stubble land, vulgarly called *sticking* or *thrusting* of potatoes, because they are sown with a stick, pointed at the end, about an inch diameter, and two feet long, with the *loy* (otherwise the Irish *spade*). In this method dung is also used, which shall be noticed in loco.

"These are the most general methods that now occur to me, or I believe that are in use. There are, however, some others arising from the quality of the seed, practised only by the curious, in which the plants are put down at nine or twelve inches asunder every way, in little hillocks (like the hop plant), as practised in several counties in England; and, if you land them at certain proper stated times, while vegetation continues, you will have a handsome nest of large oblong potatoes at every landing.

"I made the experiment of one sort in my garden; and out of half a dozen potatoes cut into several pieces, each having an eye, I had, to the best of my remembrance, without exaggeration, a quantity nearly equal to twelve Winchester bushels.

"This kind of potatoe is introduced into Ireland but of late years: it is however well known there.

"A potatoe entirely black is also in use in Fingal, near Dublin, fructifies abundantly, and eats exceeding dry, which principally marks the goodness of this root in almost every instance.

"There are several kinds of potatoes. Mr. Maxwell, of Arkland in Scotland, a very judicious gentleman, has particularly noticed six sorts, viz. the long red, the round red, the long white, the round white, or Spanish potatoe; the blue, the leather-coat, and an early kind that comes in a month sooner than the common sort, though planted at the same time.

"This root being greatly manufactured in Ireland, they mix most of the better sorts promiscuously, both for use and seed.

"I remember, about twenty-five years ago, the large red potatoe, then called the *Castonian*, (perhaps from Castile) as also the oblong Spanish white potatoe, to be chiefly in use; but now a lesser sort, such as the Munster or kidney potatoe, of a whitish or lightish yellow colour, the leather-coat, or round red Cronian potatoe, with a rough thick skin, and particularly that styled the Spanish white potatoe, are mostly in use.

"All these sorts are cut for seed, according to the number of eyes on them, and thrive generally well with very little care; so that all sorts being now so plenty, and answering so well, there are (as we may easily judge) no over nice distinction made about them there. The poorer Irish, who affect not to plant this root in bottom lands, or wet swampy grounds, unless hard pressed for soil, are even in this case seldom attentive about the kind of potatoe they put down, the return being commonly wet, unfit for eating, and only proper for seed, which (from my little experience) I think, makes but indifferent, though sown in the best prepared upland; for too much moisture, as well as too much dung, makes a potatoe wet: and plant it when you will, I am apprehensive it never loses this quality, which is the worst it can have, except being rotten, or frost-bit; nor will any eat so well, raised from dung, as without.

"As the potatoe thrives in different soils, so there are different methods of cultivating it: I will therefore now proceed to that most generally in use in my neighbourhood, (and indeed all over the kingdom) called *grafs* potatoes or *spaddane*, and by some (improperly) *con-acres*, which seems to be the natural culture, but doubtless not so good to make the land stand long proof, (notwithstanding the gravelling) as if artificial manures were added, such as dung, compost, lime, &c. for marle, limestone, gravel, sea-sand, shells, &c. I consider in the class of natural manures, and the best; and Providence hath kindly given them in every spot, (even in the unpromising deserts of Zara, &c.) had we known how to come at them.

"Land in the ley, (as I said before) and that which requires no manure, the Irish seek most greedily after; some of which has not been ploughed perhaps within this century: so that you can only just distinguish that it has been tilled, and that the tilth is generally curved, the old people inclining the plough with the casual shape of the field, so as to let the water in the furrow have a drip or a fall.

"When a peasant has the good luck to get a bit of such choice ground, (for two or three of them will be concerned in an acre, and few take more than one) he follows the old ridge with his *loy*, or Irish *spade*, unless compelled by the possessor of the land to make his ridges straight, which he most unwillingly does, and at best but awkwardly, with a rope made of hay or straw, or some of his wife's worst tow; neither of which stretching right, and often breaking, seldom admit well-looking ridges: these he makes from one end of his ground to the other, the beds being about three, or at most four feet wide, and the furrows or trenches about two. When he deposits the seed on his bed, at about four or six inches at most asunder, he divides the turf of his furrow into two equal parts, which he turns alternately in sods on the edge or verge of each bed, the green side on the potatoes cutting the sods on three sides or angles, leaving that next the bed uncut. This laborious work the poor fellow does surprisingly quick: two more men follow him, one digging the under stratum, and throwing up on the middle of the bed as much of the earth as he conveniently can with his *loy*; the remainder the third man calls on with his

his shovel, settling the bed in the form or manner in which it is to remain.

"Some cover their potatoes at first (through want of time, with only the sod; and about four or five inches of earth, and finish them, perhaps, that is, cast the last covering on them, not for a month or six weeks after; which possibly may greatly check their growth. Many account this the best way, and it is become common; but I attribute the neglect of not finishing their potatoes, (as the term is) in due time, to no want of proper knowledge in the common Irish, but their inability to give the proper attention to their own little affairs, occasioned by the greedy severity of their masters, as before observed.

"Others there are (and many) who, making the furrows unproportionably narrow to the beds, throw up a third spit or stratum, and perhaps not until two months after the first setting.

"This pernicious method may possibly destroy, or check the weeds; but certain I am, it will not contribute to the increase or largeness of the root, in the unphysical or over heavy manner in which I have seen it done; because this lower stratum, which is mostly sand, remains on the top of the richest part of the soil, and being thus unmixed with it, prevents it from receiving the proper benefits of the air, &c; besides, too great a covering on the potatoe is highly prejudicial to it.

"In other cases, these stratums thrown up, and mixed into a good tilth, would answer wonderfully; mixing well, being the life of good tillage. I would therefore in this place recommend to our farmers (who are too penurious of their land) to make their potatoe trenches so wide, as not to require throwing up much of the third or sandy stratum on the last covering, or landing of their potatoes; and they will find a much greater return, and one half (or more) less of poreens, or small potatoes: which is an object highly worthy of their notice. The experiments I have made, I purpose repeating on my return to Ireland, and hope to prove this simple method to exceed that in the hillock, or in the drill way.

"In this manner all ley land is sown with potatoes by the common people, and most others, whether manured or not. If dunged, the dung is laid out as the ridges are to be, but the sand is spread all over the surface. Commonly little boys and girls precede the setters on the ridges, laying down the seedlings or potatoe eyes, which they do very quick and tolerably well, at the appointed distance. This seems a giddy part of their business, and well suited to their years; but custom makes them perfect in it.

"The next general method is planting potatoes in stubble ground, which is, in the common way above-mentioned, by dunging it well, and sometimes by ploughing it in, and then shovelling up the ridges, a man going before, lightly digging them, that there may be a sufficient quantity of mould to cover them; but this the poorer sort cannot well compass to do, and always avoid it when they can get a fresh or ley surface.

"Nor do they sow them to choose, the second year, in the same ground, without dung or some other artificial manure, (for the natural, such as sand, marle, &c. would not do) unless it be exceeding good.

"Lime, indeed, in this case, will very probably answer, but it is rarely tried.

"There is also a custom a good deal in use, which is by sticking or thrusting potatoes in stubble land fresh ploughed, which is done in this manner: a man (but seldom two) goes on the crown of a narrow ploughed set, and sticks his loy, or Irish spade, in it, every here and there, with his right foot, holding it in his left hand, and with it pushing the spade once, and sometimes twice from him, to make an opening, (which I have seen done with a great deal of dexterity) and with the right hand, that contains the seed, (a convenient quantity of which he carries in an apron, or cloth, tied round his middle, so as to let the contents be easily come at), he throws one, and sometimes two sets, or eyes, into the opening which the loy makes behind; and on his drawing it away, the loosened earth falls in and covers them. Soon after he dungs the ridges, and covers them up, as in the preceding method, with mould out of the furrows.

"Sometimes also they do this work with a stick about eighteen inches long, and an inch or so diameter, pointed at one end, and somewhat curved at the other. By this easy means, husband, wife, children, and servants, (if they

have any) and a friendly neighbour or two, (who may be helped in return) assist at it for greater expedition, especially when the season happens to be advanced.

"In Scotland they do this work somewhat differently.

"In Ireland also there are many, who sow potatoes after the plough; the ploughman letting the sets drop in as he goes along; and a harrow matched to the same plough, following him close behind, covers them in. There is no great difficulty in this, the land being in tilth. Over all they put dung; but they should mind to give it a light covering, that the substance of it might impregnate with the adjacent earth, which it would not do, but evaporate, by being left exposed to the air, &c. yet this precaution many are very negligent in.

"The other methods, as in the drill, or hillock, or horse-hoeing way, &c. are little used there, except among the more curious; but they being well known in England, it is needless to mention them in this place.

"The next thing requisite is the fencing, which should be done, at farthest, before the stalk begins to appear; for, if the cattle, that are in that season greedy for fresh vegetables, get at them, the roots of such as they nip will never come to the size they otherwise would.

"This is well known in Ireland; and yet the poor, chiefly I believe from inability, and partly from a sort of carelessness, or rather laziness, they still inherit (notwithstanding the mixture of English and Norman blood, &c.) from their Spanish ancestors, are very remiss in this respect; especially in the chiltern, or more fertile parts of the country; where, in most matters of husbandry, they leave too much to chance, relying on the bounty of the soil.

"About me, and in many other parts, they very commonly do not put on the first covering till about the middle of May; and the second, perhaps, not for a month after; so that it is often July before they fence them properly: and where many of them are concerned in a plantation (as is usually the way) it is troublesome and difficult to get each man to do his part of ditching, which commonly is but a sorry mound of sods, with some bushes sodded down on top, to keep out sheep, that smell this plant when it rises (as cattle do corn) and are very dexterous in getting at it.

"Some of these poor people are so heedless, they never can be brought to make their fences; and then the owner of the ground, in his own defence, is obliged to get it done at an advanced price, and they do pay for it, or their potatoes remain.

"Many of them, especially in cheap years, leave them on the landlord's hands; and, unless a farmer collects himself, or has a good servant to do it, the rent is not had without immense trouble, and some of it never. Notwithstanding these difficulties, many farmers have made easy fortunes in this way.

"Thus it happens, at the time they are often finishing the fencing, they ought to be weeding their potatoes. The weed that mostly annoys them is the Scotch thistle; this should be cut away in June, and if the soil should be so rich as to require a second weeding (which is very often the case) it should be done in August. There will be no other trouble with them till digging time.

"The best time for this work is the latter end of October, or beginning of November, to avoid the early frosts, which are mortal to them: but if, by bad husbandry, they have been planted late, they should be left longer in the ground, and covered with litter, or haulm, to prevent being lost in this way.

"About Michaelmas the cattle are let through them, the roots not being then effected by the nipping or beating down of the stalk; this the peasants know by the colour of it, which becomes a dark brown, losing its verdure; as also by the apple and pear.

"The more needy begin to dig them for use in August, though they are not then near so long in ground as they are in England; which demonstrates the excellence and strength of the Irish soil.

"When gentlemen farmers dig their potatoes, they set on a great number of hands at once, two to a ridge: boys and girls gather them promiscuously, big and little, into bags containing about two Winchester bushels; and thus they are carried to the farm-house, and thrown into a room in one heap, part of which is destroyed by the frost, a great part by the kitchen, also by the hogs, who destroy them much while in ground, there being hardly

any fencing against them; a great part are also stole by the followers or hangers-on; and the remainder rarely suffices for seed, of so little value is this estimable root considered in those parts: and yet I have often known them at a very high price, from ten to twenty shillings, and upwards, the big barrel, which is the usual measure in the western parts of Ireland; that is, above two barrels, or eight bushels Winchester measure.

"Had they such places as Covent-Garden near them, the case would be very different: but where there are no convenient and brisk markets, the waste in farms is always great.

"Though, as I remarked before, low or swampy grounds do not answer well for potatoes, yet they sometimes thrive, and are large, the meat being generally scabby, close, wet, and heavy, from the too great impregnation of the water, which renders them unpalatable, and not the best for seed; however, such are chiefly used in this way: yet I have seen them planted in red bogs, which are the wettest and worst; and the bog being previously sanded and dunged, the stalk looked green and healthy, and some of the roots might perchance have eat very dry; but those planted in black, or drier bogs, have been found to succeed well.

"There is no culture perhaps yet known, will better reclaim waste and unprofitable lands, than that of the potatoe. Ireland can well prove the truth of this assertion in a numberless variety of instances.

"I have seen several tracts of woodland stubbed up, and brought into fine tilth, by means of the potatoe husbandry. America, I believe, can say the same.

"Of late years the hard-hearted sky-farmers, that is, the inferior sort, and even some of our gentlemen farmers, drive the poor into the mountains, moory grounds, wooded and stony lands, and even into the bogs; and when, by the culture of the potatoe principally they have reclaimed them, so as to be fit to admit cattle they are turned out without ceremony. I have in such places seen as fine crops of potatoes, and afterwards flax, and different kinds of corn, as I ever met with any where.

"The mountain and other surfaces, except bog, seldom fail being blessed by nature with lime-stone, gravel, (which is the commonest) or some other manure adapted, to them; so that it is nothing but hands, money, and a proper limitation of the grazing farming, that are wanting to make almost the whole kingdom look like a garden, or like England; I need go no higher with the comparison.

"It is true, in some few counties of Ireland, in particular districts, nature either has not been so bountiful, or the farmers have not found out the internal manures; being obliged to carry sea-sand, and other sorts, many miles; in which however they find their account, notwithstanding the impolitically too much limited trade of the kingdom.

"Before I dismiss this subject, it may be proper to observe, that a second crop of potatoes is sometimes taken out of the same land successively; but this is not common, at least about me, though I believe the land is as good as any in the province. On the contrary, the usual way is, after the first crop of potatoes is taken off, if the soil is strong, they immediately sow bere in it, or keep it till the following spring for flax, which requires an equally strong soil: or if the ground be but of a middling good sort, they sow it, just after the potatoes are taken out, with wheat, or keep it till the April following for barley.

"The sky-farmer generally takes the land into his own hand after the first crop of potatoes, and sows it with bere, wheat, or barley, for two or three seasons; after which, if he refreshes it with a summer or a winter fallow, he sows the said kinds of grain in it for two or three seasons more; then he takes two or three crops of oats; and when it is well impoverished, or drawn (as they call it there), he lets it for several years together, in con-acres, to the poor people, for at least one third more than the real value.

"From hence we may judge how much an alteration of method in husbandry is wanting in those parts."

Mr. Irwin is certainly right in saying, that lime would very agreeably answer; for in the isle of Man, though they are no farmers, yet they cultivate exceeding fine potatoes, as they are their principal food.

Some bring in different sorts of land by the means of them: in moory ground, after the heath is burnt off it, they mark out the beds, upon which they spread out the lime in near about the same quantity that is required in liming ground, or rather more; upon which they lay the seed in the usual manner; and after cutting the turf in the furrow, lay it on the verge of the bed with the heathy side

undermost, and cover them over with the mould out of the furrow, in the common method.

After coming up, they weed, or give them a slight covering to keep down the weeds.

When they raise them, it takes a little more labour; yet while they are digging a crop of very fine dry potatoes, they are gaining a piece of ground which was before useless, and making it fit for ploughing and bearing corn the year following.

Lime is found to be of excellent service to potatoes in cold sour land, which they manage after the same manner, and reap potatoes greatly excelling those without lime, on the same ground.

Lime is certainly a very fine manure for potatoes: they use it in the isle above mentioned without any other thing, on all sorts of land, even upon a light rich lime-stone soil; and it betters the quality of the potatoe surprisingly: besides fermenting and meliorating the soil, it has the property of attracting and absorbing any cold sour matter which may be prejudicial to vegetation.

About Castletown, in the same isle, they take a great deal of care in their culture of potatoes, and their product pays them very well for their trouble.

After marking out the bed with the spade, and spreading on the dung, or lime they begin at one end, and dig across the bed, making it a spadeful, all along, higher than the neighbouring ground.

Then they dig and cast the mould out of the furrows upon the bed in the common method; and after finishing it, they, with a kind of dibble, or shaft of a spade shod with iron, some round and sharp, others square, about three or four inches broad, plant in the seed, about six or more inches distances from one another; and when they come up above ground, they weed them as clean as a garden, and after they are stronger and higher, with a hoe, earth up the mould about the stalk; by which they kill the weeds and have exceeding fine potatoes.

This excellent root is very valuable on several accounts.

1. It is esteemed, and now very generally used at the tables of persons of all ranks; and inestimable for the poor, being a cheap and very wholesome food.

2. It is good for several sorts of cattle, particularly for hogs, either for food or fattening them.

3. It is one of the greatest improvers of land, whether new broke up, or preparatory to any other crop; and is in itself very valuable for the crop it produces. It is so likewise from another circumstance, viz. That it refuses no kind of soil, if not very wet, but will grow to considerable profit on drained bogs, heaths, or waste lands; and is of very easy culture.

Mr. Marshall, in his Minutes of Agriculture, remarking the great waste arising from the common method of cutting potatoes for planting, made the experiment with a common ivory apple-scoop about half an inch diameter, to draw out the eyes of the large potatoes in the manner which cheesemongers try their cheeses, and drew out a plug of the pulp, of a cylindrical form, about three quarters of an inch long, with an eye in the center of its end. After extracting ten or a dozen of these plants out of a root of a quarter of a pound, in weight the diminution is barely apparent; at least three ounces remained. If it had been taken from a larger potatoe, the loss of weight would have been still proportionably less; and the remaining pulp of equal value to the hogs as the same weight of entire potatoes. He then remarks, if one eye with two drachms of pulp be as prolific as seven eyes with two ounces, (which is frequently the case) what a saving! And as too frequently those employed in cutting potatoes for sowing leave six or seven eyes in each piece, it has commonly taken from ten to twelve hundred weight an acre; as many as by this method would have planted four or five acres, besides leaving eight or nine hundred weight of hog food.

Potatoes are so generally cultivated in Ireland, particularly in the province of Munster, that they are the principal, and almost the only food of the poor there, for almost eight months in the year. They do not esteem the roots for being very large, which they cannot be in their manner of planting; for they cut the roots into as many pieces, commonly, as the potatoe has eyes or buds; one bud to each piece, and set them in the ground singly with a dibble about eight or nine inches distant every way. Sometimes they cut them in slices, not so thick as a crown piece, with an eye to each slice; and, in general, are not solicitous to leave much of the potatoe to each eye; which, with

with close planting, renders the potatoes commonly small, and but few large ones among them.

Mr. Young, in his *Annals of Agriculture*, gives the following observations and experiments of different correspondents on the use of potatoes; among whom the Rev. Mr. Close, of Trimley near Ipswich, says, "March the 30th, 1781, I planted an acre with kidney potatoes, and two days after, ordered two bushel of fresh lime to be sown over the surface of the ground, leaving two rows unlimed, to see if the experiment would have any visible effect upon the crop.

"The latter end of August following, I was surprised to find the rows which were left unlimed, very much grub-eaten, and the remainder a fine, clear, and perfectly sound crop, producing one hundred and ninety-two bushels, or sixty-four sacks. I planted four acres in 1782, dressing the whole with lime, and my crop quite free from the grub; fourteen acres in 1783, with the same success; when a headland, not-top dressed with lime, suffered much, almost every plant being damaged. I believe potatoes to be the most profitable root a farmer can cultivate; wheat succeeds well immediately after them; I had thirty-two bushels per acre from the four acres above mentioned, and two bushels more per acre from the potatoe-land in 1781, than from the bean-land in the same field, both twice hoed, the potatoes being allowed twenty loads of muck per acre, the beans only fifteen loads.

"I shall trouble you with an exact account of the expence and profit attending an acre in 1781.

Rent of land,	£. 1 0 0
20 loads of muck, at 2s.	2 0 0
5 sacks for seed,	2 0 0
Tythe,	0 4 0
Rates,	0 2 6
Ploughing and harrowing,	0 8 0
Baulking for the seed,	0 2 0
Three boys dropping one day,	0 1 6
Two men half a day, covering the seed with hoes,	0 1 6
Ploughing up,	0 10 8
16 women taking up ditto,	0 9 0
Carting home,	7 0 8
Sold 20 sacks, at 7s. 6d. per sack,	£. 7 10 0
Sold 20 do. at 9s. do.	9 0 0
Sold 24 do. not quite so large, at 5s. do.	6 0 0
Received	22 10 0
Expences	7 0 8
Clear profit,	15 9 4

"The above is an exact account of what I paid and received, except the valuation of the muck, which I think cannot be worth less than 2s. per load, if good, and twice hoeing, for which I paid 7s. this makes the clear profit 15l. 2s. 4d.

"I have for several years kept my hogs entirely upon my refuse potatoes, and can always, without difficulty, or the expence and trouble of confining them, sell those of about seven or eight stone weight, to the butchers, for roasting meat, at 4s. 6d. per stone: pork fed in this method is remarkably sweet, the flesh delicate and moist. This food succeeds admirably, except for bacon-hogs, and I find from experience, that it is necessary to keep those intended for that purpose about a fortnight upon ground pease mixed with boiled potatoes. If the hogs are forwarded with potatoes before they are confined, two bushels of pea-meal, and four bushels of boiled potatoes, well incorporated, will fat a hog of twelve stone, fit for hams or bacon; this method greatly reduces the expence commonly attending the fattening of swine."

The Rev. Mr. Fuller, of Heathfield in Sussex, in a letter to Mr. Young, vol. XII, says, "My general method has been to let the sheep of the true south down breed have the after-grass, and about the middle of the month of November, to take them into the yard, with a shed or lodge adjoining, and confine them till they are ready for the market of the end of February, or the first week in March. The potatoes are cut into two or more slices, as may be deemed necessary, and put into troughs, which are fixed under the shelter. On an average I have observed,

that each sheep will eat one gallon each day. I have generally purchased my lambs at twelve, thirteen, or fourteen shillings, at the utmost, and have always sold them at good prices, and I have seldom got less than four shillings per stone. They have ever proved well on examination, and at the age of two years have amounted to nine, ten, and eleven stone; the internal fat of one, which I had the curiosity to weigh, was equal to fifteen pounds. It will not admit of a doubt, but that if fair trial is made, the potatoe system will prove the most expeditious in fattening sheep. I have made the experiment with sheep of the same age, and of the same flock, on corn of different kinds, and even with oil-cake, and have found that potatoes will do the business in the shortest time. As a farther proof of what I have said in favour of potatoes, I have remarked, that on placing two sheep from the common flock, in the yard with those that had enjoyed the best after-grass, I have found, at the usual time of selling them, little or no difference at all in point of fatness, and have sold them at the same price: I presume, therefore, you will allow me to say, that I think this method of preparing mutton for the table is the most expeditious, if not the most profitable plant to be pursued in accomplishing the end desired. Observe, that I give the sheep a little hay, morning and evening; and if the yard is properly attended to, you may easily conjecture what a mass of manure, both in point of quality as well as quantity, may be thus procured. I forgot to mention that I always plant the golden globe, and grow generally from four hundred to four hundred and fifty bushels per acre.

"The old varieties of potatoes formerly in cultivation, dwindling in produce, and being, at length, in a manner destroyed by the disease of curled top, two new varieties were introduced, under the names of goldfinders and goldendabs; the former a yellow kidney-like root (but with a scurfy rind, not unlike that of the old russet potatoe); the latter of a similar colour, but of a different form, being somewhat bell-shaped. The consequence has been, the disease vanished with the old sorts, and is now (1786), and in this neighbourhood, where no other is in ordinary cultivation, in a manner forgot.

"In 1789, I met with a similar instance in Leicestershire, where the old red sort was entirely worn out with the disease, while a white sort, now in cultivation, was never known to curl.

"In Rutlandshire, I had ocular evidence of the same nature. Observing, in a large piece of potatoes, two stripes, which were almost wholly curled, while the rest of the piece appeared to be free from the disease, I inquired into the cause of disparity; and received in answer, without hesitation, that the healthy plants were Manley's, and the diseased stripes red nosed kidneys, which heretofore was the prevailing species; but being no longer to be cultivated with any degree of success, a new sort was, some years ago, introduced, under the name of the Manley, which still remains free from the disease.

"By information, that I have no reason to doubt, and in two or three different instances, 600 bushels an acre have been produced; seven strike a rood (of eight yards square has not unfrequently, been grown. Four to five strike a rood, or three to four hundred bushels an acre, is reckoned a fair good crop.

"The potatoe root is the principal food of all labouring persons and their families: when that root is at high prices, they with difficulty subsist. It is the leading crop in our culture, but repays little above its expences. The black sandy soil of the low lands is particularly adapted to the plant.

"I now arrive at an article of infinite consequence to the cultivators of this useful and necessary root: the plant is subject to a disease, which often reduces the produce above one half; the farmers very aptly call it the curl, the leaves curling to a great degree; when that happens, you find one or two small roots, not worth the expence of taking up: this happens sometimes to a fourth of the field, or more, to the farmers great detriment.

"It has long perplexed a variety of authors and cultivators to account for this disease, but all their conjectures proved merely imaginary. Last year I accidentally discovered the real cause: looking over a field of these plants, set with whole potatoes, I observed a plant with two stems, the one curled, the other perfect: on taking up the plant and root, I found a hole at that end where the curled stem grew, from which an insect escaped about an inch long, of the millipedes species. It immediately appeared to me, that that insect was the cause of the curl; the gardener took

up several more plants; every curled plant had either the hole, or nest, or the insect itself: there remained no doubt of the cause after this examination, which several successive experiments confirmed: thus we have discovered the cause, but the remedy remains undiscovered; perhaps there is none.

"In some of Mr. Young's Annals he takes notice, the cluster potatoes never curl; this probably arises from the insect's disliking the taste of the root; my practice confirms your remark: and very fortunately for this country, an excellent table potatoe has been introduced, of the cluster species, which the insect does not attack, as I find by my practice, having set about three acres of this species this year; these are of the late, or autumn potatoes. The early summer potatoe still remains subject to the depredations of the insect. It appears to me this plant is not sufficiently known over the kingdom, especially in all sandy soils, where it would precede the carrot to great advantage."

Nathaniel Turner, esq. of Stoke, near Ipswich in Suffolk, says, in a letter to Mr. Young, vol. I. "It is well known by most farmers that have cultivated potatoes, that the common cluster sort is a red one, and that when a root of it is cut, the heart is all streaked with red marks; the skin of that sort is also red: on the contrary, the kind which I have cultivated is a white cluster; the skin is white; and, when cut, the inside is of a yellowish colour, but it grows in the same conglomerate form as the common red clustered one. The quantity of land on which the experiment was tried, is four acres, two of which were planted with the red, and two with the white, for comparison. The soil, a rich sandy loam, quite dry, hanging on a slope to the river Orwell. It yielded turneps in 1781. Manured with one hundred and three loads of rich compost, dung, earth, and chalk; half ploughed in balks, harrowed down, and then ploughed as deep as the plough could go. The potatoes were cut in slices, an eye to each, and as large a piece left to it as the size would admit; dibbled along every other furrow, and from ten to twelve inches from set to set, in which way twelve bushels of seed plant an acre: the eye should lie upwards. Bush-harrowed to fill the holes. As soon as the rows were visible above ground, horse-hoed them. Then hand-hoed among the plants; and afterwards earthed them up with a double mould board plough, and finished by hand-weeding. Dug them with three-pronged forks, children following to pick them up. Being in possession of some very large wine-vaults (built for a merchant), the potatoes were laid in them, but from the warmth of the situation, the roots indicated a tendency to sprout; they were, therefore, drawn over to prevent it.

"The product of the common red-cluster seven hundred and twenty-nine bushels, or per acre three hundred and sixty-four. That of the white-cluster eight hundred and thirty-one bushels, or per acre four hundred and fifteen, of very large fine roots.

"Produce.

364 bushels red-cluster sold at 10d.	15 3 9
Expences,	6 7 6
Profit,	8 16 3
415 bushels white-cluster, at 1s. 4d.	27 13 4
Expences as above,	6 7 6
Profit,	21 5 10

"Many of the red-cluster were given to hogs, of which stock sixty were kept a considerable time: the experiment does not permit me to decide by positive fact what the value is; but I am clear in my own mind, from attentive observation, that they are worth 6d. per bushel in this application. The most profitable method, however, is, not to let the hogs depend entirely on them, but have some beans given occasionally, or else a barn-door where there is great plenty of straw thrown out: hogs confined totally to potatoes are apt to grow tired, not coming on fast enough in flesh. At 6d. a bushel, the account would stand thus:

364 Bushels at 6d.	9 2 0
Expences,	6 7 6
Profit,	£ 2 14 6

"This moderate profit is applicable to all situations, where they cannot as well as where they can be sold; and it demands attention, that the crop, after paying an ample manuring and all charges, yields more in nett profit than turneps do in gross produce.

"But it is not only for hogs that this potatoe is to be recommended. I find that bullocks do exceedingly well on them: four (each thirty-five stone) will eat fourteen sacks a week, and seven pound of hay each per diem; and when they take to them kindly, nothing will bring them on faster.

"From the experience of several years, I can assert, that potatoes are by no means (as some persons have thought) an exhausting crop, but, on the contrary, an ameliorating one. My barley this year, after them, was so clean that not a weed was to be seen, and produced five quarters an acre."

A correspondent of Mr. Young, in vol. I. of his Annals, says, "I am situated on a breeding farm for horned cattle, but have no land to fatten them on; but now, I have got to planting potatoes, and fatten all that I breed. I think of planting ten acres this spring, if it is a dry one; for wet springs are very unkindly for potatoes.

"I plant potatoes on a wheat stubble, after three ploughings, and get a fine season, on light, dry, hazel mould, plant them in rows three feet apart, and twelve inches apart in the rows; cover them with rough dung out of the close, and the earth pulled over the dung with hoes; keep them very clean by hand and horse-hoeing; the crop from four to five hundred bushels per acre: they cost about 2½d. per bushel. It will require fifty loads of dung per acre, sixteen bushels per load, horse-dung the best; but when we have used all the horse-dung that we have, use the dung out of the close where the cattle have been eating potatoes, as we look upon that to be much stronger than where they eat only hay. I plant them as near the place where they are to be consumed as possible, for moving them far is attended with a great expence. Where I plant, one horse brings them in a cart to the place where they are laid up to be given to the cattle, which is joining to the close where they are fed. After potatoes sow wheat, and get from twenty to thirty-five bushels per acre.

"Give the potatoes to horned cattle in the cribs that we give them hay in. Give hay in the morning, about ten o'clock potatoes, at noon hay, about two o'clock potatoes, and at night hay. An ox of one hundred and forty stone (eight pounds to the stone) will eat one bushel and an half per day; from eighty to one hundred stone, one bushels, with about ten pounds of hay; they will not eat hay if they have that quantity of potatoes; we get very fat cattle with hay and potatoes, such as was never made before in this part of the country.

"I have this winter cleared about three acres of broom and goss, and intend to plant it with potatoes on one ploughing. I once grew five hundred bushels per acre, on such a piece of ground, of the eating sort."

Sir William Fordyce, in a letter to Mr. Young, vol. I. of his Annals, says of the Surinam potatoes for feeding horses, as follows: "They were boiled daily with the same fire that cooked the victuals for my table; and they were boiled in the usual manner, but not into a mash: each horse had a quarter of a peck daily, and they never fluxed them. My horses are always in a hurry, and so is their matter. I never gave them the potatoes raw, neither to them nor to my poultry, who, with pollard, live entirely on them; as did my hogs, excepting the last ten days, when I gave them pease. I had heard that pork fattened with

with them, lost the fat in boiling; but treated as above, I did not find it so.

"I have given my horses in town, sometimes chaff; but, having other affairs to mind, I can only say, that some of my horses in the stable (the young ones), and not much worked, have occasionally straw in rack, in general, good hay.

"The expence of feeding horses especially is become extreme about London. The returns which the cluster potatoe yields, if cultivated on lazy-beds, or by trenching, according to my experience, compared with the common potatoe, naturally led me to make a trial of the culture in trenches, from the opinion that unless so large a root as it grows to (oftentimes from a pound and a half, to three, four, and five, and sometimes to six, or even eight pounds weight each) was lightly covered with earth on the top of the trench, and more earth thrown upon the plants occasionally, they must be cramped in their growth, where the ground is not remarkably loose.

"Having, in the month of April 1775, ploughed half an acre of land which had been formerly trenched, which produced a good crop of turneps the preceding season, I spread upon it a quantity of litter immediately from the stable. The cuttings of the potatoes (with one or more eyes to each cutting) were laid at six inches distance from one another, on beds four feet and a half broad, and covered lightly with earth from trenches of two feet and a half. As soon as the plants appeared, three inches more of earth were thrown upon them. The plants had greater verdure, and larger leaves, than any of the common esculent sort; circumstances which probably contributed to the largeness of their growth. You could scarcely put down your finger on beds without touching the roots, they were so numerous; and, in some places, were seen like turneps above ground.

"I had the curiosity to cut one of six pounds eight ounces into twenty-four pieces, and planted them in my garden; the produce was taken up and weighed; and it yielded one hundred and sixty-five pounds weight from this one potatoe. The season was the driest I have known, and thought the crop but small; the ground was very light, and but just taken off the common.

"I sent a potatoe of eight pounds weight and upwards (by six ounces) for the emperor Joseph, by a friend.

"I had a peck boiled every day after the dinner was cooked in the kitchen, and gave my saddle-horses and my coach-horses (afterwards) a quarter of a peck each daily, on which they did their work well as long as they lasted, that is, upwards of two months, instead of oats, only a trifling quantity of which were now and then given. I doubt if they would be hearty enough for a long draught; but, from my observation in the streets, and to the five mile-stone, I never found the horses to flinch in the draught, or under the saddle. If they were roasted on kilns, as I understand other potatoes are done in some parts of England, particularly in Northumberland, and mixed with some ground oats, it would, I imagine, be a great saving in oats, and more hearty food. I found out, after a great expence in grain in my poultry-yard, that all sorts of poultry thrive extremely well on them when mixed with pollard."

Experiments on Potatoes, by John Kirby, Esq. of Ipswich.

"In the spring 1782, an old lay near Ipswich was ploughed: the first plough skimmed off the turf about an inch and half deep; women followed and laid the potatoe-fets (the globe-white, called also the champion) in that furrow; then came another plough that cut as deep as possible, covering the fets nine inches deep. There is no danger of burying them, as they rise freely. In this manner, without any manuring, planted every third or fourth furrow; part one, and part the other: in the first, the rows were twenty-seven inches asunder; in the latter, three feet. The former yielded the greater crop. They were all kept clean by horse and hand-hoeing; were taken up with three-pronged forks, at the expence of a halfpenny a bushel. The crop four hundred bushels an acre; and sold at 2s. a bushel, or 40l. an acre gained at a very trifling expence.

"Not having any cluster-potatoes of my own, I bought some of a neighbour, to try them in horse-feeding, and from the result, prefer them to carrots. They were given raw, but washed, to saddle-horses, each having a peck a day, and no oats whatever. The horses were worked moderately, the same as on oats, did their work very well, and

were in good order. At first they scoured, but it soon went off and did no more than keep their bodies gently open, To ascertain from this trial, the value of the potatoes, that of oats will decide it; reckoning half a peck of oats a day to be equal feeding, and the price 16s. a quarter, the value of the potatoes will be 1s. a bushel."

Artificial yeast made of potatoes, by John Kirby, esq. of Ipswich. See Mr. Young's Annals, vol. I.

"Boil potatoes of the mealy sort, till they are thoroughly soft; skin and mash them very smooth, and put as much hot water as will make the mash of the consistency of common beer yeast, but not thicker. Add to every pound of potatoes, two ounces of coarse sugar, or treacle; and when just warm, stir in, for every pound of potatoes, two spoonfuls of yeast. Keep it warm till it has done fermenting, and in 24 hours it may be used. A pound of potatoes will make near a quart of yeast, and when made, will keep three months. Lay your bread eight hours before you bake it.

"I have several times tried this receipt in the hard frost, when yeast was scarce, and found it to answer the purpose so well, as not to be able to distinguish the difference between the bread made from the one or the other."

In vol. X. of Mr. Young's Annals, is a letter on the culture and use of potatoes, from the rev. Mr. Abdy, who says, "in the winter 1786, I felled an acre of woodland of eighteen years growth, which, after deducting all expences, paid 3l. 10s. about 4s. per annum. I determined to stub it up in the spring, and plant it with potatoes. The produce of the acre was five hundred sixty three bushels. The expence as follows:

	£.	s.	d.
Rent of an acre of land	0	4	0
Tithe of ditto	0	3	0
Digging 160 square rod, at 6d	4	0	0
Twenty waggon loads of dung, at 4s, per load	4	0	0
Drawing ditto five days, with four horses, at 12s.	3	0	0
Ten bushels of potatoes for fets, at 2s.	1	0	0
Cutting ditto	0	2	0
Planting ditto, two men three days	0	8	0
First hand-hoeing	0	5	0
Second ditto	0	3	6
Taking up, at 3d. per rod	2	0	0
Carting home three loads, of 80 bushels, per day	1	8	0
	£.	16	13 6

"On the 5th of May I bought four Welch runts, at 5l. per head; kept them 19 weeks on clover, at 1s. 3d. per head, per week. I then put them into some aftermath, which my milch cows had the first bite of, where they staid seven weeks; the value of this keep was 1s. per week. I might then have sold them for 7l.

"They were then stalled up, and fed with potatoes and the best old hay. They eat, each of them, a bushel of potatoes and a quarter of a truss of hay, per day; the hay was worth 1s. 4d. per truss. A man, at 7s. per week, and a workhouse boy, at 4d. per day, attended these four stalled runts, five hiefters that were stalled upon grains and barley-meal, six milch cows, six Scots, and three horses in the straw-yard, and my fattening pigs; so that I reckon, supposing their dung of some value in this account, the attendance upon these runts to be worth one half-penny per day; they were up 84 days, and I then sold them for ten guineas each; their increase was 3l. 10s. a head in 84 days, eating potatoes and hay.

	£.	s.	d.
Attendance 84 days	0	3	6
Hay	1	8	0
84 bushels of potatoes, at 5½d.	1	18	6
	£.	3	10 0
Expence to procure 563 bushels of potatoes	16	13	6
563 bushels, at 5½d.	13	7	2½
Loss	£.	3	6 3½

"The potatoes were a good eating sort, and were sold at the time these were taken up, at nine-pence per bushel, had I sold them, instead of feeding these runts with them, the account would have stood as follows:

P O T

563 bushels of potatoes, at 9d.	£.	s.	d.
Expences in producing ditto	21	2	3
"Deducting the carting home, as the buyers fetched them away at their own expence	15	5	6
Profit	£.	5	16 9

"I must trouble you once more with a farming anecdote, which is the following :

Expence of half an acre of Potatoes, near my house.

Rent	£.	s.	d.
Tithe	0	9	0
Town charges for this land is rated, the other was not	0	1	6
Digging 80 rod, at 6d. full of bushes and stubs of trees	2	0	0
Five bushels of sets	0	10	0
Cutting and planting	0	4	0
Eighteen cart load of farm-yard dung, at 1s. 6d. per load; the other dung was carried in wag-gons, and the best dung from Epping being from the common fly horses	1	7	0
Carting ditto one day, two carts, four horses, two fillers	0	14	8
Digging, at 3d.	1	0	0
Carting home	0	12	0
	£.	6	19 8

"About Christmas, a Scotch cow, which had two calves, and flunk in November, was turned into the straw-yard: as it would be a long time before she would be fit for business (as it was a great chance she never might) I determind to sell her; 5l. 5s. was the most money offered for her; and the jobber I originally bought her of, advised me, as I had more potatoes than the four bullocks would eat, and my sheep did not like them, and the hogs would be then fattening on pease, to try her with some potatoes: I therefore put her up on the fourth of January, meaning to set as much flesh upon her as I could, before I gave away the meat, which, as warden of Stennard's charity, I am to give to the poor of the parish of Theyden Garren: the 563 bushels in the former account were kept by themselves, and the 230 from this half acre (which is a most wonderful produce), by themselves; as it happened the four bullocks were stalled up in the farm-yard, this cow was necessarily stalled in the cow-house, and therefore had these potatoes given her; until she was killed, I had hardly observed her, and therefore was astonished to find that she was as fat as any butcher could wish his prime beef to be: she weighed 60 stone, 8 lb. to the stone, and the way I have disposed of her, is as follows:

Sixty stone of beef, at 2s. 8d. per stone	£.	s.	d.
Fifty lb. of tallow, at 4d.	8	0	0
Hide	0	16	8
Tongue 2s. 6d. heart 1s.	0	14	0
	0	3	6
	£.	9	14 2

"She ate much the same hay as the four runts: a truss in four days, and about a bushel of potatoes per day: she was up fifty-one days.

I must charge a penny per day, attendance, as the other fattening beasts were gone	£.	s.	d.
Hay 51 days, at 4d.	0	4	3
Value of the beast	0	17	0
	5	5	0
	£.	6	6 3

Sold for	£.	s.	d.
Cost (exclusive of potatoes)	9	14	2
Fifty-one bushels of potatoes, in whole numbers	6	6	3
	3	8	0
	£.	3	8 0

exactly 1s. 4d. per bushel.

P O T

"Thus, then, stands the account of these potatoes:

320 bushels of potatoes, at 1s. 4d. per bushel	£.	s.	d.
Expence of procuring ditto	21	6	8
Profit upon half an acre of potatoes	6	19	8
	14	7	0

"The great difference between this, and the other account, arises from the dung being, though equally good for the potatoe fibres to run in, of an inferior value.

"There was no charge for keeping the beast, as in the other account: the carting the dung and of potatoes being so much less, indeed, the carting them home ought not to be charged; for the horses at plough, in the field, brought home, in the evening, what was dug in the day.

"As I have, yet, a great many potatoes still remaining, I put up, on the 25th, two small Scots, that I drew from the straw-yard; they were valued, this morning, at 5l. 15s. 6d.

They have cost me, as under:

Brought at Horlow beast-fair, two Scots, each	£.	s.	d.
Driving home, each	4	4	0
Keep, from the 10th of September to the 25th of February, on vetches, and in the straw-yard, 24 weeks, at 9d. per week	0	1	0
	0	18	0
	£.	5	3 0

In Mr. Young's Annals, vol. XV. he says, "four cows fed on 15 lb. of lucerne, and 12 lb. of wheat straw, gave daily, the first, six pints of milk: the second, five pints and three half setiers; the third, three pints and a half; the fourth, two pints and demi setier; in all, sixteen pints and an half.

"The 25th February, I changed their diet, I reduced the 15 pounds of lucerne, and substituted 30 pounds of potatoes, which by antecedent experiments I conjectured to be to the hay as one to two: I continued the straw.

"The day this new regimen was entered on, the milk of the four together amounted only to 15 pints 3-8ths; the 26th, 14 pints and an half; the 27th, the same; the 28th, 13 pints 1-8th; the 29th, 14 pints; the 30th, 13 pints 3-8ths; the 31st, 14 pints. February 1st, 14 pints; the 2d, 14 pints 1-8th; the 3d, 14 pints; the 4th, 15 pints; the 5th, 15 pints and an half; the 6th, 16 pints 1-8th; the 8th, 17 pints; the 9th, 16 pints and an half; the 10th, 17 pints and an half; the 11th, 18 pints; the 12th, 17 pints 3-8ths; the 13th, 18 pints and an half; the 14th, 18 pints; the 15th, 19 pints and an half. From this time to the 1st of March, the produce was constantly between 19 and 20 pints (of 2 lb. weight); an unexpected removal of the cows the beginning of March, and my own absence at the same time, hindered me pushing these observations farther.

"The result of this experiment, which I notice at the same time that I relate it, that these potatoes occasion the milk at first to diminish, which may be supposed to arise from the change of food, for it required near eight days to accustom the beasts to that food, which afterwards augmented their milk about a quart; and what appeared to me very singular is, that the milk of all the cows did not near follow the same progression, in its increase and its diminution; the milk of the first cow did scarcely decrease, and increased but very little; that of the second decreased at first three pints, and increased afterwards to six and an half; the two others valued much less, and in the same proportion.

"I also made some observations on the quality of the milk; but it will take up too much time to give my journal on that head; in detail, it will be sufficient to observe, that, the first days, the milk appeared to have less serum, and gave about one seventh less butter than before, and kept in this state about five or six days; after which the milk became thicker; the cream upon it was a greater quantity by about a quart, than it had been before the cows were put to this diet; without becoming yellow, the butter appeared less white; and many people who tasted of it, thought

thought it more pleasant, but that difference was not apparent to me.

"I had twelve cattle on potatoes this winter; eight steer beasts, and four cows; the steer beasts were taken from work in June, the cows had calves in the spring, the calves were weaned, so that it was the latter end of June before they were dried off; they lived on poor ground all the summer, and not so forward as I could have wished to have them when they were taken into the close, which was the 17th of November; two I sold the 16th of March, four the 6th of April, two the 20th of December, and two the 4th of May; they were sold at Tunbridge and Sevenoaks markets, to which markets butchers from London come to buy stock. The crop of potatoes last year was, on three acres and a half, 1750 bushels, and on three acres that were cleared of goss and broom with one ploughing, nine hundred bushels, without any manure. I have fattened cattle with potatoes for these ten years, and is an increasing culture in this part of the county; have sold this year potatoes to plant to the distance of twenty-two miles."

In vol. XIV. of Mr. Young's Annals are the following observations on potatoe sets. "Twenty-four loads of dung, of forty bushels, being spread on a piece of land, that had borne vetch, furrows were drawn a yard asunder, and part (sixty perches) planted with whole or uncut potatoes, the size generally from a large pullet's egg to that of a goose; and the rest (two hundred and sixty-five perches) with cut potatoes, about the size of a pullet's egg. Proportion of sets uncut $37\frac{1}{2}$ bushels per acre; of cut $20\frac{1}{2}$."

"The ground planted, three hundred and twenty-five perches in all: produce, three hundred and seventy-eight bushels. The acreable produce of the two methods nearly the same."

"The two hundred and sixty-five perch produced three hundred and twelve bushels. The sixty perch sixty-six bushels."

"If forty-eight bushels of sets, the whole quantity used, produced three hundred and seventy-eight bushels, then thirty-four bushels cut should produce two hundred and sixty-seven; but they produced three hundred and twelve, which is forty-five bushels more than the proportion."

"Again, if forty-eight bushels produced three hundred and seventy eight, then fourteen bushels uncut should have produced one hundred and ten, instead of which they yielded only sixty-six, which is forty-four bushels less than the proportion. A preference of forty per cent in favour of cut potatoes, in comparison with whole sets."

"I planted ten whole potatoes, at about eighteen inches distance from each other, whose average weight was about four ounces; and equi-distant, the parings of about fourteen potatoes, in nine divisions; the produce as taken up the beginning of October, was, from the ten whole ones twenty-nine pound four ounces, from the nine divisions of parings twenty-nine pound twelve ounces. From among these latter (a case of some admiration to me) there arose the largest bulbs, two from these parings weighing thirty-one ounces, the two largest from the whole sets twenty-five ounces; it may be requisite to remark, that the parings were from larger roots than the whole sets. These, from being pared thick, might have their gross weight diminished about one fourth, the other three-fourths answered their usual purposes. It may not be an useless intimation to observe, that such parings, in every soil and situation adapted for the usual sets, will prove an effectual substitute for the whole potatoe, and the farinaceous substance of this most edible root may be applied to all its culinary purposes."

Mr. Marshall, in his Rural Economy of the Midland Counties, says, "The species or rather varieties of potatoes, have of late years undergone a total change, in this district."

"The old varieties formerly in cultivation, dwindling in produce, and being at length in a manner destroyed, by the disease of curled-top, two new varieties were introduced, under the names of goldfinders and goldendabs; the former a yellow kidney like root (but with a scurfy rind, not unlike that of the old russet potatoe); the latter of a similar colour but of a different form, being somewhat bell-shaped. The consequence has been, the disease vanished with the old sorts, and is now (1786) and in this neighbourhood, where no other sort is in ordinary cultivation, in a manner forgot."

"In 1789, I met with a similar instance in Leicestershire; where the old red sort was entirely worn out with the dis-

ease; while a white sort, now in cultivation, was never known to curl."

"In Rutlandshire I had ocular evidence of the same nature. Observing, in a large piece of potatoes, two stripes which were almost wholly curled, while the rest of the piece appeared to be free from the disease, I enquired into the cause of disparity: and received in answer, without hesitation, that the healthy plants were manleys, and the diseased stripes red-nosed kidneys; which, heretofore, was the prevailing species; but being no longer to be cultivated with any degree of success, a new sort was, some years ago, introduced under the name of the manley, which still remains free from the disease."

"These are evidences, and strong ones, that the disease of curled-top is incident to varieties: and the circumstance of the old sorts, which have been in cultivation from the first introduction of potatoes into the island, being now almost wholly cut off by it, renders it probable that the disease is incident to declining varieties of potatoes; as the canker is to declining varieties of fruit."

"The cultivation of potatoes, in this district, though it does not require to be given in detail throughout, is entitled, in several particulars, to notice."

"Succession. Contrary to the practices of most other districts, potatoes, here succeed turf: are planted almost invariably on grass-land."

"Soil process. The plough is seldom, if ever, used here, in the cultivation of the potatoe crop. The soil is broken up with the spade: sometimes in two shallow spits, throwing the sward and the dung, if any be used, to the bottom; covering them in the gardener's manner, with the under spit: but, generally, in one full spit; merely inverting the sward; fitting the spits to each other; leaving a smooth even surface of clear free soil."

"Planting. On this surface the plants are dibbled very thick, about the middle of April. Potatoes are sometimes grown two years together on the same land; and, in this case, it is said to have been found that dibbling in the sets on the stale surface, as left on taking up the first crop, or only levelled with the harrow, without a previous ploughing or digging, is the most eligible method of putting in the second crop: this, however, by way of hint."

"The vegetating process consist in hoeing, once, twice, or as often as circumstances may require; the crop, throughout, being mostly, though not always, managed in a gardenly manner."

"The crop is taken up with forks, in the gardener's method, about the middle of October: the price of taking up is according to the crop; generally, I believe, from 1d. to 2d. a bushel."

"Preserving. The method of laying up potatoes, here, is, universally, that of camping them: a method which requires to be described."

"Camps are shallow pits, filled and ridged up as a roof, with potatoes; which are covered up with the excavated mould of the pit."

"This is a happy mean between burying them in deep pits, and laying them upon the surface."

"Camps are of various sizes; being too frequently made in a long square form like a corn-rick, and of a size proportioned to the quantity to be laid up. It has, however, been found, by experience, that when the quantity is large, they are liable to heat and spoil: much damage having sometimes been sustained by this imprudence."

"Experienced campers hold that a camp should not be more than three feet wide: four feet is perhaps, as wide as it can be made with propriety; proportioning the length to the quantity: or, if this be very large, forming a range of short ones, by the side of each other."

"The usual depth is a foot."

"The bottom of the trench being bedded with dry straw, the potatoes are deposited; ridging them up, as in measuring them with a bushel. On each side the roof, long wheat straw is laid, neatly and evenly, as thatch; and over this the mould, raised out of the trench, is evenly spread: making the surface firm and smooth with the back of the spade. A coat of coal ashes is sometimes spread over the mould; as a still better guard against frost."

"It is needless to observe that a camp should have a dry situation; or that the roots ought to be deposited in as dry a state as possible."

"These camps are tapped at the end; some battins, or a quantity of loose straw being thrust close in the opened end, as a bung or safeguard."

In Yorkshire, Mr. Marshall says, "there is only one species of potatoe, *Solanum tuberosum*: but the varieties of that species are endless. Every county has its favourite kinds; though very different from one another. To enumerate the sorts of any particular district would be filling the page with barbarous terms; without conveying any useful information to the reader.

"The varieties of potatoes are transitory in every district; having their entrances and their exits. The rough-skinned Russia potatoe of this district was long a favourite; but is now I believe, with many others which have flourished for a time, entirely lost.

"There is some reason to believe that the disease, which has of late years been fatal to the potatoe-crop in this and other districts, under the name of curled tops, has arisen from too long a continuance of declining varieties. Be this as it may, it appears to be an opinion established here, by some years experience, the fresh varieties, raised from seed, are not liable to that disease. This matter, however, may not yet be sufficiently ascertained, to be registered here as a fact. This disease made its appearance some years ago with more or less effect, in I believe, every part of the kingdom. In some parts of it, its continuance was short; its effects have ceased, and are now almost forgotten. In one instance, (which I may have occasion to mention hereafter) its removal was, in all probability, owing to the introduction of new varieties.

"The district under survey furnishes a remarkable instance respecting this disease. The Morelands are at present in a manner free from it, while the Vale is still in some degree infected with it. Plants procured from the Morelands remain free from it in the Vale, the first year; but, being continued, become liable to the disease.

"The disease of curled-tops is seldom obvious at the first coming up of the plants; but attack them as they increase in size; the entire top become dwarfish and shrivelled, as if affected by drought, or loaded with insects: they nevertheless live, and increase, though slowly in size; but the roots are unproductive. Some crops have been almost wholly destroyed by this disease.

"Where the attack has been partial, weeding out the diseased plants, as they failed, is said to have had a good effect. And, it is said, the morelanders got rid of the disease through this means.

"The method of raising potatoes from seed is known to some intelligent husbandmen here. The prevailing method is this: In autumn, when the apples are beginning to fall spontaneously, they are gathered by hand, and preserved in sand until spring, when they are mashed among the sand, or among fresh mould, separating the seeds, and mixing them evenly with the mould. As soon as spring-frosts are judged to be over, they are sown in fine garden mould; and as fast as the plants get into rough leaf, and are strong enough to be handled without injury, they are transplanted from the seed-bed into another bed of fresh, rich mould, in rows, which are kept clean during the summer. In autumn, bunches of small potatoes are found at the roots of these plants, varying in size the first year, from the hazel-nut to the crab. These being planted next spring produce potatoes of the middle size; but they do not arrive at their fullest bulk until the third or the fourth year.

"Where the use of the stove or the garden-frame can be had, this process may be shortened. The seeds being sown within either of these, early in spring, the plants will be fit to be planted out as soon as frosts are gone; by which means the size of the roots will be much increased the first year; and will, in the second, rise nearly to perfection.

"Potatoes raised from seed are a miscellany of endless varieties. Sometimes these varieties are planted miscellaneously; sometime particular varieties are selected.

"In selecting varieties from seedling potatoes, two things are to be attended to: the intrinsic quality of the potatoe, and its productiveness. If these two desirable properties can be found in one plant, the choice is determined. To this species of attention and industry we are indebted for the many valuable kinds which have been, and now are, distributed throughout the island.

"It is observable, however, that varieties of potatoes, like those of corn, are partial to particular soils and situations. Hence the propriety of husbandmen raising potatoes from seed; as by this means they obtain, with a degree of moral certainty, a sort adapted to their own particular soils and situations.

"But it has been already observed, that varieties de-

generate: the old favourite sorts of this district were driven until some of the individual plants barely produced their seed again.

"Whoever has attended closely to the work of taking-up potatoes, must have observed the great inequality in the productiveness of individual plants. The difference in the produce of adjoining roots, where no disparity of soil can influence, will sometimes be three or four-fold. Hence it is evident, that each variety has its sub-varieties; through whose means it can hardly be doubted, the parent variety may be improved, and its continuance be prolonged.

"Thus the farmer has another mean in his power of improving the quality and productiveness of his potatoe crop, by improving varieties, or in other words, selecting sub-varieties superiorly adapted to his soil and situation.

"Every attentive cultivator of this valuable root must be acquainted with the wide difference in neat profit between a full and even a middling crop. The rent of land, the seed, and the labour are the same, whether the produce prove great or small. How imprudent, then, to propagate an unproductive kind, when the means of obtaining a productive one are so easy and obvious.

"Considerable quantities of potatoes are raised in the district under survey. Almost every man, let his farm be ever so small, cultivates potatoes in the field: not in the ordinary method practised in most districts of the kingdom: not with the spade, but with the plough; a practice which has been followed invariably for near a century. I do not mean to speak of it as a practice peculiar to Yorkshire; but, I believe, there is no other county in which it is so prevalent. It therefore merits particular notice here.

"It will be necessary to consider separately, the succession; the soil and process; the manure and process; the seed and process; vegetating-process; harvest-process; and the effect of the potatoe crop on soils.

"In the common practice of the country, potatoes are cultivated as a fallow crop for wheat: the cleanest part of a stubble, or other ground, intended to be summer-fallowed for wheat being set apart for potatoes. They are seldom planted on sward, the common predecessor of the potatoe-crop in most other places. It is, however, understood here, that they do best upon fresh land; that is, land which has not been too long under the plough.

"Formerly potatoes were confined to light friable loams: and the sorts which were cultivated in those days might require this restriction: now they are grown in all soils: different varieties being found partial to different land. It is observed, however, that let the sort be ever so well adapted to the soil, heavy cold land seldom gives light well-flavoured potatoes.

"The soil is broke-up in winter or spring, and worked over two or three times with the plough and harrow, as for turneps; getting it as fine as the nature of an early spring-fallow will admit of; generally long strawy dung, which is set in heaps upon or near the patch to be planted; previous to the seed-ploughing. The quantity twenty to thirty cartloads an acre.

"Formerly it was the common practice of the district to plant whole potatoes. In taking up potatoes, they were sorted into large, small, and sets, which were of the middle size.

"At present, that practice is, I believe, entirely laid aside, it being now the custom to cut potatoes into more than one set: namely, middle-sized ones into two, large ones into three or four, leaving the cuttings much larger than is done in most other districts, where eight or ten single-eyed sets are sometimes cut out of one potatoe.

"The reason given for the use of large cuttings is, that the young plants may acquire the outset a strong vigorous habit, and thereby be enabled to throw out and maintain a sufficient number of roots and branches. And the reason I have heard given for using large potatoes in preference to smaller ones is, that large ones are more likely to produce large ones again. The reasoning, in both cases, appears to be good.

"The sets being prepared, the seed-ploughing is given. In this ploughing the land is laid up in ridgelets, similar to those in which gardeners leave the soil, in the operation called trenching, when it is not intended to be immediately cropped. The width of these ridgelets depends on the judgement of the planter: from two and a half to three feet is the usual width.

"This operation is performed with a common plough, in the way in which rice-balking is usually done; endeavouring to leave the bottoms of the drills straight, narrow

row, and clean. One strong horse, if the soil be light and fine, or two horses, one before the other, if otherwise, is the best team for this work. Horses abreast are apt to foul the drills. The usual depth of the drills is that of the cultivated soil.

"In these drills the sets are dropt, by women or boys, at twelve to eighteen inches distance, according to the judgment of the farmer. If the quantity of land be given, and the number of sets be indefinite, twelve inches may be a sufficient distance; but if, as is generally the case here, the quantity of land be greater in proportion than the number of sets, the farther they are planted asunder, the greater will be the produce in proportion to the plants.

"While one party are planting, another are carrying on the dung, in scuttles; either scattering it regularly along the drills, or applying it partially to the plants; covering each set with its due portion of manure. This may appear to be a tedious business: it certainly is a dirty one: but not so tedious as inexperience may suggest. If the loads be broken into three or four heaps, and these be distributed conveniently, five or six women will cover an acre a day in this manner.

"The plough closes the business of planting: the ridges are either returned upon the plants and dung, with a common plough, or are split with a double-mould-board plough; in either case, raising the soil into similar ridges over the drills of potatoes.

"As soon as the young plants make their appearance, the land is harrowed lengthway of the ridges; to tear up the seed-weeds which grow upon their crowns, and to smother those in the trenches with the mould. In a short time afterward the plough, with the share broad and sharp, is run through each interval, and the rows cleaned with the hoe. In a few weeks more the intervals are again stirred with the plough, and the hand-hoeing repeated. If leisure and the depth of the soil will permit, a second earthing may be given; and, when the plough and the hoe are no longer able to find admission among the tops, hand-weeding is, or ought to be, made use of.

"By these means land may be as effectually cleaned from seed-weeds as by fallowing; and no man, who has any regard for his own interest, or for his character as a farmer, would ever think of planting potatoes in a bed of couch and thistles.

"Formerly, potatoes were taken up with the plough; endeavouring to get the share below the potatoes, and to overturn the ridges. But without great care, many potatoes were cut in this operation, and many more unavoidably buried; so that picking again and again was necessary; and, at last, some were left in the land.

"At present, the prevailing practice is to take them up with common dung-forks: an operation which is at once effectual; and which is by no means so tedious when potatoes are grown in ridges, as when, in the ordinary way, the entire ground is to be dug over. In ridges, the roots are distinct, and are easily laid bare; being open on three sides, with free vent for the mould. The fork being forced down behind them, the whole ridges are at once exposed.

"The way of preserving potatoes, here, has been either to bury them in deep pits within the ground, or to house them in a barn or other out-building, guarding them on every side with straw. The dangers to be guarded against are frosts and wetness.

"At present (the evil effects of deep pits having been discovered) the growing practice seems to be that of laying them in long ridge-like heaps upon the surface of arable ground, and covering them up with the surrounding soil, ridged up in a roof-like form.

"A long arched vault, running endway into the side of a hill (or the side of a pit or other hollow), with a door at the end, level with the ground below, with a road over the top with one or more shooting holes, similar to those of coal-vaults under the streets of towns, would be an eligible receptacle for potatoes.

"Nor is the application of potatoes to fattening stock extensive. In this district swine are almost the only species to which they are applied. Some few may be given to cows.

"But in the bottom of the Vale of York, great quantities have of late years been applied to the fattening of cattle. They are, I believe, invariably given to them raw, with alternate meals of hay or barley meal: the method of fattening with potatoes being similar to that of fattening with turnips.

"The quantity of potatoes grown upon an acre under the management above described, and their profitableness as an article of food for cattle, I have not been fortunate enough to ascertain with sufficient accuracy.

"Various are the opinions of professional men on this subject. One asserts that they are great impoverishers of the soil; that they are hurtful to the corn, and ruinous to the grass which succeeds them. Another is clearly of opinion that they are friendly to corn, and not enemies to grass.

"The dispute may, perhaps, be settled satisfactorily in this manner:

"The potatoe contains, indisputably, a great quantity of nourishment; and is therefore, perhaps, as indisputably a great exhauster of the soil.

"But the quantity of vegetable nourishment carried off in the potatoe crop is not the only cause of exhaustion: it is notorious to common observation, that this crop leaves the soil in a singularly friable fertile state, causing an abundant produce of the crop which succeeds it.

"If taking the advantage of this prodigality of the soil, the husbandman keeps cropping it year after year with corn; and, when it will no longer answer his unreasonable expectations, lays it down to grass, it is no wonder that it should be unproductive: for having lavished all its riches on an ungrateful occupier, it is of course reduced to extreme poverty.

"On the contrary, if after a crop of potatoes, well dunged for, only one or two crops of corn be taken, and the land be laid down to grass, while yet in a state of fertility, the potatoe crop is, to vulgar appearance at least, friendly to the crop which succeeds it.

"Hence it follows, that land which has been cropped with potatoes should presently afterwards be laid down to grass, or should be timely replenished with a quantity of manure proportioned to the degree of exhaustion it has undergone.

"The value of potatoes as a fallow crop, and as an article of food for cattle, compared with turnips and cabbages for the same purposes, may be considered thus:

"Potatoes are more nutritious; and, in the opinion of those who have used them, fat cattle much quicker than either turnips or cabbages. Potatoes, too, being secured from the severities of winter, are a more certain article of fattening than turnips or cabbages; both of which are liable to perish under an alternacy of frost and thaw; and the turnep, more particularly, is locked up, or rendered more difficult to be come at, during a continuance of snow or frost. Turnips and cabbages, if they out-weather the severities of winter, occupy the soil in the spring when it is wanted to be prepared for the succeeding crop; while potatoes, if properly laid up, are a food which may be continued without inconveniency until the cattle be finished, or the grass has acquired the requisite bite for finishing them in the field.

"On the other hand, potatoes are a disagreeable crop to cultivate: the planting is a tedious dirty business; and taking them up, may be called the filthiest work of husbandry; especially in a wet autumn."

Mr. John Bywell, of Aglethorp, Yorkshire, says, "Four pecks, eight quarts to the peck, are sufficient for a large beast with a little hay, for twenty-four hours; they are superior to turnips in feeding, one third, both used in equal time. They are given to milch-cows with great advantage, and are healthy fodder. They are very good for draught horses, to give them half a peck a day, with hay. I never had my horses in so good condition as when fed with potatoes; they are a certain remedy to a horse with swelled legs, or out of condition (in other cases and disorders inwardly one peck a day); they are accounted good for hunters the day after they have had a severe run, to give them eight or ten large potatoes. The number of bushels of potatoes grown on one acre, are, upon an average, three hundred and sixty. I give them to cattle raw, as taken out of the ground.

"The manner of management for potatoes is to give the land three or four ploughings, and as many harrowings; twenty-four cart-loads of horse-dung to an acre; when the furrow is drawn, the plants to be planted at twelve inches distance one from another, the labourers to spread the dung, by hand, along the top of the plants with a little lime; if lime cannot be had at the time of planting, it is proper to spread a little over the ground, as they make their first appearance out of the earth; also to give them a light harrowing to mix the lime."

Mr. Young, in his Annals of Agriculture, vol. VII. gives the following account on the expences of raising potatoes, by Mr. W. Pitt, of Pondeford:

" 1784. Planted two acres of potatoes upon old turf.

	£.	s.	d.
Rent, tythe, and rates, per acre	1	1	0
20 cart loads of raw dung, at 2s. 6d. half to the potatoes	1	5	0
Digging and planting	2	10	0
20 bushels for seed, at 1s. 6d.	1	10	0
Hoeing and weeding	0	7	6
Taking up and sorting	2	10	0
	£	9	3

" Produce, per acre, 300 bushels, prime cost, 7½d. per bushel. N. B. By a bushel is always meant 80lb. weight.

" 1785. Two acres of clean clover lay, on good light loam.

	£.	s.	d.
Rent, tythe, and rates, per acre	1	5	0
Dung, as before	1	5	0
Trenching in the dung, and seed	1	5	0
Seed, as before	1	10	0
Hoeing, at 1d. the rod, of 8 yards square	0	6	3
Taking up and sorting	2	10	0
	£	8	1

" The trenching was performed by a man with a spade, digging a trench across several lands; a boy following, dropped in the seed, and another boy, putting the dung upon the seed; the man digging another trench, parallel to the former; the soil of which, covered up the former dung and seed, and the boys following, as before: it must be observed, the land was dry enough to lay quite flat; also, the lay was very mellow and tender, or the trenching could not have been done at so low a price after once ploughing.

" One acre of the above, planted with champions, and a few of other sorts, produced 300 bushels; prime cost, under 6½d. per bushel.

" The other acre, planted with a sort, called here ox-noble, which, I think, answer to your white Surinam produced 350 bushels, prime cost, therefore 5½d. per bushel.

" 1786. One acre, after turnips, upon light loam.

	£.	s.	d.
Rent, tythe, and rates, per acre	1	1	0
Dung, 16 loads, at 2s. 6d. half to the potatoes	1	0	0
One ploughing and harrowing	0	6	0
Ploughing in the sets	0	5	0
Harrowing, some time after	0	1	0
Five women dropping the seed	0	2	6
Two men dunging the seed in the furrows	0	2	6
Seed, 20 bushels	1	10	0
Taking up and sorting, the ground being light and mellow, only	1	17	6
Hoeing and weeding	0	6	3
	£	6	11

" Produce, as near as could be ascertained, 225 bushels. Prime cost, 7d. per bushel.

" The defect in produce I attribute to two circumstances; first, to dung being used too sparingly; and, secondly, the sort planted being champions, which, for cropping, are much inferior to some other sorts.

" 1786. Two acres of wheat stubble, upon a cool hazely gravel (indifferent land) has been summer-fallowed, and manured with lime, for the wheat.

	£.	s.	d.
Rent, tythe, and rates, per acre	1	0	0
Dung 16 load, half to the potatoes	1	0	0
One ploughing only, the seed being dropped in under the whole furrow	0	6	0
Five women and two men putting in seed and dung	0	5	6
Harrowing some time after	0	2	0
Seed, 20 bushels	1	10	0

Carried forward - - - £ 4 3 6

	£.	s.	d.
Brought forward	4	3	6
Hoeing	0	6	3
Taking up and sorting, at 7d. the rod, of 8 yards square	2	4	0
	£	6	13

" Produce as near as possible as before, 225 bushels per acre; prime cost, a little over 7d. per bushel.

" The defect in produce I attribute, as before, to want of more dung, (an article I did not care to be lavish in, the preceding harvest having given but small bulk of straw); also perhaps the whole furrow being turned over upon the seed, might be less favourable to produce than if the soil had been more broken or pulverised.

" The greater part of the above potatoe ground was sown with wheat, immediately after clearing of the potatoes; the wheat crop always equal to what might have been expected after any other preparation; but perhaps the wheat stubble not so clean or kindly as after fallow-wheat. I intend hereafter to dung for the potatoes more liberally, and to follow them with cabbages; either the early sort immediately; the large kinds the June following, or both.

" I have not observed in potatoes a tendency (some have charged them with) to foul the land, more than any other crop, provided the land be clean before. Indeed, if the land be previously full of couch, the dunging for the potatoes will make it run, and multiply abundantly; but upon clean land, the potatoes being in rows, may, by proper hoeing and hand-weeding, be kept as clean as turnips, or any other hoe-crop. I had an acre this season, I intend sowing with hemp in the spring, and the land at getting up the potatoes was fit to have received the seed, had the season been proper.

" The sorts of potatoes I have successfully cultivated, are the following:

" Champions, excellent for the table, come in early and have never curled; but inferior for cropping to some other sorts.

" Winter whites, Aylesbury whites, or white blossom, very good for the table, grow larger, and produce a bulkier crop than the former.

" A sort called here ox-noble, which I think answer to the cluster potatoe, and to your white Surinam; crop excellently, are readily sold in our markets, grow very large, but the large ones apt to be hollow, are very good for stock.

" A sort called here cow potatoe, and I think answers to your red surinam; very superior for cropping, on any land; have had 50 bushels (80 lb. to the bushel), upon twenty perches of indifferent land, without manure; are preferred to all other for cows, being tender and juicy, but are unfit for the table.

" A dark purple kind, called by some the pomegranate potatoe, crop very well, are hard, solid, and heavy; said to be very good for the table in spring, when other sorts decline, but have never tried them for anything but stock.

" The three last sorts, carrying long haulm, or tops, leave the land more mellow and kindly than the other sorts, whose tops wither early.

" The sort I had from you under the name of Cornwallis's, are, I think, excellent, and new to this country."

Thomas le Blanc, Esq. of Cavenham, says, " In April 1785, I broke up a saintfoin lay of four or five years growth, upon which Dutch clover had been sown with the saintfoin; the soil a blowing sand, but not so near the chalk as that on which they were grown before. It was ploughed deep with our common ploughs; part of it was sown with carrots, which totally failed; the other part, containing two acres 115½ rods, was planted in every second furrow with the cluster potatoe, both red and white; they were once horse-hoed, and once weeded by hand, at a small expence. The produce 900 bushels; the land exceedingly foul with couch-grass at the taking up the crop: if there was any difference in the produce of the two sorts, the white potatoe had the advantage; but they were not separately measured. For the consumption of this crop, I have now 13 sows, which have all littered within the last three weeks; which stock I should not think of keeping if I had not grown the potatoes. The failure of the carrot crop should not pass unnoticed, for I think it proves that carrots are more precarious than potatoes; they are more expensive in culture, and, I am convinced

vinced that they are inferior in feeding both horses and hogs."

Mr. Young, in his observations on the foregoing letter, says, "I considered the success of this trial as extraordinary: there were two circumstances to which it might be attributed; trench-digging, and the moisture of the season. The present experiment bears immediately on those points. Here is only one ploughing; and instead of a very moist season, the beginning of the summer was an uncommon drought. But so far were those circumstances from any effective operation in producing the former success, that the event of this year's trial has confirmed every conclusion to be drawn from the former. The crop amounts to 324 bushels per acre. The expenses I should calculate at about three pounds an acre; which sum produces 324 bushels, or prime cost about 2½d. per bushel. This is sufficient to shew the vast importance to saintfoin farmers of Mr. le Blanc's discovery. He has proved to them how easy it is to convert their old lays at once to great and immediate profit; a circumstance, till he took the pen in hand, quite unknown. Society is indebted to him for the attention and the care he that has matured so valuable a deduction from experimented fact."

Mr. George Bailey, of Sunderland, in a letter to Mr. Young, says, "the potatoes are set in drills about 15 inches asunder, and the seed planted about 9 inches distance in the rows. They are manured with what is bred in the farm-yard, by women and girls, who lay a little upon each potatoe; then the plough, drawn by one horse, and only one man, follows and covers up the seed. On the potatoes first coming up, the rows are harrowed down with a bush harrow, which destroys many annual weeds; in a few days the rows are earthed up with a plough and one horse; as soon as any weeds appear, they are hand-hoed and earthed again with the plough, and frequently hand-weeded after. A double mould-board plough is preferable to the common one, in earthing or furrowing potatoes, and will do twice as much work. Turnips are sown broadcast, and are hoed once or twice. After two ploughings and harrowings, and the couch-grass, if any, gathered off by women (at 6d. a day) from 15 to 20 loads of manure, all brought from Sunderland, a large trading town within four miles distance, consisting of coal-ashes and the rakings of streets, or with sea-weed, is laid on, and the ground again ploughed shallow; and as early as may be in June, the seed is sown, and harrowed in with a bush-harrow, and frequently rolled after. The barley and wheat, particularly the former, has a light dressing of Sunderland manure, or sea-weed, which is harrowed in with the seed.

"The produce of marketable potatoes, from 200 to 250 firkins an acre, besides the small, which may be reckoned 15 firkins more, and are found very serviceable in feeding cows and hogs, particularly the former, increasing the quantity of milk."

Mr. Thomas Bucke, merchant, at Worlington, Suffolk, in a letter to Mr. Young, says, "In conformity to your request, I send you the best account I can give of my two crops of potatoes, off a piece of ground little more than one acre and three rods; it was formerly pasture, but broke up about 15 years ago, from its producing small crops of grass in dry seasons, the soil being loose; and though it had been well manured whilst under the plough, of late it has afforded but light crops of grain, having been never rested, and was much subjected to warlock. Upon its falling into my hands, I gave it a summer-till; but as the summer proved extremely dry, little benefit accrued respecting the warlock, as I found by my two succeeding crops, which were of wheat and barley. Being determined to clear my land of this predominant weed, I had these crops weeded by hand; but finding this practice too expensive, it costing me 11. 4s. 6d. the first year, besides beer; and 11. 5s. 8d. the second, exclusive of beer; and not having effected my purpose, I planted it with potatoes, for the benefit of the hoeing, and now find it very clear.

"I first spread a few loads of short dung upon it, ploughed it very deep, and had the sets dibbled in at the small distance of about 10 inches, then bush-harrowed to fill the holes; and as soon as the rows appeared, it was hand-hoed, and repeated as soon as necessary; two thirds of the seed were of the Dutch upright species, the other of the pink-

nose kind. The former produced abundantly, and grew under the foil; the straw of the latter being frizzled (as they call it here) the crop was not so productive; a considerable quantity grew upon the surface, and as they were not earthed up, the colour of the upper part changed to a dull green; and many that were covered with the foil were of a rusty colour, and were porous, here called iron-moulded: the finest of this kind, as well as all of the Dutch uprights, were good flavoured. As other business prevented my taking them up till the 10th or 12th of November, what grew upon the surface suffered from three severe frosty nights; they were picked off the ground before the crop was taken up, and with those otherwise defective, were given to pigs, and charged at 6d. per bushel; though I erred in letting them continue in the ground so long, yet I think they are better in flavour for continuing in the ground till after Michaelmas, and will keep better than what are taken up earlier. This year my crop was forked up with three-pronged forks, and measured up 760 bushels; 696 were of excellent quality, and sold at 1s. per bushel; the remaining 64 bushels were the refuse.

"The year after, which was last year, I set the champion kind, and had near eleven hundred bushels off the same piece of ground; this is a prodigious crop, and exceeds, at any price, all other productions to be procured from such a foil; it was covered thinly with short dung, ploughed deep, and the sets dropped into the bottom of every second furrow, from 12 to 15 inches distant; the sets consisted of two, and some of them three eyes, and grew luxuriantly; the land was hoed twice, as before, but the crop ploughed up without a coulter. I could not perceive the horses injured the sets; nor did they or the plough produce; many persons differ respecting the earthing up the plants: from the little I have seen in my field and garden, I think some sorts (the pink-nose in particular) require such management; others will do well without; the richer and finer the moulds they are planted in, the better; and could I have spared more dung, I should have laid it upon the land. Those who are inclined to raise potatoes would do well to buy their seed early in the winter, as the price often advances cent. per cent. I am now selling at 2s. 6d. per sack, the seed of which cost me 7s. per sack.

"I am very sorry I cannot give you an account of expenses attending these crops, as they were not kept separate from other labour; this was the reason I did not write to you before upon the subject, and operates now very strongly with me, that my letter cannot be useful to you; but the method I pursued in setting and taking up my last crop must be considerably less expensive than that I used in the preceding. The first crop was very profitable, and so will the present, if I meet with a sale for what I have in hand at any tolerable rate.

"As my last crop exceeded my first greatly, I judge: from the small quantity of dung laid upon the land, that these crops are not very exhausting."

The following accurate Experiments upon Potatoes were made by Mr. Wynn Baker, in Ireland in the Year 1771.

"Notwithstanding, says he, potatoes are the principal food of the labouring people in the country, in this kingdom, and that every one cultivates them, more or less, and have done so for more than half a century: yet, extraordinary as it may seem, I find them quite incapable of answering a great number of questions, truly important to the advantageous culture and judicious choice of this useful vegetable.

"This circumstance, added to that of frequently obtaining poor crops myself, led me to try the following experiments, which I committed to the ground with the most scrupulous and minute exactness that human means were capable of; and myself attended every stage of the business in planting.

"I lay this little set of experiments before the public, by way of table, in order to have it in one view. Any one who consults it, perhaps, will be directed in their choice of potatoes, as well as in other points in dispute. To avoid all danger of inequality in the ground, I chose a bit where I had twice taken away the staple, so that they were planted in an under stratum of poor yellow earth.

Minute Experiments on the following Kinds of Potatoes, put down April 27th and 29th, 1771. The Rows 20 Inches
afunder, and each Potatoe set 12 Inches apart in the Rows, and 30 Sets in each Row.

"Whoever shall cast an attentive eye over the preceding table, will see that several circumstances of information are immediately pointed at; there are very many others which are omitted; those before us appear to be so satisfactory, in the several variations which arise upon the face of the table, that I shall, at convenient time, pursue all the changes which the subject before us will admit of. In the mean time let us proceed upon the present information.

"The first question before us is this, Whether planting potatoes under or over the dung, is most advantageous to the crop? This question appears to be conclusively answered, by every species of potatoe, in the first and second set; and the totals of each clearly determines in favour of putting the seed over the dung.

N ^o 1 to N ^o 6, over dung, gross produce	105 4
7 to 12, under dung, ditto	84 3

Over dung superior to under by 21 1

"This difference of 21 pounds, upon so small a quantity of ground, would be a very great object upon an acre. Happily in this kingdom, the potatoes are chiefly laid over the dung. In England, they practise the contrary in many places.

"Our second object in this enquiry was, to determine by fair experiment, whether the small seed is equally prolific (as thousands assert it to be) with that which is reasonably large. For this purpose, I cut single eyes with my

own hands, and was careful not to cut them thin, but like pellets. This set was planted under dung; and therefore we must compare it with our second sets of experiments.

N ^o 7 to N ^o 12, under dung, gross produce	84 3
13 to 18, under dung, gross produce	64 12

Reasonably large feed, preferable to very small, by 19 7

"This upon an acre would be a prodigious difference: and I think seems decisive in favour of seed moderately large. Whereas N^o 19 to 24, both inclusive, seems by no means to prove very large feed to be necessary: for if we compare those numbers, with N^o 7 to 12, both inclusive, we see the greater produce from the larger feed is by no means regular, and therefore that point is not decisive in the present enquiry; and the remark upon N^o 22 should not be forgotten.

"Our third object in this enquiry, is a truly important one to the poor labourer of Ireland, viz. to ascertain with accuracy, which kind is most prolific upon poor broken ground. As N^o 25 and 26, did not come to hand time enough to introduce them in the whole set of experiments, I must throw this part of our enquiry into two divisions, as there is so material a difference between planting over and under dung. To do this in the shortest manner, I shall only throw the several kinds into two little tables, according to their merit in quantity; the quality is a consideration chiefly at the gentleman's table.

* "Here in N^o 22, Crones, we have a considerable breach in the uniformity of our table, in which nature all the way appears to have been very regular. I cannot account for this great difference, other than to say, that we have a strong suspicion, that whilst the man I depended upon came home with the preceding parcel to weigh them, that the fellow he left to dig the next number, took some of N^o 22 for roasters: if he did, he ought to be hanged; because it was doubly villainous to overset such an enquiry. I immediately took him to task about it, but he stood it out, although I offered him five guineas, only to let me weigh the potatoes, and I would forgive him; however, he shall never approach a minute experiment of mine again."

“ Here we also have the order of merit in point of quantity of the merchantable potatoes, from equal culture. Our totals vary a little as in the preceding table. The wife and apple potatoes keep their place in both tales, as to produce; but the red French and Munster white, and crones, contend pretty closely as to produce; and in the second table vary in their places of merit. Hence we may conclude, that some of these kinds agree better by being put under the dung than others; but every examination of the latter point, clearly proves, that under dung lessens the crop. The Spanish potatoes, which are certainly the

best in the world for eating, uniformly keep their place, of being last in the point of produce.

“ There is another very material point, worthy of the cultivator’s attention, in his choice of his potatoes in these tables. He will observe, doubtless, that I have given the number of the merchantable potatoes of each kind; he will therefore see that there is a prodigious difference in their sizes, a circumstance that comes strong against the wife potatoes. However, for the reader’s inspection, I shall attempt a little table upon that point, framed from the preceding ones, according to the order in point of size.

The following table of the poor man’s potatoe, distinguishes the quantity, and the gentleman’s the quality, according to the foregoing experiments.

The Poor Man’s Potatoe.	The Gentleman’s Potatoe.
First. Common Wife.	First. Spanish.
Second. Apple.	Second. English White.
Third. Red French.	Third. Munster White.
Fourth. Crones.	Fourth. White French.

Mr. Baker finding it very expensive to pick and sort his potatoes for planting in the common way, got a large riddle made of very strong iron wire, the meshes whereof were 1¼ inch. “ I set to work with this, says he, a man and boy, and I am sure they will do more in a day than forty pickers. The riddle cost me five shillings and five-pence, and I am persuaded has saved me twenty pounds since I had it: but I find I must have a set of them, of different sizes.”

Land well reduced by tillage, will produce good crops of potatoes without manure, provided they are hoed with the hand-hoe; and still better by horse-hoeing. But poor or ordinary land should be well manured; and upon such land they are commonly manured highly, both for the benefit of the potatoe crop, and for the crop that succeeds; the manure and tillage given to the potatoes, by ploughing the land for them, hoeing and digging them up, together with the cover of their succulent leaves, while growing, prepare the land admirably for another crop. But though a plentiful manuring for the potatoe crop is of great service, it may be over done, and then the potatoes will be wet, and not fit for the table, but must be given to the hogs.

When land is well tilled for potatoes, and the surface made fine, a sudden dash of rain, and dry weather afterwards, will sometimes bind the surface, and form so hard a crust upon it, that the broad succulent leaves of the potatoes cannot rise and get through it. In that case, the surface should be harrowed to break the crust, taking care

that the tines do not go so deep as to wound the tops of the plants; and if proper care is taken in this respect, it is best to harrow or hoe, and loosen the surface of every crop of potatoes, when the plants are advancing towards the surface of the land.

There is a new species of potatoe lately introduced into England, by some called the Bedford potatoe, which resembles a congeries, or cluster of roots of potatoes grown together. This potatoe has a surprising force of vegetation beyond any common potatoe, but is not so pleasant tasted, and therefore not fit for the table. However the produce of it is so great, that it merits the attention of farmers, who keep many hogs, or such cattle as will eat potatoes. Some of these potatoes have weighed nine or ten pounds; and one small cutting has produced thirty pounds of potatoes, in about four square feet of ground.

Mr. Marshall, amongst many other useful experiments, says, that having planted potatoes between cabbages, though at intervals of more than three feet wide, the halm became so luxuriant that the cabbages did not thrive, being in danger of being smothered; and regretting at the same time, that so much succulent herbage should be suffered to rot where it grew, broke off some of the stems, and threw them before the cows. They eat them readily. This induced him to set some men to work with a sickle, to cut a patch of it, to try if the cows would eat it in any quantity; and likewise to try its effect on the roots. The first was presently devoured: they eat as many as a man could wheel in a large wheel-barrow presently, leaving only the woody-part of the stem; and these were thrown to the hogs, who eat them greedily or sucked them, so that the refuse might be contained in the crown of a hat. By the cows eating the halm and the roots suffering no bad effect what a saving there must be. For though the potatoes were planted wide, there was herbage equal to the middling crop of tares, besides the surface being left open for the cabbage; which could be hoed and earthed-up with the hand-hoe as if no potatoes were there. It was his opinion that checking the rising sap may reflect it to the roots, and

instead of an evil prove beneficial. The cows in consequence of their food yielded a considerable increase of milk, and of a richer quality than before; the butter was perfectly and remarkably sweet; and the cows increased in their desire of the halm. By this process the whole receives a perfect fallow, for the intervals of the potatoes are tilled before the cabbages are planted; and the intervals of the cabbages after the potatoes are taken up. The soil by this method gives four crops: viz. the halm, the potatoes, the cabbages, and the sprouts. Upon examination it appeared that the potatoes which had their halm cut were not so large as those that had their halm remain uncut, but does not the gain of the halm more than balance the loss in the roots? By some it is said that the potatoes have done growing when the halm begins to turn; therefore Mr. Marshall recommends the cutting the halm when the roots have grown large, and before the tops of the halm have lost their succulence; if possible soon enough for the halm and late enough for the potatoes.

POULTRY, is a term given to all kinds of domestic fowls brought up in a farm-yard, as cocks and hens, ducks, geese, turkeys, &c.

The country-yard cannot be said to be complete till well stocked with fowl, which advantage will appear to every one who keeps them. The poorest villager may reap the same benefit from the products as the most substantial farmer, they being able to shift for themselves the greatest part of the year, by their feeding on insects, corn, or any thing almost, that is edible by any sort of animal.

I shall not enter into a minute description of the several sorts of cocks and hens, only advise you to choose those that are the best breeders, and the best layers; the oldest being always reckoned the best sitters, and the youngest the best layers; but no sort will be good for either, if they are kept too fat; the best age to set a hen for chickens is from two years old to five, and the best month to set them is February; though any month between that and Michaelmas is good. A hen sits twenty-one days, whereas geese, ducks, and turkeys, sit thirty. Observe to let them have constantly meat and drink near them, while they sit, that they may not straggle from their eggs and chill them.

One cock will serve ten hens.

If fowls are fed with buck or French wheat, or with hemp-seed, it is said, they will lay more eggs than ordinary; and buck-wheat, either whole or ground, made into paste, which is the best way, is a grain that will fatten fowls or hogs very speedily; but the common food used is barley-meal, with milk or water, but wheat-flour moistened is best.

A good hen should not differ from the nature of the cock; she should be working, vigilant and laborious, both for herself and her chickens; in size, the biggest and largest are the best, every proportion answerable to those of the cock, only instead of a comb, she should have upon her crown a high thick tuft of feathers.

She should have many and strong claws; but it will be better if she has no hinder claws, because they often break the eggs, and besides, such as have, do sometimes prove unnatural.

Crowing hens are neither good layers nor good breeders.

The elder hens are rather to be chosen for hatching than the younger, because they are more constant, and will set out their time; but if you choose for laying, take the youngest, because they are lusty, and prone to generation; but do not choose a fat hen for either of these purposes; for if she be set, she will forsake her nest; the eggs she lays will be without shells, and besides she will grow slothful and lazy.

Those eggs that are laid when the hens are a year and a half, or two years old, are the best; you must at that time give the hens plenty of victuals, and sometimes oats, with fenugreek to heat them, if you would have large eggs; for those that are fat commonly lay but small ones; mix some chalk with their food, or mix some bruised brick with their bran, moistened with a little water, and give them their belly-full of half-boiled barley, with vetch and millet.

Some hens have the ill faculty of eating their eggs: to prevent this, take out the white of an egg, and put moist plaster round about the yolk, and suffer it to grow hard; and when the hen attempts to eat it, and finds she cannot do it, she will soon give over breaking her eggs.

You may likewise pour a clear plaister upon the yolk of an egg, and let it harden, so that it may serve for a shell, and put into the nest; or you may shape an egg of plaister, or chalk, and let that be for a nest egg.

Those hens that have spurs often break their eggs, and generally will not hatch them, and they will sometimes eat them; these must be scowered, as well as those that scratch and crow like a cock; first by plucking their great quills out of their wings, and by feeding them with millet, barley, and paste, cut into bits, pounded acorns and bran, with pottage or crumbs of wheat-bread, steeped in water, or barley-meal.

Keep them in a close place, and at rest, and pull the feathers from their heads, thighs and rumps. If a hen be too fat, or has a looseness, she will lay windy eggs.

A hen will sit well from the second year of her laying to the fifth: the best time to set a hen, that the chickens may be large and most kindly, is in February, in the increase of the moon, that she may disclose the chickens in the increase of the next new moon, being in March; for one brood of this month's chickens is worth three of those of any other month.

Hens may set from March to October, and have good chickens, but not after that time, for the winter is a great enemy to their breeding.

A hen sits just twenty-one days, and if you sit a hen upon the eggs of ducks, geese, or turkeys, you must set them nine days before you put her own eggs to her, of which a hen will cover nineteen; but always set an odd egg, what number soever you set her with.

It will also be proper to mark one side of the eggs when you put them under the hen, and to observe whether she turns them from the one side to the other; and if she does not, then take an opportunity when she is from them to turn them yourself. But a hen that does not turn them herself is of the less value.

Take care that the eggs you set a hen on be new, which may be known by their being heavy, full and clear; this may be discovered by looking through them in the sun; nor do you choose the largest, for they have oftentimes two yolks, and though some are of opinion that such will produce two chickens, it proves commonly a mistake, and if they do, they generally prove abortive and monstrous.

A hen must not be taken off or disturbed from her nest, for that will make her utterly forsake it.

While she is sitting you must place her meat and water near her, that her eggs may not cool while she is gone to seek her food. If she would absent from her nest, stir up the straw, and make it soft and handsome, and lay the eggs in the same order she left them.

It is very necessary to perfume her nest with rosemary or brimstone, and you must take care that the cock does not come at the eggs and set upon them; for he will endanger the breaking of them, and cause the hen not to like her nest so well as before.

When hens are laying, the old straw should be taken away, and fresh put in, that it may not breed fleas, or other vermin, which much incommodes them.

The maladies incident to hens are as follow:

Setting hens are sometimes troubled with lice and vermin: for the cure, pound burnt cummin and stapulgar, of each equal quantities, and mix it with wine, and rub the hens with it, or wash them with a decoction of wild lupines.

If hens are troubled with a looseness, mix a handful of barley-meal, and as much wax, in some wine; make it into a mass, and give it them in the morning before they have any other meat, or else let them drink a decoction of apples or quinces.

Hens, by laying too many eggs, sometimes exhaust their strength, and languish: the same likewise happens by hens sitting too long; to remedy this, take the white of an egg, which you must roast till it looks as if it was burnt; mix this with an equal quantity of dried railins, also burnt, and give the hen this fasting.

Your hen-house must be large and spacious, with a pretty high roof and strong walls, to keep out both thieves and vermin; let there be windows on the east side, that they may enjoy the benefit of the rising sun, strongly lathed and close shut; upwards and round about the inside of the wall upon the ground, should be made large pens of three feet high, for geese, ducks, and large fowls to set in, and near unto the covering of the house should be

be long perches, reaching from one side of the house to the other, on which should set cocks, hens, capons and turkies, each on such perches as they are disposed.

At another side of the house, at the darkest part of the ground pens, fix hampers full of straw for nests, in which hens should lay their eggs; but when they sit to hatch chickens, then let them sit on the ground, otherwise it will be dangerous.

Also let their be stakes stuck in the walls, that the poultry may climb to their perches with the greatest ease.

The floor must not be paved, but made of earth smooth and easy. Let the smaller fowl have a hole made at one end of the house, to go in and come out at when they please, or else they will seek out roofs in other places; but of larger fowl, you may open the door morning and evening.

It would be better if the hen-house was situated near some kitchen, brewhouse, bakehouse, or kiln, where it may have the heat of the fire, and be perfumed with smoke, which is to pullets both delightful and wholesome.

As soon as your chickens are hatched, if any be weaker than the rest, wrap them in wool, and let them have the heat of the fire; it will also be very good to perfume them with rosemary; the first hatched chickens may be kept in a sieve till the rest are disclosed, for they will not eat for two days; some shells being harder than others, they will require so much more time in opening; but unless the chickens are weak, or then unkind, it will not be amiss to let them continue under her, for she will nourish them kindly.

When they are two days old, give them very small oatmeal, some dry, and some steeped in milk, or else crumbs of fine white bread; and when they have gained strength, curds, cheese parings, white bread, crusts soaked in beer or milk, barley-meal, or wheaten-bread scalded, or the like soft meat, that is small and will be easily digested.

It is necessary to keep them in the house for a fortnight, and not to suffer them to go abroad with the hen to worm. Green chives chopped among their meat is very good, and will preserve them from the rye or other diseases in the head, and never let them want clear water, for puddle water will be apt to give them the pip.

Nor must you let them feed upon tares, darnel, or cockle, for these are very dangerous to young ones, nor let them go into gardens till they are six weeks old.

If you would have them crammed, coop them when the dam has forsaken them, and cram them with dough made of wheaten meal and milk, which dip in milk, and thrust down their throats, but let them not be too big, lest you choak them; and they will be fat in a fortnight.

To distinguish whether a chicken is good or not: after a chicken is killed it will be stiff and white and firm in the vent, if new killed; but tender, and green in the vent if stale.

If you rub your finger on the breast of a scalded chicken, if it be new killed it will feel rough; but if stale, slippery and slimy.

A crammed chicken, if it be fat, will have a fat rump, and a fat vein upon the side of the breast of her, like a pullet.

In order to fatten chickens, you must put them into croups, and feed them with barley-meal; put likewise a small quantity of brickdust into their water, which they ought never to be without: this last will give them an appetite to their meat, and fatten them very soon; for in this case it must be considered, that all fowls and birds have two stomachs, as they may be called, the one is their crop, that softens the food, and the other the gizzard, that macerates the food; in the last we always find small stones and sharp sand, which help to do that office, and without them or something of that kind, a fowl will be wanting of its appetite to eat; for the gizzard cannot masticate, or as it may be said, grind the food fast enough to discharge it from the crop, without such sand or stones: and in this case the brickdust is assisting.

To cure the Pip in Poultry. This disorder is occasioned by eating foul meat, and drinking dirty water, or the want of water. It is known by a thin white scale on the tip of the tongue, which prevents the fowl from eating; and it is cured by taking off the scale with your nail and rubbing salt upon the tongue.

To cure the Rump. This complaint is a swelling on the rumps, which disorders the fowl prodigiously; and observable by the feathers on the affected part, standing out of their natural position. Pulling out the feathers, opening the sore, forcing out the core, and washing the part with brine, or with salt and water, will effect the cure.

To cure them of the Flux. Eating too great a quantity of moist food occasions this disorder, which is cured by giving them bran and peas scalded.

To cure stoppage in Fowls. This costiveness affects the poultry to such a degree, that they are unable to walk. Its cure is effected by anointing the vents, and then feeding them with corn, or small bits of bread soaked in urine.

To cure their sore Eyes. An approved remedy for this disorder, is to chew leaves of ground-ivy in your mouth, squeeze out the juice and spit it into the affected part.

To cure those stung with venomous Insects. The method is to anoint them with rue and butter. They may be known to be afflicted with this disorder, by their swelling and looking very heavy.

Ducks are very necessary for the husbandman's yard, in that they require no charge in keeping; they live on lost corn, worms, snails, &c. for which reason they are very good for gardens. Once in a year they are very good layers of eggs, especially a sort of duck that turns up the bill more than the common kind; when they sit they need little attendance, except to let them have a little barley, or offal corn and water near them, that they may not straggle far from their nest to chill their eggs.

In general it is found more profitable to set a hen upon the duck's eggs, than any kind of duck whatever, because the old one leads them when hatched too soon to the water, where, if the weather be frosty, some will be lost. They follow the hen a good while upon the land, and so get hardy before they venture to the water.

About thirteen eggs is the proper number to let a duck sit upon; the hen will cover as many of these as of her own, and will bring them up well: so that every way she is more profitable for that purpose.

When the ducklings are hatched they require no care, if the weather be tolerably good; but if they happen to be produced in a very rainy season, it would be right to keep them under cover a little, especially in the night; for, though the duck naturally loves water, it requires the assistance of its feathers, and, till they are grown, is easily hurt by the wet.

The fattening of ducks at any age is very easy, and whether it be the duckling, or the grown duck, the method to be used is exactly the same. They are to be put in a quiet dark place, and kept in a pen, where they are to have plenty of corn and water: any kind of corn will do, and with this single direction, they will fatten themselves extremely well in fifteen or twenty days: and will bring a price that very well repays their feeding.

The benefit arising from *Geese* are, for food, their feathers, and their grease. They will live upon commons, or any sort of pasture, and need little care and attendance; only they should have plenty of water. The largest geese are reckoned the best, but there is a sort of Spanish geese that are much better layers and breeders than the English, especially if their eggs are hatched under an English goose.

Geese lay in the spring, the earlier the better, because of their price and of their having a second brood. They commonly lay twelve or sixteen eggs each. You may know when they will lay, by their carrying of straw in their mouths, and when they will sit, by their continuing on their nest after they have laid. A goose sits thirty days; but if the weather be fair and warm, she will hatch three or four days sooner. After the goslings are hatched, some keep them in the house ten or twelve days, and feed them with curds, barley-meal, bran, &c. After they have got some strength, let them out three or four hours in a day, and take them in again, till they are big enough to defend themselves from vermin. One gander will serve five geese.

If you fatten green geese, you must shut them up when they are about a month old, and they will be fat in about a month more. Be sure to let them have always by them in a small rack some fine hay, which will much hasten their fattening. But for fattening of older geese, it is commonly done when they are about six months old, in or after harvest, when they have been in the stubble-fields,

from which food some kill them, which is a good way; but those who have a mind to have them very fat, shut them up for a fortnight or three weeks; and feed them with oats, splitted beans, barley-meal, or ground malt mixed with milk, the best thing to fatten them with being malt mixed with beer. But in fattening of all water-fowl you may observe, that they usually sit with their bills on their rumps, where they suck out most of their moisture and fatness, at a small bunch of feathers, which you will find standing upright on their rumps and always moist, with which they trim their feathers, which makes them oily and slippery more than other fowl's feathers are, that the water may slip off them, which if cut away close, will make them fat in less time, and with less meat than otherwise. Geese will likewise feed on and fatten well with carrots, cut small, and given them; or if you give them rye before or about Midsummer, it will strengthen them, and keep them in health, that being commonly their sickly time.

In some countries they shear the geese for their feathers, and some pull them twice a year; but this latter way is more injurious to them, and therefore it is better staying till moulting time, or till their death, for their feathers.

Turkeys are fowls that prosper very well in open countries, where there is not much shelter to harbour vermin to destroy them: for they are naturally inclined to ramble. The hens likewise are so negligent of their young, that whilst they have one to follow them, they never take any care of the rest; and therefore they must be a great deal of care taken of them whilst they are young, to watch them, and to keep them warm, they being a bird that cannot bear the cold. But some, where they have a conveniency of a small cover near the house, let them take their liberty, and seek their own nests; but it is only in some particular places that they do well with such management. I knew a gentleman that had a hen-turkey of the wild kind from Virginia, of which, and an English cock, he raised a very fine breed, that bred wild in the fields, and always became tame when grown up; they were a very hardy breed, and much larger than ours, and reared their young ones without any care or trouble, breeding much better than our English.

If you keep them with corn, they are very great feeders, and will devour a great deal; but if left to their liberty when grown up, they will get their own living, without either trouble or charges, by feeding on herbs, seeds, &c.

Turkeys being very apt to straggle, will often be laying their eggs in secret places; and therefore the common sort of them must be often watched, and made to lay at home. They begin to lay in March, and will set in April. Eleven or thirteen eggs are the most they sit on. They hatch in between twenty-five and thirty days; and when they have hatched their brood, you must be careful to keep the young ones warm, for the least cold kills them. Feed them either with curds, or green fresh cheese cut in small pieces. Let their drink be new milk, or milk and water. Some give them oatmeal and milk boiled thick together, into which they put wormwood chopped small, and sometimes eggs boiled hard, and cut in little pieces. You must feed them often, for the hen will not take much care of them, and when they have got some strength, feed them abroad in a close walled place where they cannot stray; you must not let them out till the dew is off the grass, taking care to have them in again before the night, because the dew is very prejudicial to them.

For the fattening of turkeys, sodden barley is very excellent, or sodden oats for the first fortnight, and for another fortnight cram them as you do capons. They are only to be crammed in the morning, which must be given to them warm, and let out all day, being sometimes fed with corn while out; because, being a fatten bird, they are apt else not to fat so kindly.

Their eggs are reckoned very wholesome, and a great restorer of nature.

POUNCES, the talons or claws of a bird of prey.

PREGNANT, teeming, breeding, fruitful.

PRESS UPON THE HAND: a horse is said to resist, or press upon the hand, when either through the stiffness of his neck, or from an ardour to run too much a-head, he stretches his head against the horseman's hand, refuses the aid of the hand, and withstands the effects of the bridle.

To press or push a horse forwards, is to assist him with the calves of your legs, or to spur him to make him go on.

To PRICK, or PINCH, is to give a horse a gentle touch of the spur, without clapping them hard to him.

Prick with the right: pinch with the left: pinch with both.

To PRICK, or PINCH, is an aid; but to bear hard with the spur, is correction.

PRICKER, [Hunting-term] a hunter on horseback.

PRICKER, a spitter, or young male deer of two years old, that begins to put forth the head.

PRICKING [with Sportsmen] the footing of an hare, when she beats on the hard heath way, and her footing can be perceived.

PRICKING, a term used by farriers, &c. to signify the driving a nail into the soft part of a horse's foot.

If a lameness proceeds from pricking in shoeing, the foot should be pared thin on the wounded side; and after dressing with tar and turpentine, let it be stopped with two ounces of common turpentine, melted down with four of lard.

If the nail penetrates to the joint of the foot, where matter may be formed, and by its long continuance putrify, so as to erode the cartilages of the joint, the case is incurable.

If the nail has passed up to the nut-bone, it is incurable, because this little bone cannot exfoliate; and cause the cartilaginous part of it is destroyed, as soon as injured.

If the nail has not passed to the tendon, the horse will do well, without a necessity for drawing the sole: but if the tendon is wounded, the sole must be carefully drawn, because a sinovia and gleet is discharged.

When gravel is the cause, it for the most part follows the nail-holes, and if it gets to the quick, cannot return, unless it is scraped out; for the make of the hoof, which is spiral like an ear of corn, favours its ascent, so that the gravel continues working upwards towards the coronet, and forms what the farriers call a quittor-bone.

The nature of this disorder points out the method of cure, which is to be as expeditious and careful as possible in getting out the gravel: if it is found difficult to effect this, let the sole or hoof be pared thin; and if necessary, the wound enlarged to the bottom, and then dressed up as usual. Should the coffin-bone be affected, remember, always to bathe the hoof with vinegar, or repellents, in order to allay the heat and inflammation, which often happen on such occasions; and should the pain and anguish affect the legs, treat them in the same manner, or charge the leg and pastern with a mixture of wine lees and vinegar.

PRICKT, otherwise called ACCLOYED, CLOYED, or RETRATED, &c. in respect to horses, signifies only the having a prick by the negligence of the farrier in driving the nails, by their weakness, ill pointing or breaking them, which if not presently taken out, will, in time, break out into a foul sore: you may discern it by the horse's going lame; but if you would know it more certainly, pinch him round the hoof with a pair of pincers, and when you come to the place aggrieved he will shrink in his foot; or else you may try where he is pricked by throwing water on his hoof, for that place where he is hurt will be sooner dry than the rest.

PRONG, an implement much used in husbandry, consisting of two or three pieces of iron, inserted into a handle, for taking up corn, straw, dung, &c.

PRONG-hoe, a term used to express an instrument used to hoe or break the ground near, and among the roots of plants.

The ordinary contrivance of the hoe in England is very bad, it being only made for scraping on the surface; but the great use of hoeing being to break and open the ground, besides the killing the weeds, which the ancients, and many among us, have thought the only use of the hoe, this dull and blunt instrument is by no means calculated for the purposes it is to serve.

The prong-hoe consists of two hooked points of six or seven inches long, and when struck into the ground, will flir and remove it the same depth as the plough does, and thus answer both the ends of cutting up the weeds and opening the land. The ancient Romans had an instrument of this kind, which they called the bidens; but they were afraid of its use in their fields and gardens, and only used it in their vineyards. The prong-hoe comes into excellent use, even in the horse-hoeing husbandry; in this

the hoe-plough can only come within three or four inches of the rows of corn, turnips, and the like; but this instrument may be used afterwards, and with it the land may be raised and stirred, even to the very stalk of the plant. *Tull's Husbandry.*

PROPAGATION, the continuance or diffusion of successive production.

The ingenious Mr. Barns has given us the following method of propagating trees by the bud and branch:

"Every leaf, says he, upon the branch of a tree, or shrub, has usually a young bud in its bosom; and it is certain each of these buds has in it the rudiment of a tree of the same kind: therefore it appeared reasonable to think that every branch might afford as many new plants as there were leaves upon it; provided it were cut into so many pieces, and a proper dressing was found to prevent the raw ends of each piece from decay. The best mixture for this purpose, upon careful and repeated experience, I have found to be this:

"Melt together, in a large earthen vessel, two pounds and a half of common pitch, and half a pound of turpentine. When they are melted, put in three quarters of an ounce of powder of aloes: stir them all together; and then set them on fire: when it has flamed a moment, cover it up close, and it will go out: then melt it well, and fire it again in the same manner: this must be done three times. It must be in the open air, for it would fire a house; and there must be a cover for the vessel ready. After it has burnt the last time, melt it again, and put in three ounces of yellow wax shred very thin, and six drachms of mastich in powder. Let it all melt together till it is perfectly well mixed; then strain it through a coarse cloth in a pan, and set it by to cool.

"When this is to be used, a piece of it must be broke off, and set over a very gentle fire; it must stand till it is just soft enough to spread upon the part of the cutting where it is wanted; but it must not be very hot. It is the quality of this dressing, to keep out wet entirely; the part which is covered with it will never decay while there is any principle of life in the rest; and, this being secured, nature will do the business of the growing.

"This I have found true in practice; and by repeated trials, in more kinds than one, I have found that I could raise from any piece of a branch as many good plants as there were leaves upon it."

PRUNIFEROUS trees, those which bear a pretty large and fleshy fruit, with a nucleus in the middle.

PRUNING. See ORCHARDS and TIMBER.

PUBLIC PATHS. See PATHS.

PUCKBALL, a species of mushroom, full of dust.

PUDDOCK, or PURROCK, a small inclosure.

PULSE, a term applied to all leguminous plants, as tares, pease, &c.

All the species of pulse afford great abundance of excellent manure, in the state in which nature presents them. The custom of ploughing in green succulent plants, is very ancient. All the Roman writers commend it highly, and with much reason. Columella recommends particularly lupins, as a manure, which, if cut down and turned in while green, will have as good effect as the best and strongest dunging whatever. They may be sown upon poor land about the middle of September, and will enrich it greatly if ploughed in before they attain their full growth. In gravelly soils they should be cut down after they have put forth their second flower; and in strong lands, after the third. In the former of these grounds they are turned in while young and tender, that they may quickly rot; and in the latter, they are let stand till they grow stronger, that they may bear up the more solid and stiff clods of earth, and keep them the longer suspended; by which means the air has freer access to the soil, and these clods, being heated and dried by the summer sun, are the more easily opened, and resolved into dust. Thus says this judicious author, justly remarkable for his superior skill in husbandry. But Mr. Miller is of a contrary opinion.

The *Maison Rustique*, a work of very high repute, as is evident from the great number of editions it has gone through, strongly and rightly recommends pease, beans, lupins, vetches, and other succulent plants, as excellent manures, especially for sandy ground. These plants enrich the earth greatly if ploughed in, either green, or when in bloom. In strong land they should not be turned down till the pods begin to harden.

In Piedmont and other places where they fatten their

land with this manure, lupins are sown upon the fallow ground towards the end of June, immediately after the second ploughing, so that they are still green when the third ploughing is given and the corn is sown. Experience shews the husbandmen in those countries, that this method of using these plants for manure makes them ample amends for the loss of the pulse or fodder they might otherwise reap from them: but those who do not like to lose any thing, plough in the husks after they have taken out the grain.

Dr. Lister likewise recommends for the improvement of sandy, light ground, or any clay well sanded, all plants of the pulse or pea kind, and particularly, "upon experience, the wood vetch, which, besides its being perennial (at least with respect to its roots) and its thriving even in woods and among bushes in almost every country, has these farther qualifications, that it shoots out a thousand roots far and wide, and spreads itself under ground, like quick-grass; whilst it is so rampant above ground, that it will climb a fathom and a half upon measure, and preserve itself in spite of weeds or drought. It may be set, as well as sown, in furrows. For the former of these purposes the roots may be dug up in September, which is also the time for gathering the ripe seed. The growth of the plants will be greatly advanced by setting their roots; for the older they are, the stronger, more numerous, and fuller of buds their shoots will be. I sowed in the latter end of March the seed which I had gathered in September, and had that year a very great increase, the bed being thick covered over with grass above two feet high: but it did not flower that year. I reckoned that one pea had put forth above thirty shoots in August of the first year. In the second year, it flowered by the middle of June, and bore a wonderful crop, the roots being innumerable. I have observed this pea very common in all the mountains as well as plains of England, where bushes or hedges are. Both the pea and grass are very sweet, and very agreeable to cattle, as I have tried."

Buck wheat and vetches are the two plants most commonly sown in England for manure. The best time for ploughing them in, is when they are in bloom; being then in their most succulent state. Some farmers turn down their second crop of clover, to enrich the land for wheat in the autumn. This should be done early enough to give the plants sufficient time to putrefy thoroughly before the grain is sowed; otherwise, it might prove prejudicial, by bringing on a heat which would hurt the corn.

The reverend and ingenious Mr. Elliot, of New England, prefers millet to every other plant for green dressing of land, on account of the cheapness of the seed, and the largeness of the stalks and leaves, which must afford a good coat to turn in when ploughed. An old farmer who had long been in the practice of green dressing, assured this gentleman that he had increased the strength of his land to a great degree, in a few years, by the following method: After his oats were harvested, he added a little seed to the scattered grains, and then ploughed them in. Towards the end of September, he ploughed in the green oats, and sowed rye; and the next summer, when the rye was well grown and full of sap, he ploughed that in at the usual sowing season, then sowed wheat, and always had a large crop. See BEANS, PEASE, &c.

PUNCH, a well-set, well-knit horse, is short backed, and thick shouldered, with a broad neck, and well lined with flesh.

PURGING; the operation of evacuating the impurities of an animal body by stool.

Purging is often necessary in gross full horses, in some disorders of the stomach, liver, &c. but should be directed with caution. Before a purge is given to any horse, it is necessary some preparation should be made for it, in order to render the operation more safe and efficacious: thus a horse that is full of flesh should first be bled, and at the same time have his diet lowered for a week, especially those that have been pampered for sale; several mashes of scalded bran should also previously be given, in order to open the bowels and unload them of any indurated excrement; which sometimes proves an obstacle to the working of the physick, by creating great sickness and griping.

Let it be remembered, that a horse is purged with difficulty; that the physick generally lies twenty-four hours in the guts before it works; and that the tract of bowels it has to pass through is above thirty yards; and laying horizontally,

zonally, consequently resinous and other improper drugs may, and often do, by their violent irritations, occasion excessive gripings and cold sweats, shave off the very mucus or lining of the guts, and bring on inflammations, which often terminate in mortifications and death.

It is remarkable too, that the stomach and guts of a horse are but thin, compared to some other animals of the same bulk, and therefore must be more liable to inflammation and irritation.

Horses kept much in the stable, who have not the proper benefit of air and exercise, in proportion to their food, should in spring have a mild purge or two, after a previous preparation by bleeding, lowering their diet, and scalded mashes.

Horses that fall off their stomach, whether it proceeds from too full feeding, or ingendering crudities and indigested matter, should have a mild purge or two.

Horses of a hot temperament will not bear the common aloetic purges; their physic therefore should be mild and cooling.

Purging is always found very beneficial in stubborn dry coughs; but mild mercurials joined with them, make them yet more efficacious.

Horses that have those sorts of lamenesses, that are said to proceed from humours flying about (which are of the rheumatic kind, and in young horses proceed from fizy blood, and occasion lameness in every limb) require frequent purging; and should also have, between whiles, medicines that attenuate and thin the fluids.

Horses of a watery constitution, who are subject to swelled legs, that discharge a sharp briny ichor, cannot have the causes removed any ways so effectually as by purging.

The first purge you give to a horse should be mild, in order to know his constitution.

It is a mistaken notion, that if a proper prepared purge does not work to expectation, the horse will be injured by it; for though it does not pass by stool, its operation may be more efficacious, as an alterative to purify the blood, and it may pass by urine, or other secretions.

Purging medicines are very successfully given in small quantities, mixed with others; and act then as alteratives.

If mercurial physic is given, care should be taken that it be well prepared; and warmer cloathing, and greater circumspection is then required.

Purges should be given early in the morning upon an empty stomach; about three or four after the horse has taken it, he should have a feed of scalded bran; and a lock or two of hay may then be put in his rack. The same day give him two more mashes; but should he refuse warm meat, he may be allowed raw bran.

All his water should be milk warm, and have a handful of bran squeezed in it; but if he refuses to drink white water, give it him without bran.

Early the next morning, give him another mash; but if he refuses to eat it, give him as much warm water as he will drink: let him be properly cloathed, and rode gently about. This should be done two or three times a day, unless he purges violently, once or twice will then be sufficient: at night give him a feed of oats mixed with bran.

During the working, a horse should drink plentifully; but, if he will not drink warm water, he must be indulged with cold, rather than not drink at all.

We shall here insert some general forms of purges.

Take succotrine aloes ten drams jallap and salt of tartar each two drams, grated ginger one dram, oil of cloves thirty drops; and make them into a ball with syrup of buckthorn.

Or,

Take aloes and cream of tartar each one ounce; jallap two drams, cloves powdered one dram, syrup of buckthorn a sufficient quantity.

Or,

The following, which has an established character among sportsmen:

Take aloes, from ten drams to an ounce and a half, myrrh and ginger powdered each half an ounce, saffron and oil of aniseed each half a dram.

Mr. Gibson recommends the following:

Take succotrine aloes ten drams, myrrh finely powdered half an ounce saffron and fresh jalap in powder, of each a dram; make them into a stiff ball with syrup of roses, then add a small spoonful of rectified oil of amber.

The succotrine aloes should always be preferred to the Barbadoes, or plantation aloes, though the latter may be given to robust, strong horses, but even then, should always be prepared with the salt, or cream of tartar; which by opening its parts, prevents its adhesion to the coats of the stomach and bowels; from whence horrid gripings, and even death itself has often ensued. This caution is well worth remarking, as many a horse has fell a sacrifice to the neglect of it.

Half an ounce of Castile soap, to a horse of a gross constitution, may be added to any of the above; and the proportions may be increased for strong horses.

When mercurial physic is intended, give two drams of calomel over night, mixed up with half an ounce of diapente, and a little honey, and the purging ball the next morning.

The following, when it can be afforded, is a very gentle and effectual purge, particularly for fine delicate horses; and if prepared with the Indian rhubarb, will not be expensive.

Take of the finest succotrine aloes one ounce, rhubarb powdered half an ounce or six drams, ginger grated one dram; make into a ball, with syrup of roses.

The following purging drink may be given with the utmost safety; it may be quickened, or made stronger, by adding an ounce more fenna, or two drams of jalap.

Take fenna two ounces, infuse it in a pint of boiling water two hours, with three drams of salt of tartar; pour off, and dissolve in it four ounces of Glauber salts, and two or three of cream of tartar.

This last physic is cooling, easy, and quick in its operation; and greatly preferable in all inflammatory cases to any other purge, as it passes into the blood, and operates also by urine.

When horses lose their appetites after purging, it is necessary to give them a warm stomach drink, made of an infusion of camomile flowers, aniseeds, and saffron: or the cordial ball may be given for that purpose.

Should the purging continue too long, give an ounce of diascordium in a pint of Port wine, and repeat it once in twelve hours, if the purging continues. Plenty of gum arabic water should also given, and in case of violent gripes, fat broth glysters, or tripe liquor, should be often thrown up, with an hundred drops of laudanum in each.

The arabic solution may be thus prepared:

Take of gum arabic and tragacanth of each four ounces, juniper berries and caraway seeds of each an ounce, cloves bruised half an ounce; simmer gently in a gallon of water, till the gums are dissolved, give a quart at a time in half a pail of water; but if he will not take it freely this way, give it often in a horn.

When a purge does not work, but makes the horse swell, and refuse his food and water which is sometimes the effect of bad drugs, or catching cold, warm diuretics are the only remedy; of which the following are recommended:

Take a pint of white wine, nitre one ounce, mix with it a dram of camphor dissolved in a little rectified spirit of wine; then add two drams of oil of juniper, and the same quantity of unrectified oil of amber, and four ounces of honey, or syrup of marshmallows.

Or,

Take Venice turpentine one ounce, incorporate with the yolk of an egg; nitre one ounce, then add juniper berries, and fresh aniseeds pounded, each half an ounce, unrectified oil of amber two drams; make into a ball with syrup of marshmallows.

PURLIEU, all that ground near any forest, which being antiently

anciently made forest, is afterwards, by perambulations, separated again from the same, and freed from that servitude which was formerly laid upon it.

PURLIEU-*Man*, one that has land within the purlieu, and forty shillings a year freehold; upon which account he is allowed to hunt or course in his own purlieu, with certain limitations.

PURSE-NET, a net used for taking both hares and rabbits, at certain times, and three or four dozen of them are sufficient to lay over their holes: they are to be fastened, by tying strings to sticks thrust into the earth, otherwise when the rabbits bolt out, they will run away and get out of the nets; but when the nets are fixed, and all things in order, there must be one or two to lie close, to see what game comes home; while, in the mean time, you beat the bushes, to force them homewards.

Another way to take rabbits with these nets, is at their coming out of their parraces: and they should be secreted in this manner.

First hunt them up and down, to force them all in, then put in a ferret with a bell about her neck, which gives the rabbit notice of her coming, who endeavouring to avoid the ferret, runs into the net.

PURSINESS IN HORSES, is a shortness of breath,

either natural or accidental. The natural is when the horse is cock thropped; for that his thropple or wind-pipe being so long, he is not able to draw his breath in and out with so much ease as other horses do which are loose thropped, because the wind-pipe being so strait, that should convey the breath to the lungs, and vent it again at the nose, makes him pant and fetch his breath short; and in like manner when his pipe is filled with too much fat, or other phlegmatic stuff, which suffocates him, and makes his lungs labour the more.

Pursiness accidental is sometimes caused by a horse's being hard ridden after a full stomach, or presently after drinking, which causes phlegmatic humours to distil out of the head into the windpipe, and fall upon the lungs, where they settle and congeal.

It also proceeds from heats and colds, &c. causes dullness and heaviness in travelling, makes him sweat much, and ready to fall down upon every strain.

For the cure: pound aniseeds, liquorice, and sugar-candy, to a fine dowder, and put four spoonfuls into a pint of white-wine; brew them well, and mix with them half a pint of fallad oil. Give this to the horse ever after a travel, and a day before he sets out on a journey.

Q.

QUARTER BEHIND, is when a horse has the quarters of his hind feet strong; that is to say, the horn thick, and capable of admitting a good gripe by the nails.

When a horse's quarters or feet are wasted and shrunk: For the cure: raze the whole foot with a red hot knife, making large razes of the depth of a crown piece, from the hair to the shoe: and avoiding the coronet, then apply a proper poultice, and charge the foot with a *remolade*.

QUARTERS OF A SADDLE, are the pieces of leather, or stuff, made fast to the lower part of the sides of the saddle, and hanging down below the saddle.

QUARTERS OF A HORSE, fore-quarters, and hind-quarters; the fore-quarters are the shoulders and the fore-legs; the hind-quarters, are the hips and the legs behind.

QUARTERS OF A HORSE'S FOOT, are the side of the coffin, comprehended between the toe and the heel on one side, and the other of the foot: the inner-quarters are those opposite to one another, facing from one foot to the other; those are always weaker than the outside quarters, which lie on the external sides of the coffin.

QUARTER-CAST; a horse is said to cast his quarters when for any disorder in his coffin, we are obliged to cut one of the quarters off the hoof, and when the hoof is thus cut, it grows and comes on a new.

QUARTER EVIL, a disease in cattle. Mr. Young, in his *Annals of Agriculture* vol. XIV. inserts the following, by A. P. Anderson, esq. "I have procured a recipe for a preventive of that evil, which has been successfully used with us; for since it has been a rule in many of the principal dairies to apply it, the complaint has been less common. But, if the antidote is not administered before the disorder has made its attack, I never heard of its being removed.

It is generally applied the latter end of October, or beginning of November, keeping the cattle in your driest pastures.

"Take rue, wormwood, lavender-cotton, a few heads of garlic, and a little favin, cut very small; add to it flour of brimstone, diapente, and elecampane powder; boil all together in urine; then take it off the fire, and let it stand until it about milk warm.

"Give each calf two hornfuls [(bullock's horns, commonly used for giving drenches to cattle) with about a table

spoonful of Barbadoes tar in each horn, first taking off about one quart of blood from each calf.

"Put a little tar over their noses, on their loins, and on their ribs, for them to lick.

"The ingredients of this drench are to be given all together, without straining. And observe, it cannot be made too strong of the herbs, without being too thick for a drench; except only, as to the favin, which must be sparing and discreetly used."

QUEEN-BEE, a name given by late writers to what used to be called the king-bee, or king of the bees; a large and long-bodied bee, of which kind there is only one found in every swarm, and which is always treated with the greatest respect by the rest. See the article BEE.

This is, indeed, the parent of the swarm; and from the fecundity of this one female, a whole hive is easily and soon re-peopled.

It is to be observed, that the autumn and winter seasons destroy a great number of the bees; so that a hive, which was full in the summer, is often found so thinly peopled before the end of winter, that the bees seem only a few inhabitants in a very large city: by Midsummer again this same hive shall, however, be found so well filled with inhabitants that there shall be a necessity of sending out a colony in the name of a new swarm, and yet the hive will remain as full as it can well hold. This increase might well appear very amazing, if all the remaining bees of the hive were supposed to be females, and to join in it, but how much more so when it must be acknowledged, that it is all owing to one female, and that this queen-bee, or mother-bee, alone, has given origin to such an immense progeny?

The form of this bee, and there being only one such in a hive, naturally led all who saw it into an opinion of something singular in its nature, and the antients determined that it must be the king over the rest: they made it an absolute monarch, and have supposed that all the business of the hive was done by its immediate orders; and that the several parties of bees allotted to work in the making of the combs, in the filling their cells, in the stopping the crevices of the hives, and in carrying away the filth, &c. had all their several stations allotted them by this wise and provident monarch. This was giving great talents to the monarch bee; but this was mere fancy, and it is plain, that if this creature rules, it is over a people who all perfectly well know their several

several businesses : but it rather appears, that there is no sovereignty at all, but that this creature is respected in a very high degree by the rest, as the common parent of the whole nation.

There were not wanting among the antients, however, some who believed this large bee to be a female, and these pretend that she brought forth only females like herself, which succeeded her in her reign. They had a very different opinion as to the origin of the common bees, not supposing them generated of animal parents like themselves, but produced out of corruption, and born of the flesh of a bull or cow. Among the later writers, this opinion, notwithstanding the sanction of the poet Virgil, has been laughed out of the world ; yet it was long before the true origin of bees even after this, was known. The author of the Female Monarchy, though well apprized of this great bee being of the female sex, yet supposed that she only produced young ones like herself ; and pretended that the common bees copulated together for the production of other bees like themselves : this, however, has been since found to be wholly erroneous, the female, or queen-bee, giving birth to all, and these common bees being of no sex at all. Many of the authors who have not given into the idle opinion of the bees being bred of putrid flesh, have yet given them an origin not less idle and ridiculous. They pretend that the bees are exempted from the pain of producing either eggs or young ; and that the offspring are formed of the juices of flowers, the different kinds, as the drones, females, &c. owing their rise to the juices of different kinds. These and a number of other false notions, have been propagated in regard to bees ; but their true origin could not well be found till we were in a condition to see what passes at certain times within the recesses of the hive, which is done by the use of that excellent invention, the glass hive. By this, and by the help of dissections, we may easily inform ourselves perfectly of the true state of the case. The parts of generation are the subjects of our enquiry for this purpose, and, though the bodies of these animals are so small, these are usually sufficiently large to be distinguished, often taking up more room in the abdomen than all the other parts together. Thus, if the large long-bodied bee be opened, the abdomen will be found to contain vast numbers of oblong bodies, which any one acquainted with insects will easily distinguish to be eggs : vast numbers of these are large enough to be observable by the naked eye, but when the assistance of glasses is called in, there are discerned a vast number of other small eggs, which exceed all computation. It is easy to determine from this, that this creature, so long esteemed a male, is in reality, a female, and is in condition to give birth to a very numerous posterity.

In order to distinguish this, however, a proper time must be chosen for the dissection, and the most proper of all is when the creature is just ready to deposit her eggs. This is in the months of April and May, and the most certain time of all is when she is in a hive where a new swarm have been received about ten days before : if she be dissected at other times, the eggs are less visible ; and, particularly in winter, there requires a good glass to shew the rudiments of them. This is a disagreeable experiment, indeed, because it is always the destruction of a future swarm ; all the eggs we see in the dissected female being what would have produced bees to labour for our benefit.

When the body of one of the drones is opened, there is found, instead of these vast numbers of eggs, a part seeming proper for a male organ of generation, and in the abdomen a number of vessels running in several windings of contortions, and filled with a milky humour. These seem destined for the important use of impregnating the eggs in the belly of the female, and it is very natural to determine from this, that these are the males.

The common bees, when dissected, at whatever time of the year, never shew the least marks of any seeds at all. The intestine of these bees are found at times to be more or less distended with honey, and with rough wax ; but there are never discovered any eggs, nor any of the winding seminal vessels, so that it is plain they have no share in propagating the species : and the observation of the swarms from time to time, with the assistance of glass hives, gives proof to what the dissections seem to make sufficiently certain without this evidence.

The female bee resides within the centre of the hive, always living in one of the spaces between the combs ; if she occasionally comes out to the surface, and is seen walking

over the edge of a comb, she is to be well observed at those times ; for her only business is the laying her eggs in some of the empty cells of that part of the comb : which done, she always retires again.

In order to see the female, or mother-bee, employed in this operation, we are to observe in the morning hours, between seven and ten, what passes in a glass-hive, into which a swarm have been received a few days before. The speed with which the common bees labour in making their combs on this occasion is almost incredible ; and they seem not only to labour to have cells to deposit their honey in, but to know that the parent bee is at this time loaded with eggs for the production of a numerous progeny, and that she has an immediate necessity of cells for the depositing them in. This necessity is so urgent, that she is often forced to deposit them in cells not yet finished ; though the bees labour so vigorously, that they often will erect a whole large comb in one day. If the hive be narrowly watched at these times in the morning hours, the female bee will be soon found employed in her work, and will be seen dropping her tail by turns into several cells every day. If the combs be examined a day or two after this, they will also be found to contain the eggs ; one of these is placed in each cell, and appears in form of an oblong white body, fixed either to the solid angle of the base, or to one of the angles composed by the rhombs which form the triangular base of the cell, and is always attached in such a manner, that it lies nearly in an horizontal position.

The flat glass hives are the most favourable for the making these observations, since in those the combs are so narrow and so numerous, that the whole is taken in view at a time, from one side or the other ; and there are always several combs to be made choice of for the operation : in the morning hours of April and May, the female or mother-bee will be usually seen walking very soberly over one or other of these combs, attended by a guard of about twenty of these common bees, all placing themselves in such a manner, that their faces are turned towards her, and all paying her the greatest marks of homage and adoration. As she walks along in this state, she examines every cell as she passes over, and such as she finds yet empty and fit for her purpose, she rests at : and, introducing the hinder part of her body at the top, plunges it so deep in that her tail touches the bottom. Then she deposits one egg, and no more ; and this is at that time covered with a glutinous matter, which fastens it to the place where it is laid : from this cell the female passes to several others, where she deposits her eggs in the same manner.

Some authors who have written of the polity of bees, have represented the time of the female bee's laying her eggs as a season of festivity and rejoicing in the hive ; but this does not at all appear to be the case ; the few bees which attend her on this occasion seem the only ones that know any thing of the matter, and their behaviour favours more of homage and respect than of joy : they are continually stroking and brushing her clean with their legs and with their trunks, and offer her from their own mouths the finest honey, when she has occasion for food. The rest are all employed in their proper offices, and the work of the hives go on as usual ; and, indeed, it is well that it does so, for this time of rejoicing would be of very bad consequence to the affairs of the hive, if carried on as supposed, since the female bee is thus employed, more or less, during the whole summer months.

When the female bee has laid six or seven eggs, she always takes a time of respite or repose ; and, during this time, the bees which form her levee are doubly busy in their caresses, some brushing her head and breast with their trunk, but several being always employed together to cleanse the hinder rings of the body, which have been fouled by being thrust into the cells. When this is done, she begins again : but Mr. Reaumur observes that he never could see a female lay more than ten or twelve eggs at one time : he supposes that his presence disturbed the creature, and finally drove her into the inner parts of the hive, where she might continue her work in cells less exposed. It is not difficult to compute the number of eggs which the female lays every day, from the swarm which is ready to leave the hive at the end of May : this swarm usually amounts to at least twelve thousand ; and as the hive out of which these depart is not less peopled by their loss, it is evident that they were all the produce of the eggs deposited by the female in the preceding months of April, with a part of March, and a few of the first days of May. On a moderate computation, on these principles it will appear, that the female bee cannot lay

lay less than two hundred eggs every day, for a long space of time together: and this, though seemingly a monstrous increase, is yet much less than that of some other of the winged insects; in one of which, a two-winged fly, that author counted no less than twenty thousand living worms, all ready to be deposited by the parent, and to become flies of the same kind.

It has been strongly objected against this system, that, though the female bee lays eggs, she is not the only one that lays; and many will not give up the opinion of the common bees also laying some eggs, though but a few in number; observing, that if each of these lay only four or five eggs, it would be enough to give birth to a whole swarm, without supposing that this prodigious fecundity belonged to the female bee alone; but this is running into the old error of the female producing only females like herself: whereas, if we observe the cells in which we see the female deposit her eggs, we shall in the sequel find the common bees produced from these eggs, and issuing out of these cells: this is a sufficient proof to any fair reasoner, since it appears very plain, that, if the female produces them, they do not produce one another. It is also evident that not only these common or working bees, but also the drones, or male bees, are produced from the eggs of this same female: and there is this remarkable forecast in the female, that she always deposits the eggs which are to give origin to these in peculiar cells, proper for the reception of the worms which are to be hatched from them. It is observed, in examining a hive, that there are always some combs, or some parts at least of combs, the cells of which are much larger than those of the other parts or combs: these large cells are destined for the residence of the larger worms, which are to produce the drones or male bees. It has been observed as a miraculous singularity by some, that the female bee always knows before-hand, whether the egg she is going to lay will produce a male or a common bee; and that, according to this knowledge, she never deposits the eggs for a male in a smaller cell, nor that of a common bee in a large one; but there is, in reality, less wonder in this than is supposed, for the eggs of which the drones are to be hatched are much larger while in the body of the female than those of which the common bees are to be produced, and the whole occasion of this choice in regard to the placing of them is, that, when the creature finds a large egg coming forth, she seeks one of the large cells to deposit it in; and when the common small eggs are coming, she contents herself with the common cells.

It is very natural to believe that the female bee lays a third kind of eggs; and that, besides producing many thousand common or working bees, and many hundreds of the males or drones, she ought to lay one egg at least capable of producing a female like herself, which is to be the mother of a future progeny, and the queen of the present race; since, without such a one for their leader, the young brood would never leave the hive in the nature of a colony to settle themselves elsewhere. What we thus perceive ought to be the case, is also found in reality to be so; and the female, besides the other kinds of eggs, is found by a strict observation to lay also eggs of this kind. We might perhaps only expect one female bee to be produced for each swarm; but, as nature has seemed every where prodigal in the manner of the increase of her works, so it is in this also. What millions of seeds are produced on a common elm-tree, for one that strikes and succeeds so well as to grow up to be a tree! and, of the number of young produced from the spawn of a carp, how few live to the size of a parent? Thus it also is in regard to the female bees: nature, though it has allotted only one of this kind, as absolutely necessary to the new swarm, yet has given abundance of chances for that one to succeed by the female's usually laying at least ten eggs for the production of the female offspring, and often not less than twenty: there are, indeed, some seasons when not one female is produced; but in those seasons there is no swarm going out from the old hive, the creatures being informed by nature, that they have no business for combs and cells when they can have no offspring to rear in them.

The working bees are not only very obedient to, and very careful of their queen, or female parent, but they are also very solicitous about her progeny. This is very evident in the structure of the cells which they prepare for the reception of those eggs which are to be hatched into females. It has been before observed, that they prepare larger cells for the eggs which are to become drones, or

male-bees, than for those which are to produce workers like themselves. The large cells destined for the drones are, however, of the same shape and figure with the others, differing only in size; but this is not the case with those destined for the female offspring: these are not only very large, but very clumsily contrived, for the sake of strength; their sides being much thicker than those of the rest, and their figure oval. The bees are extremely sparing of their wax on all other occasions, but for the construction of these royal cells, as they may not improperly be called; they are as remarkably profuse: one of the royal cells will weigh more than an hundred and fifty of the common kind. The bees are no more sparing of the room than of the materials in the construction of these royal habitations: they are often placed near the centre of a comb, and a vast number of other cells are destroyed for their base; often also, they hang down from the rest of the comb, in form of stalactites from the roofs of subterraneous caverns.

A cell of this kind, when first formed, represents an acorn cup; but it is soon lengthened beyond the possibility of retaining that figure, and it remains thus till the creature is hatched from the chrysalis or nymph state, and comes out of it; after which the bees, to lose no room in the hive, form other common cells upon it, and the only remaining mark of the female cell, is the appearance of a knot in the place where it once stood.

The number of cells destined to receive the eggs which are to produce female bees are so few, and they are commonly placed in such close parts of the hive, that there is no great probability of seeing the female employed in laying her eggs in them; there is no reason to doubt the fact; however, since, we know that she lays eggs for the production of the females like herself.

It might seem much harder to conceive how so vast a number of bees should be produced from this one, as we know are produced from her; but, when one of the females is opened, the vast number of eggs discovered in each of her ovaries make the prodigious increase no way wonderful.

Swammerdam observed, that the number of vesicles in the ovary of the female bee was astonishingly great; he easily counted an hundred and fifty in each ovary, and could count about seventeen eggs in each vesicle large enough to be distinctly visible; each ovary contains, therefore, two thousand five hundred and fifty eggs, and both ovaries five thousand one hundred. When we find so many eggs at once distinguishable by their size, it will be easy to conceive, according to the common course of nature in the propagation of insects, that there may be many more too small to be yet distinguishable; and, at that rate, the number of twelve thousand bees, which is the quantity that composes a moderate swarm, is not wonderful for the product of the eggs of one female for one season. *Reaumur's Hist. Inf.*

QUICK, or **QUICKSET-HEDGE**, a general name for all hedges, of whatever sorts of plants they are composed, to distinguish them from dead hedges; but in a more confined sense of the word, it is applied to the white or hawthorn, the sets or young plants of which are raised by the nursery gardeners for sale. *See the article FENCE.*

QUICKSILVER, a very ponderous fluid mineral, generally called mercury.

In the year 1765, a discovery was made (or rather revived, for it is mentioned by Mr. Bradley), that quicksilver was a sovereign remedy for destroying insects on trees.

The narrative of this discovery was contained in a letter written by Dr. R—— to Dr. P——; in which the former begs the assistance of the latter "in laying before the learned world an account of some experiments, that have been tried with success, and which, when fully known, will, he believes, be of great service to the vegetable part of the creation, by totally destroying those pernicious insects, that are apt to infect the tender leaves and young shoots of our choice fruit-trees: and for which, no remedy, that he had ever heard, or read of, has been as yet proposed, that is either adequate to the disease, or effectual to the cure." Dr. R——, therefore, in the following part of the letter, desires Dr. P—— "to lay before the Society for the Encouragement of Arts, &c. the following experiment, that was tried last spring, with success, by one George Bradford, a clothier in the city of Hereford, and a very ingenious young man: in order, after the ex-

periment has been fully tried, that they may reward him in proportion as he may seem entitled to it." But Dr. R—— adds, that, "whether he may be thought worthy of any recompence, or not, he very chearfully submits it to the trial of the curious; and hopes they may reap the same advantages he did last year, by clearing their trees of those pernicious insects." The doctor then proceeds as follows, to give the relation of Mr. Bradford's invention and success. "The first tree he tried the experiment upon, was a favourite plum-tree: I think a green gage. He was afraid of trying it on the whole body of the tree at first, as he did not know but that it might kill it at once: and therefore he selected out a particular branch, that was designed to be cut quite away, at the winter pruning, for the subject of his first essay. The method of the experiment is this: he took a small awl, and pierced, sloping, through the rind, and into part of the wood of the branch, but not to the heart or pith of it; and poured in a small drop or two of quick-silver, and stoppt it up with a small wooden plug made to fit the orifice: and the result of this experiment was, that the insects all dropt off, from that very branch, the next day; and, in a day or two more, from off the other branches of the tree, without any other puncture: and the tree continued in full vigour, and throve well all the summer after. Encouraged by this success of the first essay, he next tried it upon a honey-suckle; the leaves of which were quite covered with them: and here he scraped away the top of the ground with a trowel, and run his awl, in the same sloping manner, into the main stem just above the roots; but with the same caution as above, not quite to the inner pith; and the success was the same as before. The insects all dropt off dead the next day after the experiment was made. The above facts you may safely depend upon: and I saw both the trees, on which the experiments were made, since Christmas last; and they then seemed to be both very healthy and well. I did not indeed see the operation performed, as I was at that time on my residence at L——; but the method, manner, and success, as above related, I had from Mr. Bradford's own mouth."

This letter from Dr. R——, was dated March 11, 1765, though the delivery of it to the Society was deferred from accident till February last. But Dr. P——, in his letter to the president, desiring him to lay the other before the Society, remarks, that experiments have been since made, which conform the first observations. He says, "the advantage, however, hath arisen from this delay, that Dr.

R——hath had fuller proof of the success of this discovery."

We shall only add, that this method has since been tried by several members of the Society, and found fully to answer the intended purpose.

QUINCUNX, a disposition of trees originally formed into a square, consisting of five trees, one at each corner, and a fifth in the middle; which disposition often repeated, forms a regular grove, and then viewed by an angle of the square or parallelogram, represents equal and parallel alleys.

QUIT-RENT, a small rent payable by the tenants of most manors, whereby the tenant is quit, or free, from all other services, and is said to be an acknowledgement of their subjection to the lord of the manor.

QUITTOR, an ulcer formed between the hair and hoof, usually on the inside quarter of a horse's foot; it often arises from treads and bruises, sometimes from gravel, which by working its way upwards, lodges about the coronet: if it is only superficial, it may be cured with cleansing dressings, bathing the coronet every day with spirit of wine, and dressing the sore with precipitate medicine.

But if the matter forms itself a lodgment under the hoof, there is no way then to come at the ulcer, but by taking off part of the hoof; and if this be done artfully and well, the cure may be effected without danger.

When the matter happens to be lodged near the quarter, the farrier is sometimes obliged to take off the quarter of the hoof, and the cure is then for the most part but palliative; for when the quarter grows up, it leaves a pretty large seam, which weakens the foot: this is what is called a false-quarter, and a horse with this defect, seldom gets quite sound.

If the matter, by its confinement, has rotted the coffin-bone, which is of so soft and spongy a nature, that it soon becomes so, you must enlarge the opening, cut away the rotten flesh, and apply the actual cautery, or hot iron, pointed pyramidically, and dress the bone with dossils of lint, dipped in tincture of myrrh, and the wound, with the green or precipitate ointment. When the sore is not enlarged by the knife, which is the best and least painful method, pieces of sublimate are generally applied, which bring out with them cores, or lumps of flesh: blue vitriol powdered, and mixed with a few drops of the oil is used also for this purpose, and is said to act as effectually, and with less pain and danger. *Bartlett's Farriery, p. 303.*

R.

RABBIT, a well known animal of the hare kind, with a very short tail.

The female or doe rabbit goes with young thirty days, and then she kindles; and if she takes not buck presently, she loses her month, or at least a fortnight, and often kills her young, and eats them.

In England they begin to breed at a year old, but in some places much sooner; and they continue breeding very fast from the time they begin; four, five, six, or seven times a year being common with them. They have usually from four to seven in a litter, and hence it is that a small number at first will soon stock a whole warren, if left to breed a little while undisturbed. The does cannot suckle their young till they have been at buck again: this therefore is to be done presently, else there is a fortnight lost of the time for the next brood, and the present brood probably lost. When the buck goes to the doe, he always beats and stamps

very hard with his feet, and when he has copulated with her, he falls backwards, and lies as it were in a trance; in this state it is easy to take him, but he soon recovers from it.

The buck rabbits, like our bear-cats, will kill the young ones, if they can get at them; and the does in the warrens prevent this, by covering their stocks, or nests, with gravel or earth, which they close so artificially up with the hinder part of their bodies, that it is hard to find them out. They never suckle the young ones at any other time than early in the morning, and late at night, and always, for eight or ten days, close up the hole at the mouth of the nest, in this careful manner, when they go out. After this, they begin to leave a small opening, which they increase by degrees, till at length, when they are about three weeks old, the mouth of the hole is left wholly open, that they may go out: for they are, at that time, grown big enough to take care of themselves, and to feed on grass.

People

People who keep rabbits tame for profit, breed them in hutches, but these must be kept very neat and clean, otherwise they will be always subject to diseases. Care must be taken also to keep the buck and does apart, till the latter have just kindled, then they are to be turned to the bucks again, and to remain with them till they shun and run from them.

The general direction for the choosing of tame rabbits, is to pick the largest and fairest: but the breeder should remember, that the skins of the silver-haired ones sell better than any other. The food of the tame rabbits may be colewort and cabbage-leaves, carrots, parsnips, apple-rinds, green corn, and vetches, in the time of the year; also vine leaves, grass, fruit, oats, and oatmeal, milk-thistles, sow-thistles, and the like; but with these moist foods they must always have a proportionable quantity of dry foods, as hay, bread, oats, bran, and the like, otherwise they will grow pot-bellied, and die. Bran and grains mixed together have been also found to be very good food. In winter they will eat hay, oats, and chaff, and these may be given them three times a day; but when they eat green things, it must be observed that they are not to drink at all, for it throws them into a dropy. At all other times a very little drink serves their turn, but that must always be fresh. When any green herbs or grass are cut for their food, care must be taken that there is no hemlock among it, for, though they will eat this greedily among other things, when offered to them, yet it is sudden poison to them.

Rabbits are subject to two principal infirmities. First, the rot, which is caused by the giving them too large a quantity of greens, or from the giving them fresh gathered, with the dew or rain hanging in drops upon them. It is over moisture that always causes this disease; the greens therefore are always to be given dry, and a sufficient quantity of hay, or other dry food, intermixed with them, to take up the abundant moisture of juices. On this account, the very best food that can be given them, is the shortest and sweetest hay that can be got, of which one load will serve two hundred couples a year; and out of this stock of two hundred, two hundred more may be eat in the family, two hundred sold to the markets, and a sufficient number kept in case of accidents.

The other general disease of these creatures is a sort of madness: this may be known by their wallowing and tumbling about, their heels upwards, and hopping in an odd manner into the boxes. This distemper is supposed to be owing to the rankness of their feeding: and the general cure is the keeping them low, and giving them the prickly herb, called tare thistle, to eat.

The general computation of males and females is, that one rabbit will serve for nine does; some allow ten to one buck, but those who go beyond this, always suffer for it in their breed.

Wild rabbits do great damage to vineyards, and all sorts of corn, their teeth sparing nothing that they come near; and in such countries as abound with vine-yards, they will eat the young shoots as soon as they begin to appear, and will do them so much damage, that it will endanger their ruin without some proper remedy; to prevent which, take some very small sticks of willow, well dried; dip one end of them into some melted brimstone, and stick the other into the ground; let them be about a fathom distant from each other, and set fire to them; and this will prevent the rabbits (who hate the smell) from entering into any vineyard, on the side which those sticks are set: the smell will last four or five days, at the expiration of which you must renew it, and so a third time; insomuch, that in about sixteen days, the shoots of the vine will be so strong as not to be in danger of the insults of these animals.

The wild rabbits are to be taken either by small cur dogs, or by spaniels bred up to the sport; and the place of hunting those who straggle from their burrows is under close hedges, or bushes, or among corn-fields and fresh pastures. The owners use to course them with small greyhounds, and, though they are seldom killed this way, yet they are driven back to their furrows, and are prevented from being a prey to others. The common way is by nets, called purse-nets, and ferrets. The ferret is sent into a hole to force them out, and the purse-nets, being spread over the hole, takes them, as they come out. The ferret's mouth must be muzzled, and then the rabbits get no harm. For the more certain taking of them, it may not be improper to pitch up a hay net or two, at a small distance from the burrows that are intended to be hunted: thus very few of the number that are attempted will escape.

Some who have not ferrets smoke the rabbits out of their holes with burning brimstone and orpiment. This certainly brings them out into the nets; but then it is a very troublesome and offensive method; and is very detrimental to the place; as no rabbit will; for a long time afterwards come near the burrows which have been fumed with these stinking ingredients:

"Having heard, says Mr. Weston, that a person had kept rabbits; by digging a circular ditch, and confining them to a little hill in the middle, I, from that description took the hint, and made a small artificial warren, in a lawn in the garden; in the following manner. It was a very agreeable object; and the rabbits succeeded very well in it.

"Pare off the turf of a circle, about forty feet diameter, and lay it on the outside; then dig a ditch within this circle, the outside perpendicular, the inner sloping; and throw earth sufficient into the middle, to form a little hill, two or three feet higher than the level of the lawn; the rest must be carried away. Then lay down the turf on the hill, and beat it well to settle it.

"The ditch at bottom should be about three feet wide, and three and an half deep, with two or three drains at the bottom, covered with an iron grate, or a stone with holes; to carry off the hasty rains, in order to keep the rabbits dry. In the outside bank should be six alcoves, the sides and tops supported, either by boards, or brick work, to give the rabbits their dry food in; by their different situations, some will always be dry: six boxes; or old tea chests, let into the bank, will do very well.

"If the ground be very light, the outside circle should have a wall built round it, or some stakes, driven into the ground, and boards or hurdles nailed to them, within a foot of the bottom, to prevent the bank from falling in. The entrance must be, either by a board, to turn occasionally across the ditch, or by a ladder.

"The turf being settled, and the grass beginning to grow, turn in the rabbits, and they will immediately go to work, to make themselves burrows in the side, and in the hill. By way of inducing them rather to build in the sides, to keep the turf the neater, make a score of holes, about a foot deep, and they will finish them to their own mind; and if there be a brick wall round it, it should be built on pillars, with an arch from each, to leave a vacancy for the burrow.

"Another way is, to dig the ditch only about two feet deep, which will yield about earth enough to make the hill; put some pales, about a foot high, on the outside; for that will be a sufficient height to keep the rabbits in.

"Feed them as other tame rabbits are fed; and in wet weather, sprinkle saw dust at the bottom, by which means, the quantity of manure will be increased: once a week is often enough to take it away: the quantity will be surprising; nor will the smell be in the least offensive, even though it be quite close to the house. In a very large lawn, two or three of these hills, with the rabbits feeding on tops, will not be unpleasing objects.

"If the bucks happen to be mischievous, in killing the young ones, they must be chained in an alcove; or else have their liberty, as in a warren.

"After a great snow, they will want some assistance, early the next morning; because the ditch will be near filled, and perhaps the alcove, where the hay is, will be blocked up.

"It is a great improvement to castrate the young bucks, and keep them till they are full grown, before you kill them; the flesh will be amazingly finer, whiter, and tenderer. But then it will be best to take them away, and keep them in another warren, lest they should be too numerous, and disturb the breeding does; or else have a few hutches in the alcove, to fatten them in.

"As oil cakes are found of great use in fattening cattle, it is probable they would be as useful in fattening rabbits: it is asserted, that some of the oil mixed with the pollard, or buck wheat, is cheaper than the cakes; never having made the experiment, I cannot ascertain its superior advantages.

"There ought to be one buck to every eight or ten does; and attention should be had to the breeding those sorts, whose skins are in the greatest esteem with the furriers and hatters. These skins are generally of more value than the flesh, especially in the winter, against which time contrive to have the greatest quantity of these fattened bucks.

"Where does are kept in hutches, they are supposed to breed

breed six times a year, and only five young ones are left to each, which was thirty from each doe : but as these are in a more natural way, and the young ones difficult to be gotten at, let us suppose about thirty-six to be produced from each doe, reckoning only seven pence for each ; there is a guinea profit from each doe ; as the additional value of the skins in winter, and the dung, will more than pay the expence of food, and attendance on them.

"It is quite necessary, that those who keep many rabbits, should cultivate some lucern, parsley, and carrots, as no other vegetables are such proper food for them as these ; they should also be fed on some of the best upland pasture hay ; for if it be coarse, so far from eating, they will waste it. Lucern hay is very proper for them.

"If a warren be made on the same plan for hares, it ought to be much larger, and some furz and thorns planted on it, for cover for them, but if there be not several rods of ground in it, there will be no chance of their breeding : therefore the warren can only be supported by turning leverets into it." *Weston's Tracts*, p. 133.

Mr. Marshall, in his Rural Economy of Yorkshire, says that "the Vale affords few rabbit warrens ; the northern margin is the only part of it adapted to this species of live-stock. At Dally there are two pretty large warrens. At Lockton there is one now planting. And there are other parts of these heights which might be profitably stocked with rabbits. In general, however, property is too much intermixed to admit of an improvement so singularly adapted to the nature of these high grounds.

"In situations where the ground, as well as the soil, is suitable to rabbit-warrens, and where an extent of it sufficiently large can be collected together in one property, there is a very strong reason why it may be profitably stocked with rabbits.

"The hide of a bullock (of some breeds) is not worth more than one-twentieth of his carcase. The skin of a sheep may, in full wool, be worth from a sixth to a tenth of its carcase. But the fur of a rabbit is worth twice the whole value of the carcase : therefore, supposing the rabbit to consume a quantity of food in proportion to its carcase, it is, on the principle offered, a species of stock nearly three times as valuable as either cattle or sheep.

"This theory is strongly corroborated by an incident of practice. One of the warrens of this district contains eighteen hundred acres of surface ; most of it covered with a black moreland soil ; part of it a barren dead gravel ; some little of it a thin limestone loam ; not worth perhaps, on a par, for the common purposes of husbandry, a shilling an acre ; nevertheless, these eighteen hundred acres are let, as a rabbit-warren, for three hundred pounds a year.

"I will not pretend to say that the warren here alluded to is worth three hundred pounds a year, nor assert that it is not worth a shilling an acre to a husbandman. If it be worth two hundred and fifty pounds as a warren, and supposing it to be worth even two shilling an acre as a farm, it still is a sufficient evidence of the profitableness of rabbit-warrens, in proper situations.

"As I shall, in giving a sketch of the husbandry of the Wolds, have occasion to speak fully of this species of stock, it is needless to dwell on the subject in this place."

In his Rural Economy of Norfolk. Min. 79, he says, 1782, February 23. "A considerable part of a farm which lies toward the coast, being hilly and very badly soiled, more especially the tops and sides of the hills, which have always been full of rabbits in spite of all endeavours to destroy them, the tenants last year applied for leave to convert this part, about ninety acres, into a rabbit-warren. Leave was given, and an allowance made them of half the estimated expence of raising a sodwall fence round these ninety acres.

"The fence is nearly finished, and the warren has this year turned out beyond expectation : it is valued, by one who ought to be the best judge of its worth, at forty pounds a year ; which is nine shillings an acre.

"As the part of a farm, these ninety acres are not worth five shillings an acre : at the present price of barley, they are not worth more than four shillings an acre.

"Thus, for ten pound, a real improvement of twenty pound a year has been made and secured ; for the warrener will, through necessity, hereafter keep the fence in repair.

"The fence is made about four feet high, and three feet thick ; faced with green-sward ; and capped with furze, so as to project eight or ten inches over the face. Some of it was done for a shilling a rod ; but the spring putting in,

fourteen or fifteen pence a rod of seven yards was obliged to be given.

"A neighbouring warrener, this winter, gives nine-pence for the wall, without the capping ; which he does not mean to put on till the wall be thoroughly settled. This is very judicious : several rods of that abovementioned, shot down in different places.

"There are several patches in the vallies, and some on the tops of the hills which have usually been tilled. Some of these were last year, and some of them ought to be every year, cultivated for the rabbits ; when the grass gets foul or mossy, plough it up ; fallow, sow turnep-seed for present feed (they will not let rape get up), and prepare the soil for barley and grass-seed the ensuing year. Thus a regular succession of feed might be kept up.

"The way the Norfolk warreners take to destroy eagles, kites, and other birds of prey, is natural and simple. These birds are shy and suspicious ; they like to settle where they can have a clear view round them for some distance : a naked stump or hillock is their favourite resting-place. The warreners, therefore, raise mounds of earth of a conical form, in different parts of the warren, and place steel traps upon the points of those artificial hillocks."

In Min. 38. he says "the soil of this county, viewed at large, might be termed a rabbit-soil ; and it is highly probable that, before its present system of husbandry took place, a considerable part of it was occupied by this species of live stock.

"At present, however, they are, in this district, wisely confined to the heathlets, and the barren hills upon the coast. A level country is unfit for rabbit-warrens, but convenient for the plough : on the contrary, rabbits delight in the sides of sandy hills ; which, where turnwrist ploughs are not in use, are extremely inconvenient for tillage ; and, when cultivated, are generally unproductive.

"The rabbit, on level ground, finds it difficult to make its burrow ; the excavated mould is all to be dragged upward to the surface : hence a piece of ground, altogether level, can seldom be stocked successfully with rabbits, unless it be first laid up, by art, at a great expence, into inequalities.

"On the contrary, against the side of a steep hill, the rabbit has no difficulty to encounter : the declivity affords him a ready vent for his mould ; his work is all down hill : and unless the soil be too stubborn, or too rocky, for the rabbits to work freely among, a broken hilly country may generally be stocked with advantage ; provided a tolerable market for the carcases can be had within reach.

"There are, perhaps, few sandy or other loose soiled hills, which would not pay better in rabbit-warrens than under any other course of husbandry."

RACK, a wooden frame made to hold hay or fodder for cattle.

RACKING FRUIT LIQUOR. See ORCHARD.

RADICLE, that part of the seeds of plants, which upon vegetating becomes its root, and is discoverable by the microscope.

WOOLLEN RAGS, and the nippings of the pitch marks upon sheep, are singularly good manure. The rags should be chopped small, about an inch or two square, and scattered on the earth at the second ploughing ; for being thereby covered, they will begin to rot by seed-time. They imbibe the moisture of dews and rain, retain it long, and, as Dr. Home observes, thereby keep loose soils in a moist state. They cost about four-pence a bushel at London, from whence many loads are sent every year to Dunstable, which is thirty-three miles, where they are laid even on stiff-lands, just after the sowing of the corn, allowing to the acre four sacks, of six bushels each.

RAG-WORT, or as it is called in Yorkshire, scagrim, is a very pernicious weed.

The reverend Mr. Comber, of East-Newton, has obliged the public with the following observations on the growth and destruction of ragwort, or scagrim.

"This plant, says he, has a stalk, in its early state, green, but, as it advances in age, inclining to violet or purple, especially downwards. Its flowers are yellow, and thick set, and composed each of a number of small pointed leaves. It runs to seed in the latter end of summer. The seed, both of the stalk and leaves, which are jagged, (whence probably it obtains its name), and the flower itself, are offensive to all animals, I think ; for I have observed, that hardly any creatures feed upon it, except almost starved. I have not indeed observed whether or no asses reject it.

" Like most other weeds, it thrives best in the best soils, either natural or artificial ; and I took up a plant of it in my orchard, about two years ago, (with the root) which, when in flower, touched my chin ; (my height is about five feet eight or nine inches) and its root, which is round, and thick set with taws, was much larger than a new born child's head : but the usual dimensions are much less than these.

" About four years ago, I observed the spreading of this weed in that part of this estate which was in our own hands. I took notice, that neither cows nor horses eat it ; and when I smelled it, I ceased to wonder that they did not. It was obvious to remark, that a weed so bulky as this, and so gross, must extract much nourishment from the earth, and that it was advisable to get rid of it as fast as possible. The most easy method was mowing ; I therefore ordered a servant to mow these weeds in the pastures as near to the ground as he could ; and I hoped that the common mowing in the meadows would be sufficient to destroy them : but I soon found my mistake ; for in a very few weeks these offensive strangers shot up again in a stalk and leaf, and even flower, though all in much smaller size than before, but with this disagreeable circumstance, that the root was so far from being injured with the scythe, that for one stalk several arose, and the roots seemed to have gained new vigour from the wound.

" I now applied myself to plucking up by the roots these odious inmates, and found new difficulties. For while the ground was dry, as it usually is in the latter end of summer, I found the stalks of such of the seagrims as were longest, and afforded the tightest grasp, either break in plucking, and leave the root in the ground entirely, or at best bring with it only a small part of the root ; and when the wet weather came on, and loosed the ground, and made it possible, or even easy, to bring away the whole ball of the root, yet the season of feeding was come on also, and the earliest ripe seeds had dispersed themselves, and produced an assurance of a larger crop for succeeding years than the most careful plucking of the present crop could destroy.

" But if these were the difficulties which attended my attempts to eradicate those seagrims, which had happened not to be mowed, I was much more embarrassed by those which had been ; for here it was impossible to get any such fast hold, as to pluck them up with much, or even any root.

" I now applied myself to inquire what gentlemen or farmers were plagued with this weed, and what methods they had tried with success to destroy it.

" I was told by a gentleman in my own neighbourhood, that Sir G. Cayley, of Brimpton, near Scarborough, baronet, had been plagued with this weed, and had pursued the method of plucking, with success.

" Animated by this assurance, I resolved to pursue this method with great attention ; and as it seemed to be a work which requires great care, both in the choice of season and manner of plucking, I resolved not to depute the work to others, but to endeavour to clear a spot in my cow pasture with my own hands, that, if my labour succeeded, I might employ others to follow the same method under my own eye in the rest of this pasture.

" Accordingly, in the evenings of the summer, or rather autumn, of 1762, after showers, I applied myself to this work ; and by the help of a pair of strong gloves, and a tight grasp, I brought up almost every root, in a space of about two hundred yards square, whole ; so that I had good hopes I should see this spot clear in the succeeding summer. It is true, I saw leaves of the species of this weed, and of a very vivid green too, around the plants which I pulled up : but as I reasonably concluded these to be fed by the taws which spread themselves from the main root, so I (methought reasonably) concluded also, that this main root being destroyed, the side taws would die, and consequently these young leaves.

" But how was I disappointed, when in the summer of 1763, I saw this spot of ground as much over-run with seagrims as any part else of the pasture which had been unpul-
led !

" Conversing, however, with G. Watson, of New Malton, esq. towards the latter end of the summer, on this subject, I was assured by him, that by a repetition of this labour of plucking for some years, he thought he had lessened the number of his seagrims, though they were still numerous. Urged by this example, I have gone through the whole of my pasture, which is about ten acres, and

kept five cows, at the latter end of last summer, of 1763, with the same care as was used to a small part of it in 1762 ; yet am I not elated with much hope of success ; for a little plot before my garden (in which my horses run, and which was managed with still more accuracy on account of the odious appearance of the seagrims from my windows), seems to threaten another considerable crop.

" As I did not confine my enquiries about the method of destroying this hateful weed to any one rank of men, I was told by an honest quaker, a farmer in my neighbourhood, that he had found turning of sheep in winter into his cow-pastures the only effectual method of destroying this hateful weed.

" I thought this method very likely to succeed ; for sheep are such close eaters, that I have known them destroy whole beds of the rankest docks, which could not be killed by any other means.

" I have not been able to try this experiment considerably ; for, as I am raising quick fences, both in my meadow and pasture, I keep no sheep. I have, however, occasionally admitted some of my tenant's sheep into the small plot before my garden this winter ; and, upon an accurate examination this morning, I do not entertain any sanguine hopes of great success from this method. I find that many of the young leaves of this weed, now level with the surface of the ground, are untouched by the sheep ; and that such others as appear bitten by them, do not seem in a dying condition.

" The truth seems to me, that sheep, though they may not have the same aversion to this weed as horses and cows, yet are far from being fond of it ; and if any great success is to be hoped for from their bite, (which may prepare beds for the water, and so decay the root), the sheep should be folded pretty close upon it, and obliged to eat it near, and at such a season that the winter rains may have time to work its destruction. And such a method, if carefully pursued, seems to be most probable for the extirpation of this pernicious weed.

" If the method of plucking is followed, I would subjoin some caution.

" First, In order to prevent the large plants from seeding, I would advise to cut off all the tops, and the tops only, when the flowers begin to die, that then good hold of the stalks may be gotten.

" Secondly, I would defer the plucking till the rains have moistened the ground sufficiently to bring up the whole main root.

" Thirdly, I recommend striking the root so brought up against the ground, in order to disperse the earth which adheres to it, by way of manure.

" Fourthly, I always pile the plants thus pulled up and cleaned from earth, that, if the season prove favourable, they may be burnt, and the ashes arising from them spread on the ground ; or if this cannot be conveniently done, (though it is much the better method, and may, with a sufficient fire, be done when they are ever so green), left to rot and manure the soil.

" The grossness, and even stench, of this weed, is a proof of the great quantity of salts it contains ; and in the same proportion as any plant exhausts the ground of its salts, it repays when reduced to manure. There can, however, be no question, but whilst weeds are left to rot, great quantity of the salts, which by burning would mingle with the soil, are carried into the air.

" I suppose your readers will be curious to know, in what manner I account for the sudden appearance of seagrims in vast abundance, in this estate, where they were hardly ever known before.

" I will give you an account, which, I dare say, you will esteem perfectly satisfactory. About eight years ago, I undertook to improve a piece of ground of about fourteen acres, which was overrun with thorns of both sorts, brambles, broom, and furze.

" When I had got it cleared of all this trash, my next business was to pare the hills off, and pile them, and after a winter's mellowing, to break and spread them with a mixture of lime, and all other kinds of manure which I could collect. As the soil was very poor, having been exhausted by the great quantity of trash it had nourished for many years. I was not yet satisfied, but resolved to take the advantage of the first dry summer, to lead out the riches of a pond of about thirty yards long and half as many broad, which had been occupied by a great number of greese, &c. and never thoroughly cleaned

during near thirty years. I got through this work, though at a great expence, being obliged to employ a considerable number of draughts, lest the rain should make the mud too thin, or the heat bake it too much, the mud being for a considerable space a yard perpendicular.

"All this mud I laid on my newly-improved ground, except a few cart-loads, which were brought and laid by the wall of a kitchen-garden, to be mingled with the other soil.

"I had divided my improved ground, reserving about four acres for meadow.

"Behold! the succeeding year gave me a crop of seagrims both in my new meadow, my new cow-pasture, and the plot of ground in which the mud for my garden had been scattered; and more particularly on those parts where the ground had been broke, either to stub the thorns, &c. or to take away the hills, while the adjoining ground on each side was free from this pernicious weed.

"As I knew little or nothing of this weed, I suffered it to seed before I took any necessary precautions for its destruction. The succeeding year presented me with a much larger crop, and I have been ever since struggling for its extirpation, and have the mortification to see its encroachments on adjoining grounds by the seeds which winds have carried.

"This fact, and another of the same kind, in a piece of ground which I improved since, at some distance from the former, have confirmed me in an opinion, which I before thought very probable, viz. "That all soils are originally impregnated with the seeds of almost all grasses and weeds, (though of some in greater quantities) which only want a proper stirring and manure to awaken them to vegetation, though at the expence of one another, some being suffocated by that process which gives life to the others."

"I will add another striking instance in confirmation of this sentiment, notorious in this neighbourhood.

"A considerable quantity of the park at Gilling was overrun with brakes and moss, and that wretched grass which grows in such company. Lord Fairfax, the owner, finding that he could not have his venison fat as it ought to be, destroyed his park, and applied himself seriously to the improvement of it at a vast expence. In course of time, by due tillage, he brought this worst part of it to be not only good corn-land, but even tolerable, though coarsh, meadow and pasture; yet both of them thick set with seagrims, a weed never seen there till the quantity of lime which his lordship put into that poor soil had warmed it sufficiently.

"I have only to add, on this subject, that I am persuaded seagrim does more harm in meadow than pasture land; for in the latter it only exhausts the ground, on which it stands, to no good purpose; but in the former it communicates its disagreeable stench in the sweat to the good hay, and destroys its sweetness. I advise, therefore, that hay-makers be ordered to throw it with their rake-shafts out of the swarth whenever they meet with it." *Museum Rusticum*, vol. V. p. 117.

RAM, the male of the sheep kind. See the article SHEEP.

A correspondent of the editors of the *Museum Rusticum* has obliged the world with the following method of gelding rams:

"It was, says he, a long time before I came into a proper method of gelding my rams: I used, like my neighbours, always to employ a common gelder, who cut and seared them; however, I observed that this not only put the animal to great pain, but was a considerable time before it healed, and the sheep or lamb always lost flesh in no slight degree.

"Whilst I was musing how to improve this practice, a friend of mine, a farmer, who came accidentally to see me, out of Bedfordshire, advised me to leave off gelding my rams in the manner I had practised, and, instead of it, to have them knitted.

"The method of doing this he described as follows. First take some small, yet strong, twine, not too hard twisted; add three of these together, and slightly twist them on your knee, as the shoe-makers do their thread; then wax it well with shoe-maker's wax, and it is ready for use.

"When you are thus prepared, take a proper length of this twine; tie each end of it to a short bit of stick, as thick as a walking-cane; then put it round the cod, and tying a single knot, do you take hold of one stick, and draw

it, whilst another man draws the other, as tight as you well both can; for on the tightness of the drawing depends the success of the operation.

"The animal immediately loses all sense of feeling in the cod, the circulation of the blood thither is stopped; and if it was to be let alone, it would rot off, but this is a bad, as well as a nasty and dangerous practice; for the sheep sometimes die of the stench.

"The best way is, at the end of nine days, to cut off the cod; but then you must take a great deal of care you do not cut it too close to the tying; if you do, the string may chance to slip off, and the consequence be dangerous; as by such a neglect many sheep may be lost in a season.

"Many farmers, I am informed, when they knit their rams, trust to the strength of one man's arms; and this may sometimes be well enough, when your workman is strong, attentive, and willing; but if he is failing in any of these points, ten to one but an accident happens: I therefore always chuse to employ two men at this work.

"The season I chuse, is the spring of the year, though some prefer November, after the ramming season is over: I have many reasons for this preference, and particularly, I think that the warm weather coming on, hinders them from pining, or falling off their flesh, and soon re-establishes them in their perfect health. When this operation is performed in November, and the winter is either wet or frosty, the sheep are pinched by the cold, and pine away considerably, not having that heartening food, to keep them in spirits, as they meet with in the spring of the year.

"I have observed, that if the rams are not in good flesh, or have not been pretty well fed, they do not undergo this operation so well: I therefore always take care to keep them particularly well some time before, and also some time after the business is done. This is an attention by no means thrown away, for without it some miscarriages may happen, which would otherwise be avoided.

"When I say I prefer knitting my rams in the spring, I mean before the hot weather comes on; as to the particular time, I am governed by the season: if it is deferred till summer, the flies will surely be troublesome." *Museum Rusticum*, vol. IV. p. 159.

In a succeeding Number of the same work, another correspondent has laid down the following method, which he thinks preferable to the former. He declares he has practised it for ten years, and in that time he had not lost a single one by gelding, out of several hundreds; neither do they lose flesh: on the contrary, some of them, that did not thrive before, rather fatten better after, if the pasture does not fail. The success he imputes to the evacuation of the humours, by cutting the scrotum, &c. may be the occasion of it.

"What, says he, is necessary to be observed, by way of caution, is as follows: When I am about to have my lambs gelt, I take dry, fresh weather to do it in; for which purpose I defer it until they are about two months old, which brings, at least, the middle of May for that work to be performed in; but, in order to have a settled state of weather, and the moon in decrease, I do it either a little sooner, or a fortnight latter, when I judge the work may be done with safety, according to the above caution.

"I have the lambs put into a fold that has a good wall, or dyke, about it, by seven or eight o'clock in the morning, or as soon as the dew is off. A man is appointed to stand within the fold, with his back against the wall or dyke, who may be called the holder: another is appointed to take the lambs, one at a time, taking care not to heat them either in folding or taking them.

"When he has taken a lamb, he brings it to the holder, who takes it by the hinder hough, and presses its back against his breast, with its head over his shoulders: the operator then, who generally is the shepherd, takes his knife, and cuts about an inch from the lower end of the cod quite off: he then puts one of his hands close up to the creature's belly, while he presses back the cod with the other; and by that means he causes the bare stones to put out, so that he can easily gripe them one at a time with his teeth, and pull them slowly out.

"He then takes a little salt water, which is prepared on purpose, and set near him, into his mouth, and warms it a little; then he squirts it up the cod, and all is done: the holder handing the lamb over the wall, or dyke, to one that sets it on its feet on the other side, pulling its tail.

tail pretty hard when he lets go, which makes it stretch itself out.

" Thus, in half a minute, a lamb is gelt; and in three or four days all danger is over, if kept from lying on nettles, and the like.

" It is proper to walk the lambs gently about three or four hours after they have been half a day gelt.

" If old rams are to be gelt, I do it about the same season; and the operator takes no other method than that used with the lambs, only putting a bit of salt and butter up the cod instead of squirting up a little salt water; the holder, indeed, must not now stand, but sit on the ground, gripping the ram by the houghs, while he lies on his back, with his head over one of the holders thighs, &c.

" My reasons for letting the lambs be about two months old before they are gelt, besides the reason before given, are, that at that age they are better able to bear the pain of the operation than when they are young and weakly; and the strings as they are called, are so strong that they do not break, but come entirely out along with the stones, which makes a free passage for matter to issue out by the cod; whereas, when they are gelt very young, as is the practice with some, the tunica albuginea or strings as they are vulgarly called, being but weak, they often break, probably occasioning inflammations, &c. which certainly ought to be avoided, if possible. This occasions more to die, when they are gelt young, by the operation, than when cut at two months old.

" I mentioned having the moon in decrease when I have my lambs, &c. gelt, which by some, perhaps, will be thought a circumstance not worth notice: but let such only attend to the wonderful effects the luminaries have on fluids as well the juices of the animal oecconomy, as others, when they are in the positions that constitute new and full moon; and they will, I dare say, be disposed to think the hint is not quite impertinent.

" The reasonableness of my conclusion is not deduced from argument only, but has the authority of experiment, as follows:

" I attempted to geld my lambs, one year, just at full moon: the first lamb that was cut bled very sorely; the next did the same. I tried as far as half a dozen, and none of them were otherwise. I then apprehend there was danger, so deferred cutting any more for five days, when there was a great abatement in the bleeding: besides, one of the six gelt at full moon dropt, and none of the others that were gelt five days after did, although they were above twenty times the number of the former (the weather and usage were nearly the same.) This, I own, carried conviction enough for me. Those that will not be convinced by my relation of this fact, I, notwithstanding do heartily wish them no worse luck than I have had in that way; but withal they had as good use circumspection." *Museum Rusticum, vol. IV. p. 331. See SHEEP.*

RAPE, the name of a plant much cultivated for its seed, and also as a food for cattle. *See the article COLE.*

In 1769, Mr. Baker began to make some experiments upon rape, but these were only small; in 1770, he extended them further, upon land which he thus describes. " A shallow soil, of a strong adhesive nature when wet, and when perfectly dry, in lumps, almost impregnable; but between wet dry, reducible. It lies upon a bed of limestone quarry, and has a natural declivity to the north-west; naturally very poor, and, I believe, never received any manure until I dressed it. Three acres of this land was in 1768, under potatoes, in the ordinary method of the country, in

seven feet beds, and four feet trenches. In 1769, it was under drilled turnips.

" The frost, snow, hail, and rain, which we had this year in the months of March and April, rendered it impossible to get the ground in any tolerable condition for the rape seed before the 28th day of April. On that day twenty broad sets were sown, with twelve ounces of rape-seed to each set, or ridge. I intended to have sown it earlier, but the event will shew, that, as it was, I sowed it too early, at least upon this ground.

" It was slow in coming up, and made but a poor figure until July. After which it shot forward; but instead of affording a plentiful mowing crop for the purpose of foddering cattle, it soon began to run up very fast, broke out into branches, with few and small leaves, like rape in blossom from autumn sowing, but with strong branches and few leaves: and, in a short time after, began to grow hard, pipey, and the seed to form.

" In September, I began to mow it for cattle, and they eat it with great eagerness; but every day it became worse, by growing harder; insomuch, that before it was exhausted, there was very great waste, as to the object of fodder, but it wonderfully raised the dughill, which in my mind is of the first moment to the farmer: for if he has manure in plenty, and disposes of it judiciously, there is hardly any thing he need to fear, except climate.

" It was pretty far in October, before all this rape was cut (and the seed coming forward very fast) although it was brought home in great profusion. It was so strong, that the mowing of it could not be accomplished with a common scythe; it would have broken an hundred; but I have by me a short, strong scythe, with a thick back, intended to mow bushes, and other rubbish: with this instrument I got it mowed, but not so close to the ground as I wished, it being next to impossible to mow such strong plants as these were close to the ground; and I became the less solicitous about it, as from the strength of the rape stumps and roots, and the weeds which were upon the ground, owing to the rape shooting up in tall stems, I gave up my intention of sowing the ground with wheat, as was originally intended. Hence I conclude, that the rape was sown much too early.

" On the 16th of July, I transplanted some of this rape; in rows upon ridges four feet wide; these plants flourished much better than the former, and were at least four times the size of any of those left in the ground where they were sown. Nevertheless, these also ran to seed; but the cold nights coming on, prevented their forming their seed like the former. They were vastly more sappy, and much better food for cattle.

" On the 24th of July, I drilled rape seed upon the same ground.

" No. 1. Six ridges four feet wide, and thirty-two perches long, in single rows.

" 2. Six ridges the same length and breadth, in double rows, ten inches asunder.

" N. B. The double and single rows were drilled alternately on the same ground, on the 18th day of July.

" 3. Six ridges, four feet wide and thirty-two perches long, drilled in single.

" 4. Six ridges, the same length and breadth, in double rows, ten inches asunder.

" N. B. These were sown in alternate rows, on the same ground, on the 24th of July.

" The several rows were thinned the latter end of August, and twice horse-hoed during the summer.

" On the 3d of April, 1771, I had a row of each of these cut and weighed, and the produce was as follows:

	Ton cwt. qr. lb.				Prod. p. Plantation acre.		
					Ton cwt. qr. lb.		
" No. 1. Single row produced	1	2	1	11	} Sown July 18th.	29	6 1 16
" 2. Double row ditto	1	4	3	13		32	12 2 23
" 3. Single row ditto	1	5	2	22	} Sown July 24th.	33	14 1 26
" 4. Double row ditto	1	6	3	25		34	18 0 6

" The last sowing in July, we see, affords considerably greater produce than the first, for the plainest reason, that the earlier we sow this seed, the sooner it runs; and consequently affords the less produce for our purpose of foddering cattle in the yards, for making dung, and seems to account very strongly for the state of our first experiment.

" The double rows produced uniformly more than the

single rows; and indicate that the double are to be preferred in drilling rape for foddering cattle.

" Rape-seed sown Broad-cast.

" On the 24th of July, two acres were sown broad-cast, with ten pounds of seed to each acre, in the same field where the other experiments were carried on: but the soil not

R A T

“ There is yet another circumstance, which renders this a truly valuable fodder. The milk of the cows increased prodigiously ; and the milk and butter were as good, sweet, and well flavoured, I think, in every particular, as ever I tasted in June. Even the cream for the tea, appeared to be perfectly free from any foreign flavour. The cows got hay every day, in the same manner as I have in former years mentioned them to have, when feeding upon cab-bages.

“The simplicity of the culture for rape, for this purpose of feeding cattle, I cannot but think a particular recommendation of it to the farmer, and the cheapness of the seed in purchase, or the ease with which he may raise it, are objects which cannot fail, I think, of being persuasive to him. And all persons, who have annexed to their farms, any bog, or other waste ground, the improvement of which, that can be executed by burning, might surely raise such quantities of rape for the purpose of mowing pasture, as would enable them to keep almost any number of cattle; by which they would not only be bringing in the waste land, but making that the foundation of improvement to their sound land, by the immense quantities of dung they might raise by this means, from the waste land. Here the advantage to the cultivator would be double.

“ On the first day of May, I had four perches of this rape measured out for weighing. It was mowed, immediately drawn home, and weighed. The four perches afforded seven hundred and two quarters: multiplying this by forty, shews our acreable produce to be fifteen tons. The quantity indeed but small. However, the season in which it is to be had, renders it more than ordinary valuable, and I think bids fair to make it an object of husbandry, as a pasture for cattle.

“ This year Mr. Baker ploughed up six acres of wheat stubble, as soon as the wheat came off, harrowed it down the 12th, 13th, 14th, and 15th of September, then sowed rape seed over the whole field, and gave it a light bush-harrowing. The rape came up very thin, and made so poor an appearance in the spring, that he ploughed up the field, and sowed spring corn. This is a strong indication, that but little is to be expected from sowing rape upon wheat stubble; because, after the wheat comes off, it seems to be too late in the year to sow rape. But something may be charged, as he observes, to the natural moisture of the soil. See COLE SEED.

“Recapitulation of Experiments on Rapes, as Pasture for Cattle.”

"Baker's Report for 1771."

in an unusual manner, the rest take the alarm, and become so shy and wary, that they elude all the devices and stratagems of their pursuers for some time after. This place, where the rats are to be assembled, should be some closet, or small room, into which all the openings, but one or two, may be secured: and this place should be, as near as may be, in the middle of the house, or buildings. It is the practice, therefore, to attempt to bring them altogether in some such place, before any attempt be made to take them; and, even then, to avoid any violence, hurt, or fright to them, before the whole be in the power of the operator.

The means used to allure them to one place are various : one of those most easily and efficaciously practised is, the trailing some piece of their most favourite food, which should be of the kind that has the strongest scent, such as toasted cheese, or broiled red-herring, from the holes or entrances to their accesses in every part of the house, or contiguous buildings, whence it is intended to allure them. At the extremities, and in different parts of the course of this trailed tract, small quantities of meal, or any other kind of their food, should be laid, to bring the greater number into the tracks, and to encourage them to pursue it to the center place, where they are intended to be taken; at that place, where time admits of it, a more plentiful re-

paſt is laid for them, and the trailing repeated for two or three nights.

Befides this trailing, and way-baiting, ſome of the moſt expert of the rat-catchers have a ſhorter, and perhaps more effectual method of bringing them together; which is, the calling them, by making ſuch a kind of whiſtling noiſe as reſembles their own call, and by this means, with the aſſiſtance of the way-baits, they call them out of their holes, and lead them to the repaſt prepared for them at the place deſigned for taking them. But this is much more difficult to be practiſed than the art of trailing; for the learning the exact notes, or cries, of any kind of beaſts or birds, ſo as to deceive them, is a peculiar talent, not eaſily attained to in other caſes.

In the practiſing either of theſe methods of trailing, or calling, great caution muſt be uſed, by the operator, to ſuppreſs and prevent the ſcent of his feet and body from being perceived; which is done by overpowering that ſcent by others of a ſtronger nature. In order to this, the feet are to be covered with cloaths rubbed over with aſſa ſœtida, or other ſtrong ſmelling ſubſtances; and even oil of rhodium is ſometimes uſed for this purpoſe, but ſparingly on account of its dearneſs, though it has a very alluring, as well as diſguiſing effect, as will be obſerved below. If this caution of avoiding the ſcent of the operator's feet, near the track, and in the place where the rats are propoſed to be collected, be not properly obſerved, it will very much obſtruct the ſucceſs of the attempt to take them: for they are very ſhy of coming where the ſcent of human feet lies very freſh, and intimates, to their ſagacious inſtinct, the preſence of human creatures, whom they naturally dread. To the above-mentioned means of alluring by trailing, way baiting, and calling, is added another of very material efficacy, which is, the uſe of oil of rhodium, which, like the marum ſyriacum in the caſe of cats, has a very extraordinary fascinating power on theſe animals. This oil is extremely dear, and therefore ſparingly uſed. It is exhale in a ſmall quantity in the place, and at the entrance of it, where the rats are intended to be taken, particularly at the time when they are to be laſt brought together, in order to their deſtruction; and it is uſed alſo, by ſmearing it on the ſurface of ſome of the implements uſed in taking them, by the method before deſcribed, and the effect it has in taking off their caution and dread, by the delight they appear to have in it, is very extraordinary.

It is uſual, likewiſe, for the operator to diſguiſe his figure as well as ſcent; which is done by putting on a ſort of gown or cloak, of one colour, that hides the natural form, and makes him appear like a poſt, or ſuch inanimate thing; which habit muſt likewiſe be ſcented as above, to overpower the ſmell of his perſon: and beſides this, he is to avoid all motion, till he has ſecured his point of having all the rats in his power.

When the rats are thus enticed and collected, where time is afforded, and the whole in any houſe and out-buildings are intended to be cleared away, they are ſuffered to regale on what they moſt like, which is ready prepared for them, and then to go away quietly for two or three nights; by which means thoſe, which are not allured the firſt night, are brought afterwards, either by their fellows, or the effects of the trailing, &c. and will not fail to come duly again, if they are not diſturbed or moleſted. But many of the rat-catchers make ſhorter work, and content themſelves with what can be brought together in one night or two; but this is never effectual, unleſs where the building is ſmall and entire, and the rats but few in number.

The means of taking them, when they are brought together, are various. Some entice them into a very large bag, the mouth of which is ſufficiently capacious to cover nearly the whole floor of the place where they are collected; which is done by ſmearing ſome veſſel, placed in the middle of the bag, with oil of rhodium, and laying in the bag baits of food. This bag, which before lay flat on the ground with the mouth ſpread open, is to be ſuddenly cloſed when the rats are all in it. Others drive, or fright them, by ſlight noiſes or motions, into a bag of a long form, the mouth of which, after all the rats are come in, is drawn up to the opening of the place by which they entered, all other ways of retreat being ſecured. Others, again, intoxicate or poiſon them, by mixing with the repaſt prepared for them, the coculus Indicus, or the nux vomica. A receipt for this purpoſe has appeared, which directed four ounces of the coculus Indicus, with twelve

ounces of oatmeal, and two ounces of treacle or honey made up into a moiſt paſte with ſtrong beer; but if the nux vomica be uſed, a much leſs proportion will ſerve than is here given of the coculus. Any ſimilar compoſition of theſe drugs, with that kind of food the rats are moſt fond of, and which has a ſtrong flavour, to hide that of the drugs, will equally well answer the end. If, indeed, the coculus Indicus be well powdered, and infuſed in the ſtrong beer for ſome time, at leaſt half the quantity here directed will ſerve as well as the quantity before mentioned. When the rats appear to be thoroughly intoxicated with the coculus, or ſick with the nux vomica, they may be taken with the hand, and put into a bag or cage, the door of the place being firſt drawn to, leſt thoſe which have ſtrength and ſenſe remaining eſcape.

By theſe methods, well conducted, a very conſiderable part of the rats in any farm, or other houſe, and the contiguous buildings, may be taken. *Muſeum Ruſticum, vol. I. p. 395. See VERMIN.*

RAT-TAILS, excreſcences which creep from the paſtern to the middle of the ſhanks of a horſe, and are ſo called from the reſemblance they bear to the tail of a rat. Some are moiſt, and others dry; the former may be treated with drying ointment and waſhes, the latter with mercurial ointment. If the hardneſs does not ſubmit to the laſt medicine, it ſhould be pared off with a knife, and dreſſed with turpentine, tar, and honey, to which verdigris or white vitriol may occaſionally be added; but before the uſe of the knife you may apply this ointment:

Take black ſoap, four ounces; quick-lime, two ounces; vinegar enough to make an ointment. *Bartlett's Farriery, p. 296.*

Coach-horſes of a large ſize, that have their legs charged with fleſh, hair, &c. are moſt ſubject to this, and ſuch like infirmities, which ſeldom happen to middle-ſized horſes.

The cure: ride the horſe well till he be warm, which will make the veins ſwell and appear better: afterwards bleed him well on the fetlock veins, on both ſides, and next day waſh the ſores with warm water, and then clip away all the hair about it, and anoint the part aggrieved with the following ointment:

Take green copperas and verdigris, of each four ounces; of common honey, half a pound; reduce the copperas and verdigris to a fine powder, and work them up with the honey to a due conſiſtence; uſe this ointment till the ſore be healed. Or, take a quarter of a pound of Flanders oil of bays, a quarter of an ounce of oil of turpentine, and ſix drachms of quickſilver, mix the quickſilver and oil of turpentine well together, and then add the oil of bays, and ſtir all together till you cannot diſcover any of the particles of the quickſilver; with which anoint the horſe's legs twice a day; and when he comes from exerciſe let his legs be well waſhed with ſoap and warm water and wiped dry.

REAPING CORN. Mr. Young, in his *Annals of Agriculture, vol. VIII*, gives the following account of a machine for reaping corn, by Mr. William Pitt of Pen-deford. *See PLATE XXV.**

"In purſuance of the idea contained in Mr. Loſt's tranſlation, from Pliny and Palladius, *vol. IV. p. 205*, the enclosed drawings are deſigns for a machine for reaping, or rather rippling corn in harveſt, by an horſe or ox. The farther proſecution of this idea, is earneſtly recommended to Mr. Winlaw, as preparatory to his rubbing mill; as, were it brought to perfection, the buſineſs of rippling being cheaply and expeditiouſly done in the field, the corn is rendered fit for the rubbing mill, without farther preparation. Fig. 1, ſection of the machine to be pushed forward by an horſe or ox; as the machine goes forward, the wheel A gives motion to the pulley B, fixed on the ſame center and by means of the band C, to the pulley D, and tooth wheel E, which latter gives motion to the pinion F, and rippling cylinder G, the rippling cylinder going round twice, for the wheel A once, and its iron combs or teeth, rippling off the ears of corn in rotation, let them fall into the ſmall car A, from whence a man with a prong or ſhovel is to remove them into the great car K, which being filled, the beaſt may be turned the contrary way and the whole drawn to the ſtore-rooms.

"The grain thus collected in a ſhort time of the moſt favourable weather, the ſtraw may be cut and collected at leiſure, and with leſs regard to rain or ſhowers than is neceſſarily the caſe in the common mode of harveſting."

Fig. 2. Plan of the machine : the same letters referring to the same particulars as before. See HARVESTING.

RED-CLOVER, See the article CLOVER.

RED-GAME, an English name of a bird, common in the mountainous parts of Yorkshire, and some other of our northern counties. It is of the shape of a partridge, but much larger, and of a mixed colour of red and black, and is feathered down to the ends of the toes.

RED-LAND, a term much used by husbandmen to express a sandy soil of a reddish hue, interspersed for the most part with pieces of sand-stone of the same colour, or somewhat deeper.

There are several varieties of this soil, one of which is almost entirely made up of sand ; another with an admixture of clay with the sand, the whole making a loose loamy earth, and a third full of fragments of a poor sandy iron ore, and often containing shining specks of selenitæ. *Morston's Northamptonshire.*

RED-WATER. See SHEEP.

RED-WORM, the name of an insect very destructive to young corn.

" I have often (says Mr. Baker, in his Report to the Dublin Society) heard of the havoc which red-worms make in young wheat, barley, and oats ; and in some few writers upon husbandry have read of them, but never saw them till May 1764 ; when to my great mortification, in a few days, they destroyed, almost totally, nine acres of my wheat, for I did not reap above half a barrel per acre. This misfortune induced me to propose to the consideration of the Dublin Society, whether the offer of a premium might not probably produce a discovery of some effectual method for destroying so injurious an insect, to the infinite advantage of the public : and the Society were pleased to offer a premium accordingly.

" I have now the honour to lay before them, what has occurred to me upon that subject.

" The most ingenious M. de Chateaufieux speaks of an insect, which is certainly of the same kind, if it be not the very insect which I have now under consideration. This gentleman, after saying, ' our wheat, in the month of May, 1755, sustained a loss which even that cultivated according to the New Husbandry did not escape, describes the worm thus : we found in it many little white worms, which afterwards became of a chestnut colour. They pos themselves between the blades, and eat the stems. They are usually found between the first joint and the roots ; every stalk, which they attacked, grew no more, but became yellow, and withered. The same misfortune happened to us in the year 1732. The insects appeared about the middle of May, and made such havoc, that the crops were almost destroyed.'

" It perhaps might be expected, that this great man should have made the very enquiry which we are now upon, as the loss appears to have been very great in Geneva, at the two periods which he mentions : but when we consider, how much the high office which he held in the city and republic of Geneva, must have engaged his attention, it is rather astonishing, that he could oblige the world so much as he hath done, by his repeated experiments in husbandry, and his judicious observations upon them : it is therefore less to be wondered at, that this circumstance escaped him.

" The ingenious Mr. Benjamin Stillingfleet also, in the second edition of his Miscellaneous Tracts, in a note, in page 175-6, speaks of an insect, which is probably the same as that which we are seeking to destroy. His words are,

" Thus in Suffolk, and in some parts of Norfolk, the farmers find it their interest to encourage the breed of rooks, as the only means to free their grounds from the grub, from which the tree or blind-beetle comes, and which in its grub state destroys the roots of corn and grass, to such a degree, that I myself have seen a piece of pasture-land, where you might turn up the turf with your feet.

" Mr. Matthews, a very observing and excellent farmer, of Wargrove in Berkshire, told me, that the rooks one year, whilst his men were hoeing a turnep field, fate down in part if it, where they were not at work, and that the crop was very fine in that part, whereas in the other part there were no turneps that year.

" We see, that M. de Chateaufieux describes this worm as being first white, and afterwards becoming of a chestnut colour. I have carefully sought them at different periods, during the past year, but always found them of the same chestnut colour, never varying in any particular except

that of size, which I find to be the case at all seasons, in which I have seen them.

" The insect which Mr. Stillingfleet speaks of, he calls a grub, which, he says, destroys corn and grass : this induces me to believe, that it is the same insect (though the report which he relates from Mr. Matthews seems to contradict it) because I have observed, that the red or chestnut worm, never appears voluntarily upon the surface ; but when the earth is turned up, either with plough or spade, the rooks and crows are very bold in their approach to pick them up ; a circumstance, which I own has in some degree abated my enmity to these birds : I therefore never destroy nor frighten them off my land whilst I am ploughing it ; but when I sow, when the corn rises, and when it is ripe, I destroy or banish them as well as I can, because the mischief which they do at those times is intolerable.

" A member of the Dublin Society informed me last summer that some of his turneps were destroyed by a worm ; I had some few which decayed in their leaves, and became of a lemon colour, preceding the putrefaction which followed, and destroyed the turneps ; I examined their roots, but could not discover any insect which had injured them, and therefore I cannot pronounce that it is the red-worm which destroyed this gentleman's turneps ; but I shall be very watchful with respect to this circumstance, upon every opportunity which may present itself.

" I have observed my lucerne to decay in its tops, soon after it has been up ; and upon examining the roots, I have found the red-worm, which had cut them off.

" This insect seems to be every where in Ireland called the red-worm, by some of the English writers who have spoken of an insect, which destroys the corn in the manner already mentioned ; which I think is undoubtedly the same : it is called a grub, by others the large maggot, and the rook-worm, because the rooks eat it ; but as none of the writers have given any other description of it than the name by which they respectively call it, I shall endeavour to describe it.

" Red-worms are about half an inch long, and about one tenth of an inch in diameter ; they are jointed in their skins, and are of a very firm texture : they have many short legs, two small black specks, which appear to be their eyes ; and two small points springing from their heads, with which I believe they cut the corn, and which, in that work, I apprehend, act like forceps : and all that I have seen of this species, are of a bright chestnut colour. For this reason, I should conceive it would be more descriptive to call them the chestnut worms.

" When they are exposed to the air, by turning up the earth which is infested with them, they will very soon cover themselves again in the soil, which they are very capable of doing by the strength which their make gives them, although they appear to be a sluggish insect, and have not the advantage of a sliminess upon their skins, which the common large creeping worm has, which enables that inoffensive worm to penetrate the earth, and get under timber and stones with ease.

" The red-worm, immediately endeavouring to cover itself from the air, is certainly from natural instinct, as it will soon die, when exposed to the air ; as will appear by the experiment, Numb. 10, hereafter mentioned.

" These worms destroy wheat, barley, oats, and lucerne, while in an infant state, in the months of March, April and May. Late sown barley and oats, they will destroy as late as June. I have not yet experienced that they destroy any other crops.

" The mischief done by them is in dry weather. Rain sufficient to penetrate the ground makes them desist from destroying the corn ; and I suppose, every thing else which they at any time injure.

" They cut wheat off, just above the crown of the roots ; barley and oats in the same place, and also higher up, upon any part of the stem which is below the surface of the earth.

" These worms seem to abound more in ground which is lightly tilled, than in such as hath been well tilled ; but, in lay ground, they seem to be more numerous than any where else : and the fields upon my farm, in which I have found them, are wetter than other fields where they are not ; whether that circumstance contributes to their increase, I cannot say ; but the following experiments prove, that they will live longer in water than they can when exposed to the open air.

Experiments on Red-worms.

- "Numb. 1. I put ten red-worms into a wine-glass with common salt in it. They were all dead in four hours.
- "Numb. 2. Into a glass with brine in it I put ten red-worms. They were all dead in six hours.
- "Numb. 3. Into a glass with lime in it, which had been flaked for a long time, and exposed to the weather, I put the like number. They were all dead in forty-four hours.
- "Numb. 4. Into a glass with the above lime, and some water in it, I put the like number. They were dead in twenty hours.
- "Numb. 5. Into a glass with lime newly flaked, and when cold, I put the like number. They were dead in fourteen hours.
- "Numb. 6. Into lime-water, made with cold water, I put the like number. They were dead in ten hours.
- "Numb. 7. Into a glass with foot in it, I put the like number. They were dead in four hours.
- "Numb. 8. Into foot and water, I put the like number. They were dead in four hours.
- "Numb. 9. Into fair water, I put the like number. They were dead in fifty-two hours.
- "Numb. 10. Into a glass, without any thing in it, I put the like number. They were dead in thirty-two hours.

"By these experiments we see all the articles used will kill this insect in a short time, particularly the salt and foot. I thought it necessary to consider different articles, the better to suit different parts of the kingdom.

"Where lime can be conveniently had, and that it is used as a manure, I am apt to believe, from the experiments, that no injury can be sustained from these worms; but I am afraid a small quantity will not effectually destroy them; besides, I should fear, if it were not put on before the sowing of the corn, that it might singe the blades of the corn; for, from these experiments, it appears, that lime newly flaked, is more suddenly destructive to them than old lime, and therefore it is to be preferred.

"Where lime is used for no other purpose than to destroy this worm, I should conceive, that about eight barrels, regularly sown by hand on an acre of ground, might be sufficient: it must be first flaked and cold before a man can possibly cast it upon the ground with his hand, lime being a very strong caustic; and, even when it is cold, the man should have a thick glove upon his hand.

"Where salt shall be used to destroy this worm, it must always be sown upon the ground, before the intended crop; for, although corn will vegetate, and receive benefit from salt as a manure, when it is used antecedent to the sowing the corn, yet, if it be added after the corn is growing, it will certainly destroy it: therefore, it should never be used for this purpose, but before the corn is sown, or at least before it vegetates.

"I conceive that where salt is used for this purpose only, about four hundred and a half to an acre will answer the purpose, which is a trifle more than one ounce to every square yard.

"We see by the experiment, that foot kills this worm as soon as salt; and as in most places it is to be had at a much less price than salt, I think there can be no doubt about preferring of it; besides which, it may be safely used after the corn is up.

"I had some small parcels of barley under experiments, which these worms began to destroy; and in order to convey the foot as soon as possible to the roots of the plants, I mixed a little of it in water, and poured it on the plants with a garden watering-pot: the consequence was, that I did not lose one plant afterwards.

"It will hardly be imagined, that I mean that the same method is to be pursued upon a whole farm: no; the method I would recommend to the practice of the farmer is this, to spread or cast by hand, as he sows his corn, about six or eight barrels of foot on an acre, and let him be careful to choose a calm day for the work, otherwise the wind will carry away great part of it: and as what remains cannot be regularly disposed, let him be careful to do it early enough in the spring, that the rain may wash in the foot and convey it to the roots of the plants before the worm begins the mischief; if he does this, I am persuaded his crop will be preserved.

"We see by the experiments, that this worm will live

longer in water, by twenty hours, than when exposed to the open air; but at length, i. e. in fifty-two hours, they died in the water; perhaps this might be from the effect of drowning; but if so, I might have expected they would have been totally destroyed in my two fields in the winter of 1763 and 1764, by the immoderate rains which fell at that season for a long continuance, by which the land was often flooded. But they survived that winter, as appeared by the great loss I afterwards sustained, by their destroying my wheat; and therefore, whether water be an enemy to them or not, it seems not easy to determine: but if these which died in the glass of water were really drowned, yet, I think we may conclude, that water is necessary to their existence in the earth, and probably aids them in getting their food from it: and what seems to confirm this notion is, that when the land is wet, they do not touch the corn, but as soon as ever the land is dry, they begin their mischief. However, this speculation I must submit to the consideration of persons more capable of discussing it than I am.

"We see by the experiment, Numb. 10, that they cannot live in the open air; which seems to prove, that, where they abound in land, the oftener it is ploughed, particularly in the summer, when they cannot penetrate the ground so easily as when it is moist, they must be, by such ploughing, greatly diminished: besides which, the frequent ploughing gives the crows more opportunities of picking them up, in which, as I before said, they are very watchful.

"Frequent ploughing has been recommended by some writers as the only means of destroying this worm; and they have recommended the ploughs being stuck with nails, urging, that by those nails the worms are cut to pieces; others have recommended walnut-leaves being soaked in water, to sprinkle the land: and steeping feed-corn in various liquors, as infallible remedies: but such methods as these are founded upon mistaken principles; they only mislead the farmer, and must disappoint him.

"Worlidge recommends a strong lye made of fixed salts, but that would be impracticable. Mortimer recommends sea-water, for such lands as are near the sea-coast, which I believe would answer very well. He says he used foot once with success, but that it did not succeed with him afterwards. I am persuaded he did not use the foot early enough to have it washed into the ground by rain, or perhaps he used too small a quantity.

"I would not be thought to arrogate any merit to myself, on account of what I have here offered on this subject, since it appears that other persons have used the articles which I have recommended, against this common enemy; but many persons have been disappointed in their expectations from these remedies, which must have arisen from their either having used too small a quantity, or not having observed the necessary precautions; if those which I have recommended, shall be put in practice, and found to answer, I shall think myself amply rewarded."

REED, the name of an aquatic plant, infesting low pasture-lands.

The best method of destroying reeds, is by draining the land; for if the drains be cut deeper than their roots, it will take away their nourishment, and, consequently, destroy them. Ashes, or foot, will likewise kill them; and so will ploughing up the land, laying it in high ridges. They always indicate a good soil, for a bad one will not nourish them.

REEK. See the article STACK.

REEK-STAVEL, or REEK-STAFFOLD, a frame of wood placed on stones, or which the mow or stack is raised.

REMOLADE, is a compounded honey charge for horses. To prepare it,

Take three pints of lees of wine, half a pound of hog's grease; boil them together for half an hour till they be well incorporated one with another; add black honey, pitch, Burgundy pitch pounded, common turpentine, of each half a pound; stir these with the other over the fire, till they are melted and well mixt; then add bole-armenic, or bole of Blois, of each a quarter of a pound; take the vessel off the fire, and stir it for a quarter of an hour longer.

If the charge is not thick enough, it may be brought to a due

a due consistence with a little wheat flour; and if it be too thick, it may be thinned with wine or lees of wine.

If to this charge an ounce of quicksilver be added, it will be little inferior to the red honey charge, in removing old griefs of the shoulders, legs, swaying of the back, and such like infirmities.

You may first kill the quicksilver in a small quantity of turpentine, and then incorporate it by stirring it with the other ingredients.

A remolade for the hoof-bound:

Take a pound of Burgundy pitch; half a pound of common turpentine; a quarter of a pound of olive oil, and thicken it well with a sufficient quantity of wheat-flour; charge the whole foot of the horse with this remolade lukewarm, after you have applied the following poultice:

Take two parts of sheep's dung, and one part of hen's dung; boil them with water and salt to the thickness of paste; in another pot boil as many mallows as is proper to make a mash; then add a convenient quantity of linseed powdered, and boil it a little longer: afterwards pound them in a mortar with an eighth part of raw garlic, to a paste; incorporate this with the following poultice; adding a little oil of lilies, and make a poultice; to be applied very hot to the foot, and cover it with splents.

Renew the application five or six times, once in two days, ever observing to heat the following poultice, and to mix a little fresh with it.

A remolade to dissolve kernels in the glanders before they come to an hardness:

Reduce half a pound of linseed to fine flour, mix it with a quart of strong vinegar, and boil it over a clear, but gentle fire, stirring it continually till it begins to grow thick, and then add six ounces of oil of lilies.

Another remolade:

Mix half a pound of wheat-flour with white wine, to the consistence of gruel, and boil it over a gentle fire, stirring it without intermission till the whole is united; then having melted half a pound of Burgundy pitch, add half a pound of common turpentine, and incorporate all together: mix this with the gruel moderately hot; take the vessel off the fire, and add a pound of the oriental bole in powder, and make a charge.

This will bring down swellings in the legs occasioned by blows, &c. This is to be applied hot, and repeated till the swellings be alluaged.

Another cheap remolade for swellings in the legs, occasioned by blows:

Chafe the part hard with strong brandy, and then charge the whole leg with common honey: renew the application once a day for six or seven days, washing the horse in a river or pond twice every day. See SWELLED LEGS.

Or,

Take half a pint of good vinegar, mingled with half a pound of tallow, and an ounce of flour of brimstone; or a mixture of common bole, honey and water, for small swellings.

RENNET. See CHEESE.

REPLANTING. Mr. Marshall, in his Rural Economy of Norfolk, says "It will be doing justice to the Norfolk management to mention a practice, which at present prevails, of grubbing up old worn-out hedges, and planting new ones in their stead.

"In this case the old hedge is (or ought to be) thrown down in autumn, that the soil may be thoroughly soaked and tempered with the winter's rains and frosts: early in spring the foot of the bank should be formed, and, in due season, the layer put in, and the fence completed.

"By this means a disgraceful nuisance is removed, and a new straight hedge obtained; and this at a small additional expence. The roots alone, if the old hedge be full of large stubs, and loaded with stems, will pay for grubbing: I have known one let to grub upon these terms. I have also known sixpence a rod (of seven yards) besides the roots given; also, one shilling a rod and the small roots.

"The price of re-making, that is, scouring and banking up an old ditch, is nine-pence a rod and beer; so that the difference between re-making the old one and raising a new one is but three-pence a rod."

REY-grass, a hardy sort of grass, much esteemed among the farmers for that quality. It will grow on any land, and therefore produces crops where nothing else will. It thrives best of all on sour, clayey, and weeping grounds, and equally endures the severest droughts of summer, and frosts of winter, suffering no damage from either. It is the best of all winter foods for cattle, the shorter it is eaten the better, and it springs the earliest of any. There is no danger of overstocking it, for, if it be left to grow too much, the stalk becomes hard and sticky. It is best for horses and for sheep, and very much prevents the rotting of the latter. The best way of sowing it is with clover. The common quantity of seed is two bushels to an acre, but three bushels is much better; though in some lands, where the clover is likely to succeed very well, they sow eight pounds of clover seed and one bushel of rey seed to an acre, and this makes a crop that will last seven or eight years.

Some mow it as hay, and thresh it for the seed, which, about London, sells from half-a-crown-a bushel to three shillings. Four or five quarters of this seed will be sometimes produced from an acre of the grass. If at any time a field of this grass is found to grow thin, it is only necessary to strew on a bushel of this seed, and roll it with a wooden roller, and the plants rising from this addition will make the whole crop sufficiently thick. Rey-grass has this great advantage, that it kills weeds without any other sown plant: even thistles cannot grow among it. When the rey-grass is cut for hay before perfectly ripe, the hay is the better; but the seed will not grow so well. When the seed is newly thrashed, it must not be laid too thick, for it is very apt to heat and ferment, and the whole will be spoiled. *Mortimer's Husbandry*, vol. I. p. 60.

RIBS of a horse, should be circular and full, taking their compass from their very back-bone.

RICE, the name of a plant cultivated in many parts of the East, in South Carolina, and also in Spain, Italy, and Piedmont.

The plant grows to the height of about two feet and a half, with a stalk not unlike that of wheat, but fuller of joints, and with leaves resembling those of a leek. It branches out into several stems, at the top of which the grains grow in clusters, and each of them is terminated with an arum or beard, and inclosed in a yellow rough husk. When stripped of this they appear to be of an oval shape, of a shining white colour, and almost transparent.

The following account of the culture of rice in China, is taken from M. Duhamel's Husbandry.

"1. To hasten the sprouting of the rice, it is put into baskets, and soaked for some days in a standing water.

"2. When their rice grounds are so soaked with water as to be quite like mud, they ploughed them with a buffalo yoked to a plough very simple in its make, having but one share, one handle, and no wheels.

"3. After a gentle rain, they break the clods with a kind of a large hurdle, drawn by a buffalo; the driver sitting upon it, to increase the weight.

"4. The ground is cleared of all stones, and whatever roots are in it are pulled up by a strong harrow with great iron teeth. This instrument is drawn by a buffalo, and a man guides it with the help of two handles, like those of a plough, upon which he leans hard. The earth is like mud, and partly covered with water during all this operation.

"5. The earth is afterwards smoothed with a harrow, which has several rows of teeth. A man guides this harrow by its two handles, whilst a buffalo draws it; and as fast as its teeth form little channels in the ground, the water runs in, and fills them up.

"6. When the rice that was laid to soak has sprouted, the seed is known to be good; and it is then sown by hand, very

very thick, and as equally as possible. Only part of the ground is sown in this manner, to furnish plants for the rest.

"The day after it has been sown the points of the plants appear above the surface of the water: for the ground is overflowed all this time with just enough water to cover it.

"7. When the plants have acquired a little strength, they are sprinkled with lime-water, to destroy the insects and some of the weeds that would hurt them. For this purpose a small basket is fastened to the end of a long handle, and dipt in the lime-water, which runs through it, and is conveyed over the plants.

"The Chinese have a great veneration for the first inventor of this method, which answers to our custom of steeping wheat in lime-water, or manuring land with quicklime.

"8. Towards April, when the plants are grown strong enough to cover the whole field, and look very green and even, the greatest part of them is pulled up by handfuls, all the mud is carefully washed off their roots, and, being held all this time as even as possible with one another, they are planted in tufts, pretty far asunder, and in a quincunx form, in fields prepared on purpose for them. A serene day is chosen for this operation, which must be performed as quick as possible.

"This practice of the Chinese is, with respect to the common culture of rice, what the New husbandry is with respect to the common culture of wheat.

"9. The rice must be watered: which is always done in China, by overflowing it. To this end, the rice-grounds are always near a rivulet, pond, or great pool of water, from which they are separated only by a bank or causey.

"If the water was higher than the rice-ground, a trench cut through the causey would overflow it at once: but as it is generally lower, or on a level with the rice ground, the necessary quantity is conveyed in pales or buckets, which are worked chiefly by the help of ropes.

"10. Though a man cannot step in these rice grounds without being up to his knees, the Chinese weed them three times in a summer; and that with such care, that they pull up even the roots of every weed.

"11. When the rice is ripe, which is known by its turning yellow like wheat, it is cut down with a sickle, made into sheaves, and carried to a barn, where it is threshed with flails pretty much like ours: the straw is removed with pitch-forks and shovels, and the outer husk of the grain is taken off by beating it with great wooden pestles, or a kind of mallet, after which it is sifted and winnowed: and, lastly, to get off the under husk, the grain is put between two mill-stones, which are worked by a lever fastened to the upper one.

"The two most remarkable circumstances of this culture are, 1. The care which the Chinese take not to let their plants be too close together, lest they should rob one another of their food. 2. Their weeding their rice grounds three times in a summer, which answers the end of the hoeings recommended for the alleys between the beds of other grain, cultivated according to the New Husbandry. *Culture de Terres*, Tom II. p. 180.

RICK, a pile of corn, hay, straw, &c. regularly heaped up in the open air, and sheltered from wet. See STACK.

A practical farmer has given the following account of the benefits arising to the farmer from keeping his wheat-straw in ricks, to be used when occasion requires it.

"Experience will, they say, make a fool wise: I took the hint, and have ever since guarded against a misfortune of the like nature.

"I constantly, says he, every year make a rick of wheat-straw, unless it happens to be very short, when I keep my rick two years, instead of making a new one the second year.

"This may, and doubtless will, by some of your readers be thought an unnecessary expence: yet as I find it answer, I am determined to, continue the practice. I not only rick the straw, but I also slightly thatch the rick to keep out the weather; yet, after all, I save by it.

"As I keep a very regular account of my farming expences, I find that in the space of ten years I am a gainer of fifty-three pounds, by saving in this manner a rick of straw for thatching, besides what I saved by not threshing my wheat at an improper season. When I say I am a gainer of so much money in the time, I mean a clear

gain: after deducting the expences of making up the rick, thatching it, &c. my expences in thatching for the last ten years have been fifty-three pounds less than they were the ten preceding years; and this I can easily account for, and will, for the satisfaction of your readers, at least in part, do it.

"I now always do my thatching work at the most convenient season, being never in want of straw; and, for the same reason, as soon as any part of my thatching is deficient, I have it immediately repaired, which is a great saving.

"My thatching now lasts longer than it used to do, for I never thatch with short straw, having always, as I observed before, long straw to use; for in the years when the straw is long, I save the largest rick, which I have sometimes kept two or three years, till the wheat straw has been long again.

"In the space of the last ten years I had two accidents happened, which would have proved very expensive to me, if I could not have resorted to my straw rick.

"The first was, that one of my sons (a boy about ten years of age at the time) set fire to the thatch of a large barn by means of a squib. It burnt furiously for some time, and so far damaged the roof, that I was obliged to have it new thatched; for which purpose I made use of a part of my straw rick, and it was finished in a few days; whereas, if I had not had this rick, I must have bought short straw, for there was scarcely any other to be had, at a large price, and the thatching could not have been finished so soon: by which means I should have had a considerable quantity of barley, that was in the barn, damaged, for it rained very hard for a considerable time, in a few days after the thatch was repaired.

"The other accident was occasioned by a gust of wind which stripped off a good deal of thatch; but it was soon repaired, without any damage to the corn that was in the barns at the time.

"All this, perhaps, may not be enough to persuade your practical readers to rick their long straw. If this is the case, they must even continue their old practices: yet I hope I may be permitted to say one thing, which I know to be true; what I mean is this, that farmers, if they would attend to matters which they generally think beneath their consideration, would get more money than they do: profits arise from what appear to be trifles at first sight, and the merest trifle should be by a farmer attended to.

"A habit of industry, frugality, oeconomy, and perseverance is absolutely necessary to the occupier of land, if he does not mean soon to shift his quarters." *Museum Rusticum*, vol. III. p. 245.

RIDDLE, an oblong sort of sieve used to separate dust, and the seeds of plants from corn.

RIDE, a cluster of sprigs of hazel, or the underwood, shooting out of the same root.

RIDGE, a long piece of rising land between two furrows.

Mr. Tull observes, that the method of ploughing lands up into ridges is a particular kind of tillage, the chief use of which is the alteration it makes in the degree of heat and moisture. But the principal advantage this gentleman proposes from ridges is the draining wet hills, where the upper stratum is mould, and the second stratum clay. These ridges he observes should be ploughed across the hill, almost horizontally, that their parting furrows lying open, may each serve as a drain to the ridge next below it; for when the plough has made the bottom of these horizontal furrows a few inches deeper than the surface of the clay, the water will run to their ends very securely, without rising into the mould, provided no part of the furrows be lower than their ends. These ridges and their parting furrows must be made more or less oblique, according to the form and declivity of the hill; but the more horizontal they are, the sooner the rain-water will run off the lands: for in that case, it will run to the furrows, and reach them at right angles. Every one of these horizontal trenches receives all the water from the rills, or little gutters, which in these quagmire-hills run betwixt the mould and the clay; these are all cut off by the trenches, which receive the water at the upper sides, and carry it away, as the gutters of lead placed under the eaves of a house carry away the rain water. These ridges should be ploughed in pairs, without throwing any earth into the trenches; and at every time of ploughing, the pairs must be changed, so that the fur-

rows which had two ridges turned towards it one time, must have two turned from it the next. *See the article PLOUGHING.*

RIDGES, in a *Horse's Mouth*, are wrinkles or rifings of flesh in the roof of the mouth, running across from one side of the jaw to the other, with furrows between them.

RIDGELING, the male of any beast that has been half castrated.

RIDGIL LAMBS. *See the article SHEEP.*

RILLS, *artificial.* Mr. Marshall, in his *Rural Economy of Yorkshire*, vol. I. says, that, "the heights of the northern margin have neither springs nor rivulets (some very few instances excepted), nor any other natural waters than the brooks which wind at the bottom of the deep vallies that divide them, and the rivulets which generally run at the feet or the precipices that terminate them."

"Formerly these brooks and rivulets were the only resources which the villages that are scattered on these heights had for water, both for the use of cattle and for domestic purposes."

"In process of time wells were sunk; but they are of such a depth as to make the labour of raising the water little less than that of fetching it from a moderate distance."

"This kind of natural necessity has led to an expedient, which, though not new in principle, is perhaps entirely so in simplicity of execution, and might be practised with great advantage in many similar situations."

"The moreland mountains rise with generally an easy ascent, from the beds of the rivulets last mentioned, to a height much exceeding that of the hills to be watered, frequently abounding with springs almost to their highest swells."

"These springs are collected and conducted by a narrow channel down the slope of the mountain sides, and along the face of the precipice, until the summit be gained; the waters being thence conveyed to the place or places desired."

"In planning an artificial rill, a level and some little knowledge of the country are the requisite guides. The surveyor begins at the place to which water is required to be brought; and ascertains the lowest part of the brink of the precipice from which water can be conducted. The face of the precipice is traced in like manner; and, if necessary, the ascent of the moreland hills, until springs, or their natural rills, can be commanded."

"If his level bring him to the bottom of the steep soon enough to catch the rivulet which runs at its foot, the work is readily completed. If not, he goes above its highest bend; generally to the head or highest part of the valley (between the heights and the morelands) and winds along the side of the opposite swell to some more elevated source."

"If, when he arrives on the moreland hills (or by an observation from the top of the precipice) he find that nature does not furnish the requisite quantity of water high enough to give the necessary fall, the work is of course impracticable."

"In executing an artificial rill, opening a shallow channel, of a width proportioned to the quantity of water to be conducted, is the main operation. In making stagnant pools we have found that much art is necessary to make them retentive; but in forming the bed of a rill no such art is requisite. It is the nature of running waters to render the surface on which they run firm and retentive. Sand is, I believe, the chief material used in forming the channels of these rills; and this only in places where an open rock or other porous stratum is crossed."

"Much however depends on the quantity of fall and the quantity of water. If the fall be but little, and the quantity of water at the source be such as not to admit of much waste, great care is requisite in forming the bed of the rill."

"The fall is therefore regulated in a great degree by the quality of the ground. On good ground the channel is nearly level. Over faulty ground the water runs with a current for the double purpose of getting quickly over it, and rendering its channel more retentive."

"The principal enemies of artificial rills are leaves in autumn and snows in winter. To remove the obstructions which these not unfrequently cause, and to repair such breaches as time will always make in the works of art, a superintendent is necessary to every artificial rill."

"The rill of Kirbymoorside is, I believe, the largest,

and was the first which was brought upon these heights. This rill was brought to the village of Gillimore and Fadmore near forty years ago; and has been extended to Kirby about thirty years, by Joseph Ford; a self-taught engineer, of great ingenuity and some judgment; a man to whom the country owes much. Since the introduction of this, several others have been raised; and some few unsuccessful attempts have been made: the channel was in one instance (that of Newton) extended a considerable way before the impracticability of completing it at a moderate expence was discovered; a piece of misconduct which nothing but a want of accuracy in the use of the level can lead to. The miscarriage in this case was not owing to a want of elevation in the source, but to a depression of the channel at the foot of the steep; the head of the valley (if such it may be called) being lower than the top of the precipice at the given point. This shews the necessity of tracing the entire channel with sufficient accuracy before any other expence is incurred."

"In the case of Kirby, the channel is raised some feet by a bridge-like mould of earth thrown across the crown of the valley."

"The same mould serves the purpose of conducting another rill across the same difficult pass; from whence the Kirby-rill takes an eastward, the rill of Wellburn (applied principally to the watering of pasture grounds) a westward direction."

"The first cost of Kirby-rill was not altogether one hundred pounds. The distance about ten miles, watering (besides the town of Kirby) two villages and a line of cultivated waterless upland country about four miles in length. Besides the first cost, which was raised by subscription, a superintendant has ten pounds a-year for keeping it in repair and free from obstructions; which yearly salary is paid by the voluntary contribution of the persons benefited; each being rated agreeably to the estimated benefit received." *See DRINKING-POOLS and PONDS.*

RING-BONE, a hard swelling on the lower part of the pastern of a horse, and generally reaches half round the fore-part. It has its name from the resemblance to a ring.

It often arises from strains, &c. and when behind, from putting young horses too early upon their haunches; for in that attitude a horse throws his whole weight as much, if not more, upon his pasterns, than on his hocks."

When it appears distinctly round the pastern, and does not run downwards towards the coronet, so as to affect the coffin-joint, it is easily cured; but if it takes its origin from some strain or defect in the joint originally, or if a callosity is found under the round ligament that covers that joint, the cure is generally dubious, and sometimes impracticable; as it is apt to turn to a quittor, and in the end to form an ulcer upon the hoof."

The ring-bones that appear on colts and young horses will often insensibly wear off of themselves, without the help of any application; but when the substance remains, there needs no other remedy besides blistering, unless when by long continuance it is grown to an obstinate hardness, and then it may require both blistering and firing."

To fire a ring-bone successfully, let the operation be performed with a thinner instrument than the common one, and let the lines or razes be made not above a quarter of an inch distant, crossing them obliquely, somewhat like a chain; apply a mild blister over all, and when quite dried up, the rupture plaster; and then turn the horse to grass for some time. *Barthol's Farriery*, p. 264.

RIPPLING of Flax, the operation of taking off the seed from the flax by drawing it through a ripple or large comb. *See the article FLAX.*

RISING, yeast, or barm.

RIVER, a current, or stream of fresh water flowing in a bed or channel, from its source into the sea.

RIVULET, a little river or small stream of water.

ROAD-HORSES. A road horse is he, which in general performs the most laborious work; and frequently enjoys the least accurate attention of any in the kingdom. Under this description comes the greater part of all the horses in constant use, as it includes carriage-horses of every kind, roadsters and hacks, whether of gentlemen, tradesmen, or travellers; all which constitute an infinity, as well in the metropolis as every part of the country. Road horses of every denomination are, from their constant hard work, entitled to a proportionable degree of care and attention with the best horses in the kingdom; and should

Fig. 1.

Fig. 6. Stump.

Fig. 3.

undergo, the useful minutiae of stable discipline that so clearly contributes to the preservation of health, in horses of a superior description: those which have incessant journeying, or travelling post, must be supplied, at least, with a peck of corn a day. Large and strong carriage-horses, in perpetual work, require considerably more, or become emaciated by loss of flesh in frequent perspiration. These rules are offered as a kind of general standard.

ROAN, a roan horse is one of a bay sorrel, or black colour, with grey or white spots interspersed very thick: when this party-coloured coat is accompanied with a black head, and black extremities, he is called a roan with a blackmoor's head; and if the same mixture is predominant upon a deep sorrel, it is called claret roan.

ROD, a measure in length, consisting of sixteen feet and a half.

RODDEN CRIBS. Mr. Marshall in his Rural Economy of the Vale of Gloucester, says, "these are a kind of large basket, made of the topwood of willow pollards; an utensil common to this country and to Lincolnshire, though situated on the opposite sides of the island: but they are alike grassland countries, wherein cattle are fattened on hay. They are about six feet diameter. The height of the basket-work is two feet and a half; of the stakes three feet and a half; their heads rising about a foot above the rim of the basket. The width between the stakes twelve to fourteen inches. The size, that of large hedge stakes. The size of the rods vary from that of a hedge stake, down to a well-sized edder.

"In making these hay baskets, the stakes are first driven in a ring of the required size, firmly into the ground. Some of the larger rods are then wound in at the bottom, in the basket-work manner. Upon these the smaller rods are wound; the middle part of the work requiring the least strength, reserving the largest for the top. In the winding and due binding of these, the principal part of the art of withy crib making rests. Some makers warm these thick rods in burning straw; others wind them cold; one man drawing them in with a rope; while another beats them at the stake with a wooden beetle, until they acquire a degree of suppleness. They are mostly made by men, who go about the country; and who by practice, make them very completely; winding in the top rods so firmly and so regularly, that it is difficult to know which has been the last put in.

In use, the cattle lay their necks between the tops of the stakes. Each being thus kept in its place, the master cattle are, in a degree, prevented from running round and driving away the underlings. The closeness of these cribs prevents a waste of hay, either by the wind or by the cattle.

On the whole, they are useful, simple, cheap; and, if well made will last several years.

ROLLER. See DRILL ROLLER

ROLLER, a large piece of wood turning on its axis, and drawn over the surface of the ground to break the small clods, and render it smooth and even.

The plain roller does not seem to have that attention paid to it which is due to its merit. It is seldom used on a fallow, except to burst clods, and seldom used after sowing, except to smooth the surface for the scythe. Perhaps rolling when damp is not prejudicial, provided the soil be afterwards harrowed. Rolling not only bursts some of the clods, but fixes others, and prevents them from rolling under the harrow. Applied to fallows, the plain roller is the grand arcanum of Agriculture, which makes light land stiff, and stiff land light. One essential crush by a plain roller is worth a dozen partial indentures by a spiky one; but where the clods bear a heavy plain one, the spiky roller is worth its weight in gold. *Marshall's Minutes of Agriculture.*

Spiky ROLLER. See SPIKY ROLLER.

ROLLING, the operation of drawing a roller over the surface of the ground.

"Rolling, as well as ploughing and harrowing, says Mr. Clarke, if admitted in the culture of fallow lands, would, I presume, much facilitate eradicating of weeds, and promote the prolific capacity; for it often happens, that after land has been ploughed and worked with the great harrow, &c. there still are grass and weeds remaining, that will the next ploughing cause the furrows to be ropy, and then much labour and time is required to make it to the mind of the judicious husbandman, which rolling it in the following order will be found to elude.

"Thus, when the land has been once ploughed, bracked, and harrowed, immediately give it a double rolling with a stone cylinder about four feet long and three feet radius, which with its furniture, is a roller about one ton weight: the pressure of such roller; when there is little moisture in the land, fixes it so much, that no weeds nor grass can vegetate; next, in about a month after, put in manure by another ploughing, viz. dung or compost, whereof dung is the major part; but lime is at this time very improper, as it resists putrefaction: then give the land a stroke with the great harrow, and roll it as before: this puts the manure, soil, and juices in contact; by which, together with the vivifying heat of the sun, (that must be greater on rolled land than on loose, rough, unsteady particles of earth, because it thereby becomes quiescent, and the surface acquires a kind of polish) fermentation and putrefaction must be ardently already excited.

"That these are salubrious and most powerful agents in the fertilizing of land, by loosening the composts, and setting at liberty the more subtle parts of the manure and soil, and generating that sort of air which is found so necessary to animal as well as vegetable life, none conversant in these matters can make the least doubt.

"Now indeed may a quantity of quick-lime be applied to great advantage, by being spread on the surface; for the weeds that are harrowed up, will not only soon be dissolved by it, and converted into nourishment for vegetables, but the very principle of vegetation, which is going off in exhalations by the effervescence within, is by it absorbed and retained for the nutrition of the crop, which it will communicate when it is ploughed in; and that may be done about fourteen or twenty days after, sooner or later, as the weather answers, or the experimenter sees it necessary: and if it is a soil fit to grow turneps, and the season proper, the seed may be sown immediately, either in the drill or common way; but the drill, on many accounts, in sowing turneps, deserves precedence; or, if it is to be winter corn, one ploughing more, which is the third only, makes it in fine order for the seed.

"The utility of rolling does not end here neither; for to roll wheat, rye, barley, &c. with a roller about twice the length, and half the weight of the one above described, may be advantageous, as it presses down the soil that has been raised by the frosts, about the minute ramification of the attracting ducts, and augments the quantity of mould upon them by breaking the little lumps of soil; which, indeed, were very serviceable in winter by affording shelter, but in spring will still be of greater use, by such immixtion in filling up the fissures, and preventing in a great measure the ill effects droughts have on light soils, by retaining and filtering rain-water; whereby the soil imbibes whatever is nutritive; what is superfluous of the simple fluid only escapes.

"These are some of the many advantages rolling produces in agriculture; notwithstanding which, it amounts to more than mere conjecture, that in general rolling corn may do more damage than it can do good, if such as the following cautions be not carefully attended to, viz. never to roll corn but in dry fresh weather; by no means use heavy rollers; nor roll too early, i. e. before the blades be pretty strong, for the wounds that the blades may receive, the roots, being then tender, will be unable ever to recover; nor too late, i. e. when the stalks are hardened and grown to any height, for the roller will break them, which injury hardly can be repaired, and the crop is thereby hurt; that none but light lands are proper to be rolled, and those which have been manured that or the preceding year with only dung: in short, none but rich, light soils, in general, can be improved by rolling: for in poor lands it opposes the most active primogeneous agents, and undoes all that has been done for the crop by ploughing, &c.

"Thus the soil, the condition, the growth of the corn, the weather, and the weight of the roller, are all to be most scrupulously regarded: when all coincide, the advantages of rolling will be great; but when they do not, the disadvantages may be insuperable.

"Rolling then is neither the least critical, nor most insignificant piece of the husbandman's profession; therefore ought not to be performed at random and without circumspection." *Museum Rusticum, vol. IV. p. 5.*

Rolling is also of use to land in grass, by pressing down mole-hills, &c. It also makes the grass taller, and grow thicker.

There

There is a sort of land, which, when clover is sown upon it, throws out the young plants after a frost. Rolling in the beginning of winter, and immediately after the frost is gone, will, in some measure, prevent this. The first rolling hinders the frost from penetrating so deep as it would otherwise do; and the second makes the land firm, after having been loosened by the change from frost to open weather.

Mr. Marshall, in his *Rural Economy of Norfolk*, makes the following observation on rolling. "Very little general matter falls under this head. One circumstance, however, requires to be mentioned.

"The roller, notwithstanding the lightness of the soil, and its proneness to be injured by dry weather, is never used in Norfolk for the purpose of compression. I never saw one used by a farmer either upon fallow or upon a lay; not even upon the first year of a clover-lay, to smooth the surface for the scythe.

"The only uses to which I have seen a roller put, in this district, are that of smoothing the surface before sowing, to prevent the seed from running down too low, and that of smoothing it afterwards as a preparation for the scythe: and even this operation is performed with a roller not more perhaps than seven or eight inches in diameter; a circumstance which, I confess, I am no way able to account for: nevertheless, it would be rashness to condemn an established practice, unless I could, from my own experience, or from adequate observation on the experience of others, prove it to be ineligible."

ROOD, a quantity of land equal to forty square poles or perches, that is, a quarter of an acre.

ROOK, a well-known bird, resembling a crow; but feeds on grain, insects, &c.

Great care should be taken to guard against these mischievous birds at the time when the wheat is just shooting up; for they perceive it shooting much sooner than the farmer can, and are led by the shoot to pick it up. They must therefore be carefully kept off the ground about a week or ten days after this season; for at the end of that time the blade will be grown up, and the grain so exhausted of its substance, that they will not give themselves any trouble about stealing it. They never molest the wheat which is sown about Michaelmas; because so much grain of the late harvest then lies scattered about the fields, that they find it much easier to pick up that, than to search for corn under-ground in new-sown lands. They do most harm when the snow is first going off from the green wheat towards the end of winter; for having been pinched for food during that season, they then greedily pluck up the young plants, in order to come at the remainder of the seeds still adhering to their roots; and are greatly assisted in this by the loose state of the earth at that time.

Among the many contrivances to frighten them away, such as feathers stuck up, the limbs of rooks scattered about the ground, dead rooks hung on sticks, the gun, a boy to halloo, and throw his hat, or to toss a dead rook up in the air, Mr. Tull says he found this last to be the most effectual. They will immediately quit their usual places of abode, if the earth is turned up around the trees, in which they have built their nests; and will not return to them till the grass is grown again; as has been experienced in the repairing of Fountain-court in the Temple: Mr. Lisle assures us, that the taking down of their nests, with their young ones in them, and burning under the trees they were built in, will effectually make all the old ones desert that place. However, it has been doubted, and perhaps with reason, whether they do not, upon the whole, compensate pretty fully for the mischief they do to corn, by destroying vast quantities of grubs, worms, and other pernicious insects, in the spring, as crows are also of service in the neighbourhood of populous towns, by devouring a great deal of carrion.

It is a common proverbial saying of the countrymen, that at whatsoever farm a colony of rooks plant themselves, and make a rookery, it is a sign of prosperity to the occupier of that land; and that, on the contrary, their deserting it, betides misfortunes and poverty; for both which remarks, Mr. Lisle accounts very rationally, by observing, that where a man is a good husbandman to his land, and improves it, the worms, which are a great food to these creatures, especially at certain times of the year, multiply, and grow to a much greater bulk and fatness, than in a poor neglected soil: the strength of land being as discernible by the large size of worms, as from the growth of plants; and that the grubs or maggots of the beetle kind in parti-

cular, on which the rooks feed greatly, as is apparent from their following the plough, in order to pick them up, not only grow fattest and largest in rich well-tilled ground; but that the beetles themselves, while in their state of flies, always choose to lay their eggs in such lands as will best nourish and provide for their young. The contrary to this soon happens under a bad husbandman.

Mr. Marshall, in his *Rural Economy of Norfolk*, vol. I. says, that "the method of frightening rooks, in practice there, especially when they take to patches of corn which are lodged before harvest, is simply to stick up a tall bough in the part infested; if a gun be fired near the place, before the bough be set up, this simple expedient seldom fails of being effectual.

"If rooks make an attack after seed-time, or when they take generally to the crop before harvest, a boy is set to scare them; they being seldom attempted to be shot at in Norfolk; where a notion prevails, and is perhaps well-founded, that rooks are essentially useful to the farmer, in picking up worms and grubs; especially the grub of the cock-chaffer, which, it is believed, is frequently injurious to the meadows and marshes of that country."

ROOKERY, a nursery of rooks, or place where they build their nests.

ROOP, hoarseness.

ROOT, the lower part of a plant, by which it adheres to the earth, and by which it draws its nourishment, and transmits the juices to the other parts. For the method of clearing lands from the roots, *see the article GRUBBING*.

The roots of plants are of use to them principally in two respects, viz. to give the plants stability in the ground, that they may not be displaced, or blown down by high winds, or other accidents. Another important use of roots, is their spreading in the ground, and from thence collecting food for the whole plant. Plants are in part fed or nourished from the air, fine vapours, &c. that enter at their leaves and branches, but principally by what enters at their roots; for which reason the husbandman takes infinite pains to prepare the land by tillage and manure, whereby it is opened, pulverized, and made easily penetrable for the roots to spread in it, and collect the aliment or vegetable nourishment.

Roots may be divided into two sorts, viz. perpendicular roots, which penetrate deep in the ground, and run down usually single and perpendicularly, as carrots, parsneps, the perpendicular roots of trees, &c. which are also called tap roots. Those that divide near the surface of the ground, and spread in it, in various directions, are called horizontal roots, fibrous roots, and if very small, capillary roots. The tap roots have also fibrous roots, issuing from their sides, all round the tap root; and these lateral roots are longest near the surface of the ground, and gradually shorter as the tap-roots descend deeper.

The surfaces of the roots are spongy and porous, particularly of the small or fibrous roots, and at these pores the vegetable food enters, and is distributed to all parts of the plant. The large roots are close, and have few pores on their surfaces; by which it appears, that they are chiefly intended for the support and stability of the plant, and the fibrous roots for collecting the nourishment for the plant, and large roots.

The branches of roots are formed, with their extreme ends, pointing from the stem of the plant; and hence it appears, that roots once formed, do not afterwards encrease, or extend further longitudinally; they lengthen at their ends, but not at their intermediate parts: for if they did, the branches being left behind, would be drawn back, with their ends pointing towards the stem: but they are constantly found in a contrary position, with their ends pointing in a direction from the stem. If a root is cut, it extends no farther in length, as before observed, but new roots are formed near the cut end of the old root; two or more new or young roots are formed in the room of the former old one. Hence the fibrous roots of plants are multiplied by cutting them with a spade or hoe: and this is often a great benefit to the plant. The pores of the fibrous root are the mouths by which the whole plant is fed, and the more they are multiplied, the more nourishment they collect for it.

Thus a plant that naturally extends its roots to a considerable distance, is in danger of being killed by transplanting, unless it is also furnished with fibrous roots, which must be carried with it to the new ground; or new ones must be formed, to make the plant thrive. Hence it is, that

that plants, which have long straggling roots are removed with difficulty ; but plants of the same kind, and age, and that grow in the same ground, are transplanted with safety and success, if they have been previously dug round with a spade, whereby their fibrous roots have been cut and multiplied, so that they rise with a ball of earth adhering to them.

There is a communication between the roots of a plant, and when some of them are well nourished, the others are benefited thereby. If some of the roots of a plant are laid in dry earth or sand, and others in water, they will furnish the dry roots with water sufficient to keep them, and the earth about them, moist, so long as they have a supply of water : for this reason deep rooting plants are little affected by drought ; the tap roots finding moisture below, send up some of it to the roots near the surface : for which reason lucern and saintfoin flourish in such dry hot weather, by which common grass, and other fibrous rooted plants, that do not descend deep, are scorched and burnt up.

As roots communicate moisture to each other, they therewith communicate also nourishment : for it is found by experience, that drilled plants, well hoed, one side of a row only, are better nourished than sown plants standing at equal distances ; or upon an equal surface of ground with the drilled, and not hoed.

The attentive farmer will discover many other particulars concerning roots : whereof the knowledge is useful in the common culture, and in hoeing necessary.

ROSIL, or *Rosills*, land neither light nor heavy, being a medium between sand and clay.

ROT, a disease incident to sheep, arising frequently from wet seasons, and too moist pasture.

" But the rot in sheep, says an ingenious and practical writer, does not always either proceed from moisture alone, or the nature of the soil alone ; for all moist grounds do not cause the rot in sheep, and there are some lands which rot sheep in wet years only.

" The rot, in fact, arises from a certain putrefaction, both in the air, and in the grass or herbs that usually grow in such moist years : these, together with their moist food, corrupt their livers, and bring on the disease.

" It is indeed very difficult to cure this disorder, unless it is attempted before the liver is too much wasted : where there is a convenience of doing it, the best remedy is, an immediate removal to salt marshes ; but this is far from being in every farmer's power : I shall endeavour therefore, from my own former experience, to supply the deficiency.

" In such cases as these, a prevention of the evil is to be recommended to the practice of every rational farmer.

" Some grounds naturally yield a soft, spongy grass, which is, more than any other, subject to breed the rot in sheep ; I would therefore advise, that other cattle be fed in these grounds, and the sheep kept in the driest, hardest, and healthiest pastures.

" I have known land that has kept sheep in health for many successive years, yet afterwards, when the months of May and June have proved wet, a firm and frothy grass has suddenly sprung up, which, together with the bad air that must of course follow, has caused a rot in the sheep that were then on it : the evil was observed in time, the sheep were removed to a dry and almost barren heath, and in the succeeding winter they were foddered with good, dry, sweet hay, and a great loss was prevented : this happened to an old friend of mine, since dead.

" This unwholesome grass is most apt to grow in cold land, and in the summer time ; and it is a general opinion, and well founded on experience, that if the summer does not rot sheep, the winter will not, the power of the winter alone not being strong enough to begin a rot.

" A very sensible writer, whose book I have just turned to, I mean Mr. Lisle, says that broom is very good for the rot ; and indeed I have often experienced it ; for in a farm I occupied some years ago there were several broom-fields, and I have often observed that such of my sheep as were part of the year fed in them were never infected with the rot, whilst others in my possession had it to a great degree. I profited however by experience, for I took care thenceforward that all my sheep should, by turns, enjoy the advantages to be derived from their feeding on the young shoots of the broom.

" As to what Mr. Lisle says, on the authority of Mr. Ray, that the marsh-trefoil will cure the rot, I cannot from experience corroborate it : I have heard its efficacy in this disorder often mentioned, but never yet heard any particular

fact related so circumstantially as to induce me to depend on its effects.

" That salt is good, I agree with the above gentleman and Mr. Boyle ; and this gives me an opportunity of communicating a receipt which I know to be a good one.

" When you perceive, by the colour of your sheep's eyes, that the rot has taken them, drive your flock into a barn, a covered fold, or some such convenient place : around this place let there be wooden troughs, like mangers, in which you should feed your sheep with good, dry, clean oats, for forty-eight hours : then have ready some bay salt finely powdered and seared, of which you are to sprinkle a little among the oats, increasing the quantity till it disgusts the sheep, and you perceive they fall off their appetites : afterwards, for the two following days give them again clean oats ; and then mix your salt with them as before, continuing this process till their eyes have recovered their natural colour, when you will find them perfectly cured ; and to be convinced, it will only be necessary to kill one or two of the flock.

" To this I shall add a receipt for the rot in sheep, which was communicated to me by a friend, a man of credit and veracity, who says he has often tried it with success :

" Steep some regulus of antimony in ale ; adding thereto some grains of paradise and a little sugar to sweeten it. Of this infusion somewhat less than a gill is to be given to every one of your affected sheep : they are to have two or three doses, according as they are more or less affected by the distemper, allowing two days intermission between each dose.

" This is said, as I have already observed, to be a cure almost certain.

" I just now took notice, that when rain falls in the months of May and June, it is apt to cause the rot in sheep : it will be necessary to add, that folding them in the above months increases the disorder ; for after having been deprived of their liberty during the whole night, they bite the noxious grass the more greedily in the morning, having less ceremony in their choice of herbs than if they were not folded. This is a matter of some consequence, therefore worthy of being attended to.

" One thing more I must, on the authority of Mr. Lisle, communicate to your readers, viz. an observation of a Leicestershire farmer ; that sheep, when first touched with the rot, will thrive mightily in fattening for ten weeks ; but if they are not disposed of when they are come up to a pitch, they will, in seven or eight days time, fall away to nothing but skin and bone. The same farmer observed, that he had often had them die in the height of their pitch, in half an hour's time, with twenty-seven pound of tallow in their bellies." *Museum Rusticum*, vol. I. p. 434.

To this account we shall add a receipt communicated to Mr. Mills by a gentleman of Lincolnshire.

" Steep a handful of rue in a pail of water all night, and at morning put in as much salt as will make it bear an egg. Give each sheep half a pint of this liquor, and repeat it thrice, every other morning.

" A farmer who kept four hundred sheep tried this receipt in the last general rot (about five years ago), and did not lose any, though his neighbours lost almost all theirs. For the sake of the experiment, he set apart about twenty, and did not give them this drink. Many of these were rotten." *Mill's Husbandry*, vol. III. p. 416.

Buck-bean, or marsh-trefoil, is also excellent in this distemper. See the article BUCK-BEAN.

ROUGHINGS, latter-grass, aftermaths.

ROUP, the name of a filthy disease in poultry, consisting of a boil or swelling upon the rump, and is known by the staring, or turning back of the feathers.

The roup, if not soon remedied, will corrupt the whole body of the fowl ; to prevent which the feathers should be plucked away, the swelling laid open, the matter pressed out ; after which the part is to be washed with brine, or salt and water.

ROWEL, a kind of issue made in horses for the cure of various disorders, as inward strains, hard swellings, &c.

The operation is performed in the following manner :

A little slit being made through the skin, about a hand-breadth below the part aggrieved, big enough to put a swan's quill in, the skin is raised from the flesh, the end of the quill put in, and the skin blown from the flesh upwards, and all over the shoulder; then, the hole being stopped with the finger, the part blown is beat with a hazle-stick, and the wind spread with the hand all over, and then let go; this done, a skain of horse-hair, or red farset-net, half the thickness of the little finger, is put in a rowelling-needle, seven or eight inches long, and the needle is put into the hole, and drawn through again, six or seven inches higher; then the needle is drawn out, and the two ends of the rowel tied together, anointing it every day, as well before the putting it in, with sweet butter and hog's grease, and drawing it backwards and forwards in the skin, to make the putrid matter discharge itself more plentifully.

Others disliking these rowels, as making too large a fore and scar, use the French rowel, which is a round piece of stiff leather, with a hole in the midst, laying it flat between the flesh and the skin, the hole in the rowel just against that in the skin, sewing it with a needle and thread drawn through the hole and the skin, cleaning it once in two or three days, and then anointing it afresh.

"The general and absurd reasoning of farriers, says Mr. Bartlet, on the effects and use of rowelling, makes the following observations the more necessary, as it is too notorious how impertinently they talk on this subject: for in short, with them a rowel is to draw off all the bad and corrupt humours from the blood, by a sort of magic.

"It is necessary to observe that the matter generally discharged by a rowel is nothing more than an ouzing from the extremities of the vessels divided in the making of it; in fact then, it is blood, which loses its colour, by being sliced out of the vessels, the warmth of the part, and its confinement.

"If this is granted, it will evidently appear, that the good effects ensuing this operation, must be owing to a gradual depletion, or emptying of the vessels in general; by which means the surcharge or load on a particular part, is taken off and removed; and impurities or bad juices (generally called humours) run off with the good, in proportion to their quantity in the blood.

"To imagine particular humours are thus separately, and alone discharged from the blood, through these orifices, is an opinion but too generally received, though a very absurd one; and must be very pernicious in its consequences, from the bad effects it may have in practice; as must the same reasoning also in regard to purging.

"Thus to lean hide-bound horses, and those of a dry hot constitution, the discharge, by depriving the constitution of so much blood, and fluids, is daily exhausting the strength of the animal; and may be productive of bad consequences, by defrauding the constitution of a necessary fluid.

"But in disorders from fulness, attended with acrimony, or sharpness of the juices, and with defluxions on the eyes, lungs, or any part of consequence; the gradual discharge brought on by these means, will contribute to lessen the fulness on the parts affected, and give the vessels an opportunity of recovering their tone, while evacuating and alterative medicines are doing their office.

"It may be necessary however to observe, that there is a wonderful communication between the vessels of the cellular membrane under the skin, which remarkably appears, by inflating those of sheep, calves, &c. by the butchers: hence probably it is that some disorders of this integument, are so apparently relieved by issues, or rowels, without our having any recourse to that general depletion of the vessels we have just observed, to account for it; and hence also may be deduced their utility, sometimes in draining off any extravasated fluids, which may lodge between the interstices of the muscles, after violent strains of the shoulder; also in discharging such vicious, or sharp fluids, as are thrown on the membranes, and occasion those flying pains and lamenesses, which we find are often removed by this local remedy. *Bartlet's Farriery, p. 220.*

ROWEN, or Rowet, winter-grass.

ROWTY, over-rank, too strong.

RUBBING-POST. Mr. Marshall, in his *Rural Economy of Norfolk, vol. II.* says, "it is an excellent custom of the Norfolk farmer to erect *rubbing-posts* in the different parts of the inclosure he is feeding or teathing; they keep the stock from the fences, and furnish them no doubt with an agreeable, and perhaps a salutary, amusement.

"Some I see draw the crown of a tree, with the lower

part of the boughs left on, into the middle of the clove: this is less trouble than putting down a post, is easily rolled out of the way of the plough, and seems to be still more agreeable to the cattle."

RUDDLE, a sort of red earth, of a lax texture, and very easily reduced to powder. It is found in several parts of England, especially in Derbyshire; and is much used in marking sheep.

RULES for buying horses. What has been treated of under the name of draught-horse, concerning buying, shape, usage, &c. being confined, in a manner, wholly to those employed for plough and cart, these rules are more general and comprehensive; and many things under this head are of great use, and therefore must be particularized: as,

"Election; which is the end for which a man buys, and is a thing only shut up in his breast.

"Breed; which must be either taken from faithful report, a man's own knowledge, or from some known and certain characters, by which one strain, or one country, is distinguished from another.

"As the Neapolitan horse is known by his hawk nose, the Spanish by his small limbs, the Barbary by his fine head and deep hoof, the Dutch by the roughness of his legs, and the English by his general strong knitting together: and so of divers others.

"The colour; and though there are none exempt from goodness, yet some are accounted better than others, as the dapple grey for beauty; the brown bay for service; the black, with silver hair, for courage, and the liard, and true mixt roan, for countenance: as for the sorrel, the black without white, and the unchangeable iron-grey, they are reckoned choleric; the bright-bay, fleabitten; the black with white marks are sanguinists; the black, white, yellow, dun, kite-glu'd, and the pye-bald, are phlegmatic; and the chefnut, the mouse-dun, the red bay, and the blue grey, are melancholy.

"For pace in general, with either trot, amble, rack, or gallop; it must be referred to the end for which a horse is bought, particularly if it be for the war, running, hunting, or for a man's own pleasure, the trot is most tolerable; and this motion is known by a cross moving of the horse's limbs, as when the fore-leg, or near hinder-leg, or the near fore-leg and the fore hinder-leg, move and go forward in one instant; and in this motion, the nearer the horse takes his limbs from the ground, the opener, the evenner, and the shorter is his pace; for to take up his feet slovenly, shews stumbling and lameness; to tread narrow or close, shews interfering or falling; to step uneven, indicates toil, and weariness; and to tread strong, shews over-reaching.

"Ambling; which is chose for ease, great men's seats, or long travel, is a motion contrary to trotting; for now both the feet of one side must move equally together, that is, the far fore-leg and the far hinder-leg, and the near fore-leg and the near hinder-leg; and this motion must be just, smooth, large and nimble, for to tread false takes away all ease, to tread short rids no ground, to tread rough shews rolling, and to tread slow shews a false pace, (which never continues), as also lameness.

"Racking; a pace required for buck-hunting, galloping on the highway, post hackney, or the like; and it is the same motion as ambling, only it is a swifter time, and a shorter tread; and though it rids not so much ground, yet it is a little easier.

"Galloping is the last, and must be joined to all the other paces; and this every trotting and racking horse naturally does, but the ambler is a little unapt to it, because the motions are both one, so that being put to a greater swiftness or pace than formerly he had been acquainted with, he manages his legs confusedly and disorderly, but being trained gently, and made to understand the motion, he will as well undertake this as any trotting horse whatever. Now in a good gallop, you must observe first, that the horse that takes up his feet nimbly from the ground, but does not raise them high, that neither rolls nor beats himself, that stretches out his fore-legs, follows nimbly with the others, and neither cuts under his knee, (which is called the swift cut) nor crosses, nor claps one foot on another, and ever leads with his fore-foot, and not with the near; such an one is said ever to gallop comely and true, and he is fittest for speed, or any swift employment; but if he gallops round, and raises his fore-feet, he is then said to gallop strongly, and not swiftly, and is fittest for the great saddle, the wars, and strong encounters; if he gallops slow,

slow, yet sure, he will serve for the high road : but if he labours his feet confusedly, and gallops painfully, then the buyer may conclude, he is good for no galloping service ; besides, it betrays some hidden lameness in him.

“ His nature ; which must be referred to the end for which a horse is bought, ever observing, that the biggest are fittest for strong occasions and great burdens, strong draughts, and double carriage : the middle size for pleasure and general employments ; and the least for ease, sweet walks, and summer hacknics. But to be yet something more particular as to the rule of choice, it is contained in the discovery of natural deformities, accidental outward forrances, or inward hidden mischiefs, which are so many and so infinite, that it is very tedious, though exceeding necessary, to explain them. Wherefore you are, upon this occasion, to observe how a horse stands to view, that is, seeing him stark-naked before you, and placing yourself before his face, take a strict view of his countenance, and the cheerfulness thereof, that being an excellent glass wherein to discern his goodness and perfection.

“ On ordering him out, let no one be the last in the stable but yourself ; you should also, if possible, be the first in, lest the owner, or some of his quick emissaries, take an opportunity to fig him ; a practice common among dealers, in order to make the tail shew as if carried very high, when, in reality, the day after he will in appearance be five pounds worse.

“ His ears ; which if they are small, thin, short, pricked, and moving, or if they be long, be well set on, and well carried, it is a mark of beauty, goodness, and mettle ; but if they are thick, laved, or lolling, wide set, and unmoving, then they are signs of dullness, doggedness, and ill nature.

“ His face ; which, if wan, his forehead swelling outward, no mark or feather in his face set high as above his eyes, or at the top of his eyes ; if he has a white star, or white ratch of an indifferent size, and placed even, or a white snip on his nose or lip, they are all marks of beauty and goodness : but if his face be flat, cloudy, or scouling, his forehead flat as a trencher, which is called mare-faced, for the mark in his forehead stands low, as under his eyes : if his star or ratch stand awry, or in an ill posture, or instead of a snip, his nose be raw or unhairly, or his face generally bald, they all denote deformity.

“ The proper time to examine his eyes, is in a dark stable, with a candle, or rather in the day-time when he is led from the stall ; cause the man who leads him to stop at the stable-door, just as his head peeps out, and all his body still within. Never look at the eye full ; but let your observations be oblique. If the white of the eye appears reddish at the bottom, or of a colour like a withered leaf, I would not advise you to purchase him. A moon-eyed horse is known by his weeping, and by keeping his eyes almost shut at the beginning of the distemper : as the moon changes, he gradually recovers his sight ; and in a fortnight or three weeks sees as well as before he had the disorder. Dealers, when they have such a horse to sell, at the time of his weeping, always tell you that he has got a bit of straw or hay in his eye, or that he has received some blow ; they also take care to wipe away the humour, to prevent its being seen ; but a man should trust only himself in buying of horses, and above all be very exact in examining the eyes. In this he must have regard to time and place where he makes the examination. Bad eyes may appear good in winter, when snow is upon the ground ; and often good ones appear bad, according to the position of the horse. Never examine a horse's eyes by the side of a white wall, where the dealers always choose to shew one that is moon-eyed.

“ The moon-eyed horse has always one eye bigger than the other, and above his lids you may generally discover wrinkles or circles.

“ If you observe a fleshy excrescence that proceeds from the corner of the eye, and covers a part of the pupil, and is in shape almost like the beard of an oyster, though seemingly a matter of no great consequence, yet it is what I call a whitlow in the eye, and if suffered to grow, it draws away a part of the nourishment of the eye, and sometimes occasions a total privation of sight.

“ His eyes ; which, if round, big, black, shining, starting or staring from his head ; if the black of the eye fills the pit, or outward circumference, that in the moving, very little, if any, of the white appears, they are all signs of beauty and goodness. But if his eyes are uneven, and of a wrinkled proportion, or if they be small, which in horsemanship is called pig-eyed, both are uncomely signs of

weakness : if they be red and fiery, beware of moon-eyes, which is next door to blindness ; if white and walled, it betrays a weak, slight, and unnecessary starting, or finding of baggards : if with white specks, take heed of the pearl, pin, and web : if they water or appear bloody, it indicates bruises : and if any matter, it shews old age, and over-riding, festering, rheums, or violent strains ; if they look dead or hollow, or much sunk, beware of blindness at the best : if the black does not fill the pit, but that the white is always appearing, or if in the moving the white and black be seen in equal quantity, it is a sign of weakness, and a dogged disposition in him.

“ Cheeks and chaps ; upon the handling whereof, if you find the bones lean and thin, the space wide between them, and the thropple or windpipe as big as a man can gripe, and the void place without spots or kernels, and the jaws generally so great that the neck seems to couch within them, they are excellent signs of great wind, courage, and soundness of heart and body ; but if the chaps are fat and thick, the place between them closed up with gross substance, and the thropple little, they all are signs of short wind and much inward foulness ; if the void place appears full of knots and kernels, beware of the strangles and glanders, the former of which may be easily discovered by a swelling between the two nether jaw-bones, which discharges a white matter. This disorder usually appears about three, four, or five years old ; there is no young horse but what is subject to it either perfectly or imperfectly ; there is also a disorder which is called the bastard-strangles, which appears sometimes like, and some different from the true strangles. The bastard-strangles are what proves that the horse has not thrown off his true strangles, but that some foul humours are still left behind ; this disorder may come at four, five, six, or seven years of age. A continual languor at work, and seemingly perpetually weary, without any visible ailment, is a certain sign that he is not clear of this disorder, which sometimes will affect the foot, the leg, the ham, the haunch, the shoulders, the breast, or the eye, and without care in this latter case, may corrupt the pupil of the eye, as the small-pox does in men.

“ Feel if he has any flat glands fastened to the nether jaws, which give him pain when you press him, and remember they indicate the glanders.

“ There is also another disorder, much like the strangles, which is called morfoundering, and appears by a running at the nose, but the swelling under the jaw is less. If his jaws be so straight that his neck swells above them, if it be no more than natural, it is only a sign of short wind and purfiness, or grossness ; but if the swelling is long, and close by his chaps, like a whetstone, then take care of the viverris, or some natural imposthume.

“ His nostrils ; which, if open, dry, wide, and large, so as upon any straining the internal redness is discovered, and if his muzzle be small, his mouth deep, and his lips equally meeting, then all are good signs of wind, health, and courage ; but if his nostrils are straight, his wind is but little ; or if his muzzle is gross, his spirit is dull ; if his mouth be shallow, he will never carry a bitt well ; and if his upper lip will not reach his nether, old age or infirmity have marked him out for carrion : if his nose be moist and dropping, when it is clear water, it is a cold ; if foul water, then beware of the glanders.

“ His breast ; look down from his head thereto, and see if it is broad, out-swelling, and adorned with many features, for that shews strength and durance ; whereas the little breast is uncomely, and denotes weakness ; the narrow breast is apt to stumble, fall, and interfere before ; that which is hidden inwards, and wants the beauty and division of many features, indicates a weak-armed heart, and a breast that is unwilling, and not fit for any violent toil or strong labour.

“ In shewing a horse, a dealer or jockey will generally place him with his fore foot on a higher ground than his hind ones, in order that the shoulder may appear further in his back, and make him higher in sight than he really is ; but be sure to cause him to be led on level ground, and see that his shoulders lie well into his back ; for an upright shouldered horse carries his weight too forward, which is disagreeable, and unsafe to the rider. Have his fore legs stand even, and you will then have it in your power to judge of his shoulders. If you do not observe this, the dealer will contrive that this near leg stands before the other, as the shoulders in that position appear to lay further in the back. If his knees stand nearly close, and his toes quite in

in a line, not turning in, nor yet turning out, be assured he will not cut : if he takes his legs up a moderate height, and neither clambers, nor yet goes too near the ground, he will most likely answer your purpose.

" His thighs ; look down from his elbow to his knees, and see that his fore-thighs are ruff-grown, well hardened within, sinewed, fleshy, and out-swelling, they being good signs of strength ; whereas the contrary betokens weakness, and are unnatural.

" His knees ; which, you are to see, if they carry a proportion, be clean, sinewy, and close knit, for then they are good and comely, but if one be bigger and rounder than the other, the horse has received some mischief ; if gross, he is gouty ; if seared or hair-broken, it is a true mark of a stumbling ~~mate~~, and a perpetual faller.

" His legs ; which look down to from his knees to his pasterns, and if they are found to be lean, flat, and sinewy, and the inward bow of the knee without seams or hair-broken, it shews a good shape and soundness ; but if there are hard knots on the inside of the legs they are spleints, if on the outside they are screws or excretions ; if scabs be under his knee on the inside, it is the swift cut, and he will badly endure galloping : but if above his pasterns, on the inside, scabs are found, it shews interfering : again, if the scabs be generally over his legs, it is extreme foul-keeping, or else a spice of the mange : if his legs be fat, round, and fleshy, he will never endure labour : and if seams, scabs, and hair-brokenness, be found on the inward bow of his knees, it shews a malander, which is a cancerous ulcer.

" Circled feet are very easy to be known : they are when you see little excrescences round the hoof, which enclose the foot, and appear like so many small circles. Dealers, who have such horses, never fail to rasp round their hoofs, in order to make them smooth ; and to conceal the rasping, when they are to shew them for sale, they black the hoof all over, for without that, one may easily perceive what has been done, and seeing the mark of the rasp, is a proof that the horse is subject to this accident. As to the cause, it proceeds from the remains of an old distemper, or from having been foundered ; and the disease being cured, without care being taken of the feet, whereupon the circulation of the blood not being regularly made, especially round the crown, between the hair and the horn, the part loses its nourishment, and contracts or enlarges itself in proportion as the horse is worked. If these circles were only on the surface, the jockies method of rasping them down would then be good for nothing ; but they form themselves also within the feet, as well as without, and consequently press on the sensible part, and make a horse limp with ever so little labour. One may justly compare a horse in this situation, to a man that has corns on his feet, and yet is obliged to walk a long way in shoes that are too tight and stubborn : a horse therefore is worth a great deal less on this account.

" After having well examined the feet, stand about three paces from his shoulders, and look carefully that he is not bow-legged, which proceeds from two different causes ; first, from nature, when a horse has been got by a worn-out stallion : and secondly, from his having been worked too young ; neither in the one case nor the other is the horse of any value, because he never can be sure footed ; it is also a disagreeable sight if the knees point forwards, and his legs turn in under him, so that the knees come much further out than the feet : it is also called a bow-legged horse, and such an one ought to be rejected for any service whatsoever, as he never can stand firm on his legs ; and how handsome soever he may otherways be, he should on no account be used for a stallion, because all his progeny will have the same deformity.

" Pastern and pastern-joints ; the first of which must be short, strong and upright standing ; the second, clear, and well knit together, for if they are swelled or big, beware of sinew-strains, and gourdings : and if the other be long, weak, or bending, the limbs will hardly be able to carry the body without tiring.

" The hoof ; which should generally be black, smooth, tough, rather a little long than round, deep, hollow, and full of sounding, for white hoofs are tender, and carry the shoe ill : a rough gross-seamed hoof discovers old age, or over-heating : a brittle one will carry no shoe at all, and an extraordinary round one is bad for foul ways and deep hunting ; a flat one that is pumiced, shews foundering ; and a hoof that is empty and hollow sounding betokens a decayed

inward part, through some dry wound or founder. Then as for the crown of the hoof, if the hair lies smooth and close, and the flesh flat and even, the hoof is perfect ; but if the hair be staring, the skin scabbed, and the flesh rising, you may expect a ring-bone, crown-scab, or quitter-bone.

" You are to consider the setting on of his crest, head, and mane. As for his head, stand by his side, and see that it does not stand too high nor too low, but in a direct line : that his neck be small at the setting on of his head, and long, growing deeper to the shoulders, with an high, strong and thin mane, long, soft, and somewhat curling, they being beautiful characters, whereas to have the head ill set on, is the greatest deformity : for if thick set, be assured it will cause him to toss up his nose for want of wind, which causes a horse to carry his head disagreeably high, and occasions a ticklish mouth. To have any bigness or swelling in the nape of the neck, shews the poll-evil, or beginning of a fistula : to have a short thick neck, like a bull, to have it falling at the withers, to have a low, weak, a thick or falling crest, shews both the want of strength and mettle : to have much hair on the mane, denotes intolerable dullness : to have it thin, shews fury ; and to be without any, or shed, shews the worm in the mane, the itch, or else plain manginess.

" In the next place, you are to consider his back, ribs, belly, and stones. First view his chine, that it be broad, even, and strait ; that the ribs are well compassed, and bending outward ; that the fillets be upright, strong and short, and not above a handful between his last rib and the hucklebone : his belly should be well laid down, yet laid within his ribs, and his stones well trussed to his body, which are all good marks of health and perfection ; be careful in observing that he has no swelling in his testicles, a disorder that proceeds either from some strain in working, or from the horse's having continued too long in the stable, or from putting one leg over any bar, and being checked by the halter, or from any other accident that confines a horse, makes him kick or sling, and bruise his cods, and there is no other way of knowing this distemper, but by some outward swelling upon the part. To have his chine narrow, he will never well carry a saddle without wounding : and to have it bending or saddle-backed, shews weakness : to have his ribs flat, there will be no liberty for wind ; to have his fillets hanging, long, or weak, he will never clamber a hill, nor carry a burden ; and to have his belly clung up or gaunt, or his stones dangling down, loose or aside, are both signs of sickness, tenderness, foundering of the body, and unfit for labour.

" You must view his buttocks, that they are round, plump, full, and in an even level with his body, or if long, that they be well raised behind, and spread forth at the setting on of the tail, which is comely and beautiful, whereas the narrow-pin buttock, the hog or swine rump, and the falling and downlet buttocks, are full of deformity, and shew both an injury in nature, and they are neither fit nor becoming for pad, foot-cloth, or pillion. The horse that is deep in his girthing-place, is generally of great strength.

" His hinder thighs, or gaskins ; which observe that they be well let down, even to the middle joint, brawny, full and swelling, which is a very good sign of strength and goodness, whereas the lank, slender thighs shew the contrary.

" View his cambrels ; from the thigh-bone to the hock it should be pretty long, but short from the hock to the pastern ; have an eye to the joint behind, and if it be but skin and bones, veins and sinews, or rather somewhat bending than too straight, it is then perfect, and as it ought to be ; but if it has chaps or sores on the inward bow or bending, then it is a sclander : if the joint is swelled generally all over, then it betokens a blow or bruise : if the swelling be particular, as in the pit or hollow part, or on the inside, and the vein full and proud, and that it be soft, it is a blood-spavin ; if hard, a bone-spavin : but if the swelling be just behind, before the knuckle, then you may know it is a curb.

" His hinder legs ; which, see if they be lean, clean, flat, and sinewy, then all is well, but if fat, they will not endure labour : if swelled, the grease is melted in them : if the horse be scabbed above the pasterns, he has the scratches : if chapped under his pasterns, he has reins, and none of these are noisome.

" There is also a defect which is more common in the hind than the fore-legs, though the latter are not quite ex-

empt from it; and it is called the rat's tail, and is thus known: When you see from the hind part of the fetlock, up along the nerves, a kind of line or channel that separates the hair to both sides, this is a rat's tail; and in summer there appears a kind of small dry scab along this channel; and in winter there issues out a humidity like the water from the legs. A horse may work notwithstanding this disorder, for it seldom lames him; it sometimes occasions a stiffness in his legs, and makes them trot like foxes, without bending their joints. The hind-legs should be lean, clean, flat, and sinewy; for if fat, they will not bear labour; if swelled, the grease is molten into them; if scabbed above the pasterns, it is the scratches, and if he hath chops under his pasterns, he hath what is generally called the reins. If he has a good buttock, his tail cannot stand ill, but it will be broad, high, flat, and couched a little inward.

Having with care examined the horse, let him be run in hand a gentle trot; by this you will soon perceive if he is lame or not. Make the man lead him by the end of the bridle, as in this case you cannot be deceived by the man's being too near him. The far fore-leg and near hind-leg, or the near fore-leg, and far hind-leg, should move and go forward at one and the same time; and in this motion, the nearer the horse taketh his limbs from the ground, the opener, the evenner, and the shorter is his pace.

If he takes up his feet slovenly, it shews stumbling or lameness; to tread narrow, or cross, shews interfering, or failing; to step uneven, shews weariness, and if he treads long, you may be apprehensive he forges; by which I mean, that when he walks or trots, he strikes the toes of his hind feet against the corners of his shoes before, which occasions a clattering noise as you ride; and this proceeds generally from the weakness of his fore legs, he not having strength in them to raise them up sufficiently quick to make way for the hind ones. A horse of this kind is not near so serviceable as the horse exempt from it, and the dealers, to get rid of him, will make abundance of pretences: if he has been just shod, they will say the farrier has put him on too long shoes; if his shoes are old, they will tell you he is just come off a long journey, and is much fatigued; you must not therefore be over credulous to any thing a jockey or dealer affirms, for what they say in this manner is too often with intent to deceive; and it is very certain that a horse who forges can never be sure-footed, any more than one who has tottering or bow legs.

On his being mounted, see him walk. Observe his mouth that he pulls fair, not too high, nor bearing down: then stand behind him, and see if he goes narrower before than behind, as every horse that goes well on his legs goes in that manner. Take notice that he brushes not by going too close; a certain sign of his cutting, and tiring in travelling. Have nothing to do with that horse who throws his legs confusedly about, and crosses them before: this you may observe by standing exactly before or behind him, as he is going along. In his trot he should point his fore legs well, without clambering, nor yet as if he were afraid: and that he throws well in his hind-legs, which will enable him to support his trot, and shoot his fore-parts forwards.

In his canter, observe he does not fret, but goes cool in this pace; and in his gallop he should take his feet nimbly from the ground, and not raise them too high, but that he stretcheth out his fore-legs, and follows nimbly with his hind ones, and that he cutteth not under his knee, (which is called the swift or speedy cut) that he crosses not, nor claps one foot on another, and ever leadeth with his far fore-foot, and not with the near one. If he gallops round, and raises his fore-feet, he may be said to gallop strongly, but not swiftly; and if he labours his feet confusedly, and seems to gallop painfully, it shews some hidden lameness; for in all his paces, you should particularly observe that his limbs are free, without the least stiffness.

After he has been well exercised in those different paces, it is your time to examine for an infirmity, not easily discovered, and that is, what I call tottering legs: you cannot perceive it till after a horse has galloped for some time, and then, by letting him rest a little, you will see his legs tremble under him, which is the disorder I mean: how handsome soever the legs of such a horse may be, he never can stand well on them; you are therefore not to mind what the jockey says when he talks of the beauty of the limbs, for if you oblige him to gallop the horse, or fatigue him pretty much, (which is commonly done in order to

try the creature's bottom) you will in all likelihood discover this defect, unless you suffer the groom to gallop him to the stable door and put him up in a moment, which he will certainly endeavour to do, if he is conscious of it, while the master has another horse ready to shew you, in order to take off your attention from what he is afraid you should see.

RUNCHEs, charlock when dry and withered.

RUNNEL, pollard wood.

RUNET, the acid juice found in the stomachs of calves, that have fed on nothing but milk, and are killed before the digestion is perfect. It also signifies a liquor made by steeping the stomach of a calf in hot water. The latter is the runnet used in making cheese, &c.

RUNNING-THRUSH, or **FRUSH**, is an imposthume that sometimes gathers in a horse's frog; or a scabby and ulcerous disposition, which sometimes causes it to fall off.

When this discharge is natural, the feet should be kept clean, but no drying washes should be made use of, it being thought as unsafe to repel some of these discharges as to cure some sweaty feet.

When an imposthume, or gathering appears, the safest way is to pare out the hard part of the frog, or whatever appears rotten; and wash the bottom of the foot two or three times a day with old chamber-lye; this is the safest and best way of treating them. But when a horse has been neglected, and there is a strong flux to the part, it is apt to degenerate into a canker; to prevent which, use the following:

Take spirit of wine and vinegar, of each two ounces; tincture of myrrh and aloes, one ounce; *Ægyptiacum* half an ounce; mix together.

Bathe the thrush with this, wherever there appears a more than ordinary moisture, and lay over the ulcer a little tow dipped in the same. The purges and diuretics recommended in the grease, should be given at this time, to prevent the inconveniences that the drying up these discharges frequently occasion. See the article **CANKER**. *Bartlett's Farriery*, p. 312.

RUNT, a name given to small black cattle brought out of Wales and Scotland.

RUNT, is also an epithet applied to several species of pigeons: as the Leghorn, Spanish, and Friesland runt, &c.

The Leghorn runt is a stately large pigeon, seven inches or better in the legs, close feathered and fast-fleshed, extremely broad-breasted, and very short in the back. He carries his tail, when he walks, somewhat turned up like a duck's, his neck is longer than any other pigeon's, and he carries it bending like a goose or swan. He is goose-headed, and his eye lies hollow in his head, with a thin skin round it, like that of the Dutch tumbler. His beak is very short for so large a bird, and has a small wattle on it, and the upper chap falls a little over. It is a very valuable pigeon, but is tender, and requires care.

The Spanish runt is the longest-bodied of all the pigeons; it is short legged and loose-feathered, and does not walk so upright as the Leghorn runt. These are of a great variety of colours, but are apt to have accidents in sitting, from their sitting too heavy, and often breaking their eggs.

The Friesland runt is a large pigeon, and has all its feathers reversed, or looking as if placed the wrong way.

The Roman runt is a pigeon of the same general make with the common kind, but so large and heavy that it can hardly fly.

The Smyrna runt is middle-sized, and is feather-footed, and to such a degree sometimes is to look as if there were wings upon the feet; the feathers of these are sometimes four or five inches long, and often pull the eggs and young out of the nests. The common runt is the common blue pigeon kept for the table, and known to every body. *Moore's Columbarian*.

RUPTURE, a preternatural eruption of the guts or caul.

In regard to ruptures, though they are generally divided into particular classes, we shall only observe, that by violent efforts of the horse, or other accidents, the guts or caul may be forced between the muscles of the belly at the navel, and through the rings of the muscles into the scrotum or cod. The swellings are generally about the size of a man's fist, sometimes much larger, descending to the very

hock; they are frequently soft, and yield to the pressure of the hand, when they will return into the cavity of the belly with a rumbling noise; and in most the vacuity may be felt, through which they passed.

On their first appearance, endeavours should be made to return them by the hand; but if the swelling should be hard and painful, in order to relieve the stricture, and relax the parts through which the gut or caul has passed, let a large quantity of blood be immediately taken away, and the part fomented twice or thrice a day, applying over it a poultice made with oatmeal, oil and vinegar, which should be continued till the swelling grows soft and easier, or the gut is returned. In the mean time it would be proper to throw up emollient oily clysters twice a day, and to let the horse's chief diet be boiled barley, scaled malt, or bran.

Should the swelling afterwards return, we apprehend the restraining applications usually recommended on these occasions, will avail little, without a suspensory bandage; so that an ingenious mechanic in that art is chiefly to be relied on, for any future assistance; though it has been observed, that with moderate feeding and gentle exercise, some horses have continued to be very useful under this complaint. *Bartlett's Farriery, p. 334.*

RUSH, the name of a well-known plant, too common in wet lands.

Rushes always intimate a good soil, and may be destroyed by lime, even after it has been slaked, by sea-coal ashes, and by draining the land.

Rushes thrive most in land that is too wet and cold for most other plants. Ashes and other warm manures of various kinds, laid on plentifully, will keep down the rushes for a time; but to eradicate them perfectly it is necessary also to well drain the land.

RUST, a distemper incident to corn, and generally called mildew. *See the article MILDREW.*

RYE, a species of corn greatly cultivated in the northern parts of England.

Mr. Miller is of opinion, that all the rye sown in England is of the same species, though distinguished by farmers into two varieties, of winter, and spring rye, as he has not been able, by the most sedulous experience, to find any difference.

The winter rye, which is the largest grain, is what the generality of farmers cultivate. It is usually sown in autumn, or at the same time as wheat; and in many of our northern counties, as well as in Wales, they are often mixed and sown together; though as Mr. Miller rightly observes, this must be very bad husbandry, because the rye will always ripen sooner than the wheat; so that if the latter be suffered to stand till fully ripe, the grain of the former will shed, nor can this be practised where the people are not accustomed to eat rye-bread; for though some account it good when mixed, it is so very clammy that few who have been used to wheaten bread will ever relish it.

Rye is generally sown on poor, lime-stone, dry, gravelly, or sandy soils, where wheat will not thrive, and in such places it does very well. The ground should be dry when it is sown: for if much rain falls even after the sowing, before the rye is come up, it often rots in the earth. It indeed rises in a much shorter time than wheat.

When sown upon light land, it ripens much earlier than a cold stiff ground, and by continuing to sow it in such a soil during two or three years, it will be forwarded so much as to ripen a month earlier than that which has been long raised upon strong cold ground. For this reason, those who are obliged to sow rye toward spring, generally provide themselves with this early seed. A little sprinkling of dung or mud, though it be but half the quantity commonly used for other corn land, will, if laid upon the rye ground, greatly advance the crop. The usual allowance is two bushels of seed to a statute acre, or, if it be new broke up ground, or land subject to worms, about a peck more: and the produce commonly is about twenty bushels upon an acre.

In the summer of the year 1699, which was uncommonly dry, Mr. Mortimer reckoned ninety grains a piece in several ears of rye.

The small rye may be sown in the spring, about the same time as oats, and usually ripens as soon as the other sort: but if the season prove wet, it is apt to run much to straw, and the grain is generally lighter than the other. The chief use of this sort is to re-sow land where the autumnal crop has failed.

This corn is ripe when its straw turns yellow, its ear hangs, and its grain is hard. It is not very apt to shed: and therefore, if it be weedy (though this ought never to be the case with any corn) it should be let lie upon the ground, or gavel, as some call it, a week or ten days after it is cut, if the weeds do not dry sooner, before it be bound up; for otherwise those weeds will give in the barn, make the rye not thrash well, and render it musty. But as this grain will grow in the ear sooner than any other, if it be wet, particular care must be taken, especially if rain comes on, to turn it at least once in two or three days, and lay the ears upon the stubble as high above the ground as can be. This will help to preserve it from hurtful moisture: but if it be cut in perfectly dry weather, and without weeds, it may be housed as it is reaped.

The general use of rye is for bread, either alone, or mixed with wheat, in which it is called messin corn. It also yields a strong spirit when distilled: and, if sowed only for dressing of land, is of vast service to the ground where it is ploughed-in green and succulent. The truly worthy and reverend Dr. Elliot informs us, that he has not only been told, but knows by his own observation, that if rye be sowed successively every year upon the same land, both the crop and the land will be greatly improved; insomuch that some grounds which would yield but five bushels to the acre at first, have, in time, afforded a crop of fifteen bushels to the acre, without the charge of dung or any other manure. But it should be remembered that the land sown by Dr. Elliot was newly broke up.

This plant is likewise sown in autumn to great advantage, purposely for green feed for cattle, particularly for ewes and lambs in the spring, before there is plenty of grass. When this is intended, the rye should be sown early, that it may have strength to furnish early fodder. In this light, it supplies the want of turnips where they have failed, or where their season is over: so that in such cases, it is very good husbandry to sow the land with rye, especially where there are flocks of sheep which cannot be well supported without green food early in the spring. The farmer who has many sheep would consider, that turnips are always a very precarious crop: and therefore he should, besides sowing some places with cole-seed, in order to have green fodder, sow rye in others, to guard against accidents. If some of the ground sowed late with turnips, which have failed, be sown in the autumn with rye, he will find it turn to good account. To have green fodder for cattle in April, which is the scarcest time of all the year, some split the ridges of their wheat stubble, and sow them with rye, allowing about a bushel to an acre, which they harrow in, and feed about April, or when they want it; and in May they plough it up for a fallow.

Mr. Marshall, in his Rural Economy of Yorkshire, says that "the only species of rye cultivated in these kingdoms is the *secale cereale* of Linnæus; of which two varieties are cultivated in this district.

"Black rye, formerly the only sort, and white rye, or Dantzick rye, introduced into this country about half a century ago, and is now the almost only sort which is cultivated.

"Before the use of lime was prevalent, much rye was grown on the lighter lands upon the margin of the Vale; and in the Morelands scarcely any other crops than rye and oats were attempted. Now, rye is principally confined to the Moreland-dales; and even there the alteration of soils by lime has been such, that wheat is become the more prevalent crop.

"Nevertheless, on light sandy Moreland soils rye is generally more profitable than wheat; and the bread, which is made from a mixture of the two grains, is here esteemed more wholesome to persons in general, than that which is made from wheat alone."

RYE-GRASS. *See GRASS.*

S.

SADDLE-GALL; when a horse's back is hurt or fretted by the saddle, it may be cured by bathing the part with urine, or warm wine: and sometimes when the sore is large, with the second water strewing over it the powder of an old rope, or flax, and eating away the proud flesh with vitriol or colcothar.

SAFFRON, a genus of plants with narrow grass-like leaves, which have a white line running along the middle: the stalk is short and undivided, and bears on the top a purplish blue flower, deeply cut into segments: in the middle of the flower arises, among the stamina, a whitish pistil, divided at the top into three chives or fleshy filaments, the lower part of which is slender and pale coloured, the upper broader, of a deep orange red, and very finely indented about the sides: these filaments, carefully picked, and pressed together into cakes, are the saffron of the shops. The plant is perennial, and flowers in autumn.

As saffron grows at present most plentifully in Cambridgeshire, and has grown formerly in several other counties in England, the method of culture does not, I believe, vary much in any of them; and therefore I judge it sufficient to set down here the observations which I employed proper persons, in different seasons, to make, in the years 1723, 1724, 1725, and 1728, up and down all that large tract of ground that lies between the Saffron-Walden and Cambridge, in a circle of about ten miles diameter.

In that county saffron has most been cultivated; and therefore it may reasonably be expected, that the inhabitants thereof are more thoroughly acquainted with it than they are any where else.

I shall begin with the choice and preparation of the ground: the greatest part of the tract already mentioned is an open level country, with few inclosures; and the custom there is, as in most other places, to crop two years, and let the land lie fallow the third. Saffron is always planted upon fallow ground; and, all other things being alike, they prefer that which has borne barley the year before.

The saffron grounds are seldom above three acres, or less than one; and in choosing, the principal thing they have regard to is, that they be well exposed, the soil not poor, nor a very stiff clay, but temperate dry mould, such as commonly lies upon chalk, and is of an hazle-colour; though, if every thing else answers, the colour of the mould is pretty much neglected.

The ground being made choice of about Lady-day or the beginning of April, it must carefully be ploughed, the furrows being drawn much closer together and deeper, if the soil will allow it, than it is done for any kind of corn; and, accordingly, the charge is greater.

About five weeks after, during any time in the month of May, they lay between twenty and thirty loads of dung upon each acre; and, having spread it with great care, they plough it in as before; the shortest rotten dung is the best; and the farmers, who have the convenience of making it, spare no pains to make it good, being sure of a proportionable price for it. About Midsummer they plough a third time, and between every sixteen feet and a half or pole in breadth, they leave a broad furrow or trench, which serves both as a boundary to the several parcels, when there are several proprietors to one inclosure, and to throw the weeds in at the proper season.

To this head likewise belongs the fencing of the grounds, because most commonly, though not always, that is done before they plant. The fences consist of what they call dead hedges, or hurdles to keep out not only cattle of all sorts, but especially hares, which would otherwise feed on the saffron leaves during the winter.

About the weather we need only observe, that the hottest summers are certainly the best: and therewith, if there be gentle showers from time to time, they can hard-

ly miss of a plentiful crop, if the extreme cold, snow, or rain of the foregoing winter have not prejudiced the heads.

The next general part of the culture of saffron, is planting or setting the roots: the only instrument used for which is a narrow spade, commonly termed a spit-shovel.

The time of planting is commonly in July, a little sooner or later, according as the weather answers. The method is this: one man with his spit-shovel raises between three and four inches of earth, and throws it before him about six or more inches: two persons, generally women, following with heads, place them in the farthest edge of the trench he makes, at three inches distance from each other, or thereabouts: as soon as the digger or spitter has gone once the breadth of the ridge he begins again at the other side, and digging, as before, covers the roots last set, and makes the same room for the setters to place a new row, at the same distance from the first as they are from one another: thus they go on till a whole ridge, containing commonly one rod, is planted; and the only nicety in digging is, to leave some part of the first stratum of earth untouched, to lie under the roots; and, in setting, to place the roots directly upon their bottom.

What sort of roots are to be preferred, shall be shewn under the fourth head; but it must be observed in this place, that formerly, when roots were very dear, they did not plant them so thick as they do now, and that they have always some regard to the size of the roots, placing the largest at a greater distance than the smaller ones.

The quantity of roots, planted in an acre, is generally about sixteen quarters, or one hundred and twenty-eight bushels; which, according to the distances left between them as before assigned, and supposing all to be an inch in diameter one with another, ought to amount to three hundred and ninety-two thousand and forty in number.

From the time that the roots are planted, till about the beginning of September, or sometimes later, there is no more labour about them; but as they then begin to spire, and are ready to shew themselves above ground, which is known by digging a few out of the earth, the ground must be carefully pared with a sharp hoc, and the weeds, &c. raked into the furrows, otherwise they would hinder the growth of the plants.

In some time after appear the saffron flowers; and this leads us to the third branch of our present method. The flowers are gathered as well before as after they are full blown; and the most proper time for this is early in the morning. The owners of the saffron get together a sufficient number of hands, who place themselves in different parts of the field, pull off the whole flowers, and throw handful by handful into a basket, and so continue till all the flowers are gathered, which happens commonly about ten or eleven o'clock. Having then carried home all they have got, they immediately spread them upon a large table, and fall to picking out the filamenta styli, or chives, and together with them a pretty long proportion of the stylus itself, or string to which they are joined; the rest of the flower they throw away as useless. The next morning they return into the field again, whether it be wet or dry weather; and so on daily, even on Sundays, till the whole crop be gathered.

The chives being all picked out of the flowers, the next labour about them is to dry them on the kiln. The kiln is built upon a thick plank, that it may be removed from place to place, supported by four short legs: the outside of eight pieces of wood about three inches thick, in form of a quadrangular frame, about twelve inches square at the bottom of the inside, and twenty-two inches at top; which is likewise equal to the perpendicular height

hock; they are frequently soft, and yield to the pressure of the hand, when they will return into the cavity of the belly with a rumbling noise; and in most the vacuity may be felt, through which they passed.

On their first appearance, endeavours should be made to return them by the hand; but if the swelling should be hard and painful, in order to relieve the stricture, and relax the parts through which the gut or caul has passed, let a large quantity of blood be immediately taken away, and the part fomented twice or thrice a day, applying over it a poultice made with oatmeal, oil and vinegar, which should be continued till the swelling grows soft and easier, or the gut is returned. In the mean time it would be proper to throw up emollient oily clysters twice a day, and to let the horse's chief diet be boiled barley, scaled malt, or bran.

Should the swelling afterwards return, we apprehend the restraining applications usually recommended on these occasions, will avail little, without a suspensory bandage; so that an ingenious mechanic in that art is chiefly to be relied on, for any future assistance; though it has been observed, that with moderate feeding and gentle exercise, some horses have continued to be very useful under this complaint. *Bartlett's Farriery*, p. 334.

RUSH, the name of a well-known plant, too common in wet lands.

Rushes always intimate a good soil, and may be destroyed by lime, even after it has been flaked, by sea-coal ashes, and by draining the land.

Rushes thrive most in land that is too wet and cold for most other plants. Ashes and other warm manures of various kinds, laid on plentifully, will keep down the rushes for a time; but to eradicate them perfectly it is necessary also to well drain the land.

RUST, a distemper incident to corn, and generally called mildew. See the article MILDEW.

RYE, a species of corn greatly cultivated in the northern parts of England.

Mr. Miller is of opinion, that all the rye sown in England is of the same species, though distinguished by farmers into two varieties, of winter, and spring rye, as he has not been able, by the most sedulous experience, to find any difference.

The winter rye, which is the largest grain, is what the generality of farmers cultivate. It is usually sown in autumn, or at the same time as wheat; and in many of our northern counties, as well as in Wales, they are often mixed and sown together; though as Mr. Miller rightly observes, this must be very bad husbandry, because the rye will always ripen sooner than the wheat; so that if the latter be suffered to stand till fully ripe, the grain of the former will shed, nor can this be practised where the people are not accustomed to eat rye-bread; for though some account it good when mixed, it is so very clammy that few who have been used to wheaten bread will ever relish it.

Rye is generally sown on poor, lime-stone, dry, gravelly, or sandy soils, where wheat will not thrive, and in such places it does very well. The ground should be dry when it is sown: for if much rain falls even after the sowing, before the rye is come up, it often rots in the earth. It indeed rises in a much shorter time than wheat.

When sown upon light land, it ripens much earlier than a cold stiff ground, and by continuing to sow it in such a soil during two or three years, it will be forwarded so much as to ripen a month earlier than that which has been long raised upon strong cold ground. For this reason, those who are obliged to sow rye toward spring, generally provide themselves with this early seed. A little sprinkling of dung or mud, though it be but half the quantity commonly used for other corn land, will, if laid upon the rye ground, greatly advance the crop. The usual allowance is two bushels of seed to a statute acre, or, if it be new broke up ground, or land subject to worms, about a peck more: and the produce commonly is about twenty bushels upon an acre.

In the summer of the year 1699, which was uncommonly dry, Mr. Mortimer reckoned ninety grains a peck in several ears of rye.

The small rye may be sown in the spring, about the same time as oats, and usually ripens as soon as the other sort: but if the season prove wet, it is apt to run much to straw, and the grain is generally lighter than the other. The chief use of this sort is to re-sow land where the autumnal crop has failed.

This corn is ripe when its straw turns yellow, its ear hangs, and its grain is hard. It is not very apt to shed: and therefore, if it be weedy (though this ought never to be the case with any corn) it should be let lie upon the ground, or gavel, as some call it, a week or ten days after it is cut, if the weeds do not dry sooner, before it be bound up; for otherwise those weeds will give in the barn, make the rye not thrash well, and render it musty. But as this grain will grow in the ear sooner than any other, if it be wet, particular care must be taken, especially if rain comes on, to turn it at least once in two or three days, and lay the ears upon the stubble as high above the ground as can be. This will help to preserve it from hurtful moisture: but if it be cut in perfectly dry weather, and without weeds, it may be housed as it is reaped.

The general use of rye is for bread, either alone, or mixed with wheat, in which it is called messin corn. It also yields a strong spirit when distilled: and, if sowed only for dressing of land, is of vast service to the ground where it is ploughed-in green and succulent. The truly worthy and reverend Dr. Elliot informs us, that he has not only been told, but knows by his own observation, that if rye be sowed successively every year upon the same land, both the crop and the land will be greatly improved; insomuch that some grounds which would yield but five bushels to the acre at first, have, in time, afforded a crop of fifteen bushels to the acre, without the charge of dung or any other manure. But it should be remembered that the land sown by Dr. Elliot was newly broke up.

This plant is likewise sown in autumn to great advantage, purposely for green feed for cattle, particularly for ewes and lambs in the spring, before there is plenty of grass. When this is intended, the rye should be sown early, that it may have strength to furnish early fodder. In this light, it supplies the want of turnips where they have failed, or where their season is over: so that in such cases, it is very good husbandry to sow the land with rye, especially where there are flocks of sheep which cannot be well supported without green food early in the spring. The farmer who has many sheep would consider, that turnips are always a very precarious crop: and therefore he should, besides sowing some places with cole-seed, in order to have green fodder, sow rye in others, to guard against accidents. If some of the ground sowed late with turnips, which have failed, be sown in the autumn with rye, he will find it turn to good account. To have green fodder for cattle in April, which is the scarcest time of all the year, some split the ridges of their wheat stubble, and sow them with rye, allowing about a bushel to an acre, which they harrow in, and feed about April, or when they want it; and in May they plough it up for a fallow.

Mr. Marshall, in his Rural Economy of Yorkshire, says that "the only species of rye cultivated in these kingdoms is the *secale cereale* of Linnæus; of which two varieties are cultivated in this district.

"Black rye, formerly the only sort, and white rye, or Dantzick rye, introduced into this country about half a century ago, and is now the almost only sort which is cultivated.

"Before the use of lime was prevalent, much rye was grown on the lighter lands upon the margin of the Vale; and in the Morelands scarcely any other crops than rye and oats were attempted. Now, rye is principally confined to the Moreland-dales; and even there the alteration of soils by lime has been such, that wheat is become the more prevalent crop.

"Nevertheless, on light sandy Moreland soils rye is generally more profitable than wheat; and the bread, which is made from a mixture of the two grains, is here esteemed more wholesome to persons in general, than that which is made from wheat alone."

SADDLE-GALL; when a horse's back is hurt or fretted by the saddle, it may be cured by bathing the part with urine, or warm wine: and sometimes when the sore is large, with the second water strewing over it the powder of an old rope, or flax, and eating away the proud flesh with vitriol or colcothar.

SAFFRON, a genus of plants with narrow grass-like leaves, which have a white line running along the middle: the stalk is short and undivided, and bears on the top a purplish blue flower, deeply cut into segments: in the middle of the flower arises, among the stamina, a whitish pistil, divided at the top into three chives or fleshy filaments, the lower part of which is slender and pale coloured, the upper broader, of a deep orange red, and very finely indented about the sides: these filaments, carefully picked, and pressed together into cakes, are the saffron of the shops. The plant is perennial, and flowers in autumn.

As saffron grows at present most plentifully in Cambridgeshire, and has grown formerly in several other counties in England, the method of culture does not, I believe, vary much in any of them; and therefore I judge it sufficient to set down here the observations which I employed proper persons, in different seasons, to make, in the years 1723, 1724, 1725, and 1728, up and down all that large tract of ground that lies between the Saffron-Walden and Cambridge, in a circle of about ten miles diameter.

In that county saffron has most been cultivated; and therefore it may reasonably be expected, that the inhabitants thereof are more thoroughly acquainted with it than they are any where else.

I shall begin with the choice and preparation of the ground: the greatest part of the tract already mentioned is an open level country, with few inclosures; and the custom there is, as in most other places, to crop two years, and let the land lie fallow the third. Saffron is always planted upon fallow ground; and, all other things being alike, they prefer that which has borne barley the year before.

The saffron grounds are seldom above three acres, or less than one; and in choosing, the principal thing they have regard to is, that they be well exposed, the soil not poor, nor a very stiff clay, but temperate dry mould, such as commonly lies upon chalk, and is of an hazle-colour; though, if every thing else answers, the colour of the mould is pretty much neglected.

The ground being made choice of about Lady-day or the beginning of April, it must carefully be ploughed, the furrows being drawn much closer together and deeper, if the soil will allow it, than it is done for any kind of corn; and, accordingly, the charge is greater.

About five weeks after, during any time in the month of May, they lay between twenty and thirty loads of dung upon each acre; and, having spread it with great care, they plough it in as before; the shortest rotten dung is the best; and the farmers, who have the convenience of making it, spare no pains to make it good, being sure of a proportionable price for it. About Midsummer they plough a third time, and between every sixteen feet and a half or pole in breadth, they leave a broad furrow or trench, which serves both as a boundary to the several parcels, when there are several proprietors to one inclosure, and to throw the weeds in at the proper season.

To this head likewise belongs the fencing of the grounds, because most commonly, though not always, that is done before they plant. The fences consist of what they call dead hedges, or hurdles to keep out not only cattle of all sorts, but especially hares, which would otherwise feed on the saffron leaves during the winter.

About the weather we need only observe, that the hottest summers are certainly the best: and therewith, if there be gentle showers from time to time, they can hard-

ly miss of a plentiful crop, if the extreme cold, snow, or rain of the foregoing winter have not prejudiced the heads.

The next general part of the culture of saffron, is planting or setting the roots: the only instrument used for which is a narrow spade, commonly termed a spit-shovel.

The time of planting is commonly in July, a little sooner or later, according as the weather answers. The method is this: one man with his spit-shovel raises between three and four inches of earth, and throws it before him about six or more inches: two persons, generally women, following with heads, place them in the farthest edge of the trench he makes, at three inches distance from each other, or thereabouts: as soon as the digger or spitter has gone once the breadth of the ridge he begins again at the other side, and digging, as before, covers the roots last set, and makes the same room for the setters to place a new row, at the same distance from the first as they are from one another: thus they go on till a whole ridge, containing commonly one rod, is planted; and the only nicety in digging is, to leave some part of the first stratum of earth untouched, to lie under the roots; and, in setting, to place the roots directly upon their bottom.

What sort of roots are to be preferred, shall be shewn under the fourth head; but it must be observed in this place, that formerly, when roots were very dear, they did not plant them so thick as they do now, and that they have always some regard to the size of the roots, placing the largest at a greater distance than the smaller ones.

The quantity of roots, planted in an acre, is generally about sixteen quarters, or one hundred and twenty-eight bushels; which, according to the distances left between them as before assigned, and supposing all to be an inch in diameter one with another, ought to amount to three hundred and ninety-two thousand and forty in number.

From the time that the roots are planted, till about the beginning of September, or sometimes later, there is no more labour about them; but as they then begin to spire, and are ready to shew themselves above ground, which is known by digging a few out of the earth, the ground must be carefully pared with a sharp hoe, and the weeds, &c. raked into the furrows, otherwise they would hinder the growth of the plants.

In some time after appear the saffron flowers; and this leads us to the third branch of our present method. The flowers are gathered as well before as after they are full blown; and the most proper time for this is early in the morning. The owners of the saffron get together a sufficient number of hands, who place themselves in different parts of the field, pull off the whole flowers, and throw handful by handful into a basket, and so continue till all the flowers are gathered, which happens commonly about ten or eleven o'clock. Having then carried home all they have got, they immediately spread them upon a large table, and fall to picking out the filamenta styli, or chives, and together with them a pretty long proportion of the stylus itself, or string to which they are joined; the rest of the flower they throw away as useless. The next morning they return into the field again, whether it be wet or dry weather; and so on daily, even on Sundays, till the whole crop be gathered.

The chives being all picked out of the flowers, the next labour about them is to dry them on the kiln. The kiln is built upon a thick plank, that it may be removed from place to place, supported by four short legs: the outside of eight pieces of wood about three inches thick, in form of a quadrangular frame, about twelve inches square at the bottom of the inside, and twenty-two inches at top; which is likewise equal to the perpendicular height

height of it. On the foreside is left a hole about eight inches square, and four inches above the plank, through which the fire is put in. Over all the rest laths are laid pretty thick, close to one another, and nailed to the frame already mentioned; and then are plastered over on both sides, as are also the planks at bottom very thick, to serve for an hearth. Over the mouth or widest part goes an hair-cloth, fixed to the sides of the kiln; and likewise to two rollers, or moveable pieces of wood, which are turned by wedges or screws, in order to stretch the cloth. Instead of the hair cloth, many people now use a net work, or iron wire, with which it is observed that the saffron dries sooner and with a less quantity of fuel: but the difficulty in preserving the saffron from burning makes the hair-cloth be preferred by the nicest judges in drying.

The kiln is placed in a light part of the house; and they begin by laying five or six sheets of white paper on the hair-cloth, upon which they spread the wet saffron between two and three inches thick: this they cover with other sheets of paper, and over these they lay a coarse blanket five or six times doubled; or instead thereof a canvas pillow filled with straw; and, after the fire has been lighted for some time, the whole is covered with a board, having a large weight upon it.

At first they give it a pretty strong heat, to make the chives sweat, as their expression is; and in this, if they do not use a great deal of care, they are in danger of scorching, and so of spoiling all that is on the kiln.

When it has been thus dried about an hour, they take off the board, blanket, and upper papers, and take the saffron off from that which lies next it; raising at the same time the edges of the cake with a knife: then, laying on the paper again, they slide in another board between the hair-cloth and under papers, and turn both papers and saffron upside down: afterwards covering them, as above.

The same heat is continued for an hour longer; then they look to the cake again, free it from the papers, and turn it: then they cover it, and lay on the weight, as before. If nothing happens amiss during these first two hours, they reckon the danger to be over: for they have nothing more to do, but to keep a gentle fire, and to turn their cakes every half hour, till thoroughly dry: for the doing which, as it ought, there are required full twenty-four hours.

In drying the layer of plump chives, they use nothing more, but towards the latter end of the crop, when these come to be smaller, they sprinkle the cake with a little small beer, to make it sweat as it ought: and they begin now to think, that using two linen cloths next the cake, instead of two innermost papers, may be of some advantage in drying: but this practice is followed as yet but by few.

Their fire may be made of any kind of fuel: but that which smokes the least is best; and charcoal, for that reason, is preferred to any other.

What quantity of saffron a first crop will produce, is very uncertain; sometimes five or six pounds of wet chives are got from one crop; sometimes not above one or two, and sometimes not enough to make it worth while to gather and dry it. But this is always to be observed, that about five pounds of wet saffron go to make one pound of dry, for the first three weeks of the crop; and six pounds during the last week; and now the heads are planted very thick, two pounds of dried saffron may at a medium be allowed to an acre for the first crop, and twenty-four pounds for the two remaining; the third being considerably larger than the second.

In order to obtain these, there is only a repetition to be made every year of the labour of hoeing, gathering, picking, and drying, in the same manner as before set down, without the addition of any thing new; except that they let the cattle into the field, after the leaves are decayed, to feed upon the weeds: or, perhaps, mow them for the same use.

About the Midsummer after the third crop is gathered, the roots must all be taken up and transplanted: the management requisite for which is the fourth thing to be treated of. To take up the saffron heads, or break up the ground, as the term is, they sometimes plough it, sometimes use a forked kind of hoe, called a pattock, and then the ground is harrowed once or twice over; during all which time of ploughing or digging, and harrowing, fifteen or more people will find work enough to follow and gather the heads, as they are turned up.

They are next to be carried to the house in sacks, and there cleaned and raised: this labour consists in cleaning the roots thoroughly from the earth, and from the remains of old roots, old involucra, and excrescences; and thus they become fit to be planted in new ground immediately, or to be kept for some time without danger of spoiling.

The quantity of roots taken up, in proportion to those which were planted, is uncertain; but, at a medium, it may be said, that, allowing for all the accidents which happen to them in the ground, and in breaking up from each acre, may be had twenty-four quarters of clean roots, all fit to be planted.

The owners are sure to choose for their own use the largest, plumpest, and fattest roots; but do least of all approve the longest pointed ones, which they call spickets, or spickards, for very small round or flat roots are sometimes observed to flower. This is the whole culture of saffron in the county above-mentioned; and we have only now to consider the charges and profits which may be supposed, one year with another, to attend that branch of agriculture; and of these I have drawn up the following computation for one acre of ground, according to the price of labour in this county.

	l.	s.	d.
Rent for three years	3	0	0
Ploughing for three years	0	18	0
Dunging	3	12	0
Hedging	1	16	0
Spitting and setting the heads	1	12	0
Weeding or paring the ground	1	4	0
Gathering and picking the flowers	6	10	0
Drying the flowers	1	6	0
Instruments of labour for three years, with the kiln, about	0	10	0
Plowing the ground once; and harrowing twice	0	12	0
Gathering the saffron heads	1	0	0
Raising the heads	1	12	0
Total charge	23	12	0

This calculation is made upon supposition, that an acre of ground yields twenty-six pounds of net saffron in three years; which I stated only as a mean quantity between the greatest and the least; and therefore the price of saffron must be judged accordingly, which I think cannot be done better than by fixing it at thirty shillings per pound; since, in plentiful years, it is sold at twenty, and is sometimes worth three or four pounds: at this rate, twenty-six pounds of saffron are worth thirty-nine pounds: and the net profits of an acre of ground, producing saffron; will, in three years, amount to fifteen pounds thirteen shillings, or about five pounds four shillings yearly.

This, I say, may be reckoned the net profit of an acre of saffron, supposing that all the labourers were to be hired for ready money: but, as the planter and family do a considerable part of the work themselves, some of this expence is saved: that is, by planting saffron, he may not only reasonably expect clear about five pounds yearly per acre, but also to maintain himself and family for some part of each year: and it is upon this supposition only, that the result of other computations can be said to have any tolerable degree of exactness; but the calculations themselves are undoubtedly very inaccurate.

I have said nothing here concerning the charge in buying, or profits in selling the saffron heads; because in many large tracts of ground, these must at length balance one another, while the quantity of ground planted yearly continues the same; which has been pretty much the case for several years past. *Philosophical Transactions, Numb. 405.*

SAGE-CHEESE. See CHEESE and DAIRY.

SAINTFOIN, or **SAINFOIN**, the name given by the French, and continued by us to a species of plant, frequently used for the food of cattle, either fresh or dried; it is called holy-hay, or wholesome hay, from its excellent nutritive quality. The stalks of the plant are commonly about two feet long, but they grow sometimes to five or six feet, and it has tufts of red flowers of three, four or five inches in length.

This plant will make a forty times greater increase in poor ground than the common turf; and this is owing

to its having a long perpendicular root, of that kind, called tap roots, which sinks to a great depth to attract its nourishment. The length of this root is scarce to be credited by any but those who have seen it; it is frequently drawn out of the ground to the length of twelve or fourteen feet, but is said to be often thirty feet or more in length.

The farmers have a general opinion, that this plant never succeeds well in any land, where there is not an under stratum of stone, or chalk, or some other hard matter, to stop its running; but that otherwise it spends itself in root, and comes to nothing above ground. This is an error too gross to need much refutation. It is certain, that the roots being to plants what the stomach and guts are to animals, the more and larger roots any plant has, the more nourishment it receives, and the better it thrives.

Saintfoin always succeeds where its roots run deep, and the best crops of all are produced upon lands where there is no hard underfoil to obstruct their passage. An underfoil of clay may kill the plants, by retaining the water, and chilling and rotting their roots.

The long root of saintfoin has, near the surface, many horizontal roots issuing from it, which extend themselves every way; there are of the same kind all the way down, as the roots go, but they grow shorter and shorter all the way. Any dry land may be made to produce this valuable and useful plant, though it be ever so poor, but the richest and best land will produce the best crops of it. The best way of sowing it is by drilling; but the earth must be very well prepared, and the seed well ordered, or else very little of it will grow. The heads of these feeds are so large, and their necks so weak, that, if they be much more than half an inch deep, they are not able to rise through the incumbent mould; and, if they are not covered, they will be malted, as the farmers express it; that is, it will send out its roots while it lies above-ground, and be killed by the air; and whether the farmer plants bad seed that will not grow, or good seed that is buried or malted, the event will be the same. The ground will be understocked with plants. A bushel of seed to an acre of land is full twenty seeds to each square of foot land; but, as there are some difference in the largeness of the seeds, there is no absolute certainty as to this calculation. The worst seasons for planting are the beginning of winter, and the drought of summer; the best is the beginning of the spring; and it is also strongest when planted alone, and is not sown together with corn, as is the practice of some farmers. If barley, oats, or any other corn, sown with the saintfoin, happens to be lodged afterwards, it kills the young saintfoin. If it be planted with any other corn, it is best done by drilling in the horse-hoeing way; in this case it is not much liable to be killed by the lodging of the corn, as the drilled corn seldom falls at all, and, when it does, never falls so low as the sown corn.

The quantity of seed to be drilled upon an acre of land will depend wholly upon the goodness of it; for there is some seed of which not one in ten will strike, whereas in good seed not one in twenty will fail. The method of knowing the goodness, is, by sowing a certain number of the seeds, and seeing how many plants are produced by them. The external signs of the seeds being good are, that the husk is of a bright colour, and the kernel plump, of a light grey or blue colour, and sometimes of a shining black. The seed may be good, though the husk be black, as that is owing sometimes to the letting it receive the wet in the field, not to its being half rotted in the heap.

If the kernel be cut across, and appear greenish and fresh, it is a certain sign that it is good. If it be of a yellowish colour, and friable, and looks thin and pitted, they are bad signs. The quantity of seeds allowed to an acre in the drill way is much less than that by sowing, and it is to be computed according to the number of plants that are to be allowed in that space, allowing for the common casualties. It is not necessary to be exact in this calculation, or to say whether two, three, or four hundred plants are to be allowed to a square perch; neither is it possible to know before hand the precise number of plants that may live out of those that come up; for sometimes the grub takes them when they have only the two first leaves, and the crop is greatly diminished by this means. Four gallons of good seed to an acre of land will cover it with plants, when judiciously managed.

Single plants of saintfoin make the greatest crops; but

the farmers, in general, plant them so close, that they starve one another. The single plants always run the deepest, and those which do so will always draw most nourishment. The plants which stand crowded starve one another, and often die after a few years: but the single ones grow to a vast bigness, and are every year better and better.

The best way to calculate how many plants are to be allowed to a perch, is to compute how much hay each single large plant will produce; for, if kept single, and well cultivated, they will all be large ones. Without culture, these plants never arrive at a fourth part of the size that they do with it. The hay of a large single cultivated plant will weigh more than half a pound, a hundred and twelve plants upon a square perch, weighing but a quarter of a pound a piece, one with another, amount to two tons to an acre. If saintfoin be planted on some sorts of land early in the spring and hoed, it will sometimes produce a crop the following summer; in a garden the seed sown in February will yield plants of two feet high that will flower in the month of June following: and, though March be frosty, the young plants seldom suffer by it. This shews, that this plant is naturally a quick grower; but the farmers usually plant it on poor or cold land, and give it too little culture, which make it backward, and slow of growth with them. The poor land, usually allotted to this plant, also makes it generally yield but one crop a year, but on a rich land it will yield two very good crops annually, with a moderate share of culture and management.

The farmer who expects to make a profit of this plant must not expect a good crop the first year. Nothing is so injurious to saintfoin as its standing too thick; if it be sown so thick as to cover the ground the first summer, the plants will starve one another for ever after; but, if the owner will be content to place them so thinly as to have but a small crop the first year, they will increase prodigiously, and every succeeding crop will be better and better. When saintfoin is well hoed, it will grow as much in a fortnight as it would otherwise do in six weeks; and this quick growing is of advantage to it every way, not only making the plants large, but of better nourishment to the cattle, whether they are eaten green or made into hay.

The proper distance to drill this plant for the horse-hoeing husbandry is at double rows with eight inch partitions between them, and thirty inch intervals between every two and two. These intervals need only be hoed alternately, leaving every other interval for making the hay on. This method of hoeing is of vast advantage, and poor land by means of it will always produce two crops a year. The land is always to be perfectly cleared of grass before the sowing the saintfoin, and the lumps of earth carefully broken. But no harrowing is to be allowed after it is drilled, for that would bury it; and, it is not proper to roll it at all, unless for the sake of barley, when they are sown together; and when that is done, it should be with a light roller, and in dry weather. This should be done lengthwise of the rows, and as soon as it is drilled; if it be not done at this time, it is best to stay three weeks before it be done, that the necks of the young saintfoin may not be broken.

No cattle are to be suffered to come in the first winter upon the saintfoin, after the corn is out among which it was sown. Their feet would injure it by treading the ground hard, as much as their mouths by cropping it, and it would never come to good. Sheep should not be suffered to come at it, even the following summer and winter. One acre of drilled saintfoin, considering the difference of the quantity and goodness of the crop, is worth two acres of sown saintfoin on the same land, though the expence of drilling be twenty time more than that of sowing. The first winter is the time to lay on manure after the corn is reaped off. Peat-ashes, or the like, are very proper, and a small quantity of them will do, as there are at this time no other plants to partake of the benefit, but the young crop has it all; and the young plants, being thus made strong at first, will continue so, and be long the better for it.

It is observed, however, that in the drilling and horse-hoeing-way there is no necessity for any manure at all. Some farmers sow eight or ten bushels of the seed of saintfoin to an acre, along with their corn, with intent that it should kill all the other weeds; but the consequence is,

that the plants stand close, and starve one another, and are no bigger than where the plant grows wild on the hills in Calabria, where it is so small and seemingly despicable a plant, that it seems a wonder that any body should be tempted to think of cultivating it: yet, when rightly managed, it seems capable of being as useful a plant as any in the world. Where these plants stand so thick, they draw out all the nourishment from the ground, in a few years, and so die, though manured ever so carefully. Six or seven years seems their greatest duration; whereas, when the seed is drilled in, and the plants are horse-hoed, they will be as strong and vigorous as ever at thirty years standing.

Some people who have turned their thoughts to husbandry, have been of opinion, that the cytissus would succeed better with us than the saintfoin; it is probable enough that it would grow well; but the labour of sheering it would, with us, where the pay of servants is so dear, run away with the greatest part of the profits of the crop.

Lucern is another thing which many have thought of introducing among us in the place of saintfoin, but it requires so much care to suit it with a proper soil, that, whatever are the profits of it, it never can be so general as saintfoin. *Tull's Horse-hoeing Husbandry.*

Saintfoin, says Mr. Duhamel, deserves the farmer's utmost attention, as one of the most profitable plants he can cultivate. It will do on almost any land; and though it succeeds best in good soils, yet it will grow even on dry barren spots, where scarce any other grass can live; provided its roots be not chilled by a cold clay, or other substance which retains water: and it has this farther advantage, that it may be mowed at different degrees of ripeness, with nearly the same profit.

1. It may be mowed before it is in bloom, for it is then admirable food for horned cattle; and when cut thus early, it yields a second crop, which makes ample amends for what was lost by not letting the first come to its full worth. This early cutting is likewise attended with another benefit, which is, that it purges cattle, in the beginning of the summer, and thereby frees them from disorders occasioned by the winter's cold, or dry food.

2. If the weather be rainy, the saintfoin may be left standing till it is in bloom; when it still is excellent fodder for cows. But care must be taken in making it into hay, that the flowers do not drop off, as they are very apt to do: for cattle are so fond of these flowers, that they often induce them to eat the rest of the plant.

3. If the rain continues, the saintfoin may be left standing till some of its seeds are formed, and the crop will then be the more plentiful; not only because it will have attained its full growth, but likewise because its leaves, being more substantial, diminish less in drying. It is not indeed then quite so sweet as before; but horses eat it readily, because they love to feel between their teeth the seeds, which now begin to be formed.

Mr. Tull says this fodder is so excellent, that horses need no oats when they are fed with it. He affirms that he kept a team of horses with it a whole year in good plight, without giving them any oats, though they were worked hard all the time. He adds, that he fattened sheep with it, in less time than others which were fed with corn. But the hay of this plant can never be so good as when it is cultivated with the horse-hoe: for in the common husbandry, it blossoms almost as soon as it is out of the ground.

If the season continues rainy, it may be more advisable to let the saintfoin remain standing, than to run the hazard of having it rot upon the ground: for then the seed will ripen, and nearly make up for the loss of the fodder; not only because it will fetch a good price, but also because two bushels of it will go as far in feeding of horses, as three bushels of oats; and cattle in general, as well as poultry, are extremely fond of it.

The first of these sorts of saintfoin hay, cut before the bloom, is Mr. Tull's virgin hay, which, he says, is the best beyond comparison, and has not its equal, in the world, except lucerne. He gives the next place to the second sort, cut whilst in bloom, and says that an acre of land well cultivated, may yield three tons of this blossomed hay: and he esteems the third sort, which he calls the full grown, many degrees inferior to either of the former; though it yields a greater crop, because it has grown to its full bulk, and shrinks but little in drying.

Even the saintfoin that has yielded its seed, may be cut down and dried; and when other fodder is scarce, this will be better food for horses and large cattle, than the coarse hay of flowered meadows, or any kind of straw.

The manner of making saintfoin hay is thus directed by Mr. Duhamel.

In a day or two after the saintfoin has been mowed, it will be dry on the upper side, if the weather be good. The swarths, or mowed rows, should then be turned, not singly, but two and two together: for by thus turning them in pairs, double the space of ground is left betwixt pair and pair, and this needs but one raking, whereas, if the swarths were turned singly, that is, all the same way, the ground would require as much raking again.

As soon as both sides of the swarths are a little dry, they should be made up into small cocks, the same day they are turned, if possible: for when the saintfoin is in cock, a less part of it will be exposed to the injuries of night, than when it lies scattered upon the field. The sun and dew would exhaust almost all its juices, in this last case, in less than a week's time.

These little cocks of saintfoin may be safely made into large ones, without waiting for their being so thoroughly dry as those of common hay ought to be before they are laid together; because common hay, by sinking down closer, excludes the air necessary for keeping it sweet; so that if the weather prevents it being frequently stirred and opened, it will heat, turn yellow, and be spoiled; whereas saintfoin, by admitting the air more freely, because its stalks are less flexible, will remain much longer without any danger of fermenting.

Saintfoin hay is never better than when it has been dried by the wind only, without the assistance of the sun. A little rain, or a mist, which will turn common hay, clover, and even lucerne, black, will do no hurt to saintfoin, which is not really spoiled till it rots upon the field.

If the weather threatens rain, and the saintfoin is not yet dry, it may be laid in cocks, without fear of its heating, provided a large basket, or bushy faggot, be set up in the middle of each cock, where it will serve for a vent-hole, through which the superfluous moisture of the hay will transpire.

As soon as all danger of heating is over, these cocks should be made into ricks, and thatched. That which is laid up quite dry, will come out of the rick of a green colour: that which has heated much in the rick, will look brown.

It requires some experience to know of what degree of ripeness it is best to cut the seeded saintfoin; because all its seeds do not ripen at the same time. Some ears blossom before others; every ear begins blossoming at its lower part, and continues to blow gradually upward, for many days; so that before the flower is gone off at the top, the seeds are almost filled at the bottom. By this means, if the cutting be deferred till the top seeds are quite ripe, the lower, which are the best, would shed, and be lost. The best time, therefore, to cut it, is when the greatest part of the seed is well filled, the first blown ripe, and the last blown beginning to be full. The unripe seeds will ripen after cutting, and be, in all respects, as good as those that were ripe before. Some, for want of observing this, have suffered their saintfoin seed to stand till all of it has shed, and been lost in cutting.

Saintfoin should never be cut in the heat of the day, while the sun shines out; for then much, even of the unripe seed, will shed in mowing. The right time for this work, is the morning or the evening, when the dew has rendered the plants supple.

If the weather is fine and clear, the saintfoin will soon dry sufficiently in the swarths, without turning them; but if any rain has fallen, and there is a necessity for turning them, it should be done very gently, while they are moist, and not two swarths together, as in the other hay made of saintfoin before it has seeded. If the swarths are turned with the handle of the rake, it is best to raise up the ear-sides first, and let the stub-side rest on the ground in turning: but if it is done with the teeth of the rake, let the stub-side be lifted up, and the ears rested on the earth.

If saintfoin be cocked at all, the sooner it is done the better; because, if the swarths are dry, much of the seed will be lost in separating them; the ears being entangled together. When moist, the seeds stick fast in the ear; but

but when dry, it drops out with the least touch or shaking.

There are two ways of threshing it: the one in the field, the other in the barn. The first cannot be done but in very fine weather, and while the sun shines in the middle of the day. The best manner of performing this, is to have a large sheet pegged down to the ground, for two men to thresh on with their flails, while two others bring them fresh supplies in a smaller sheet, and two more clear away the hay that has been threshed. The seed is emptied out of the larger sheet, and riddled through a large sieve, to separate it from the chaff and broken stalks; after which it is put into sacks, and carried into the barn to be winnowed. Care should be taken not to let the hay get wet, because it would then be spoiled.

A very important, and at the same time very difficult article, is the keeping of the seed that has been threshed in the field, without having been wetted. If it be winnowed immediately, and only a little of it laid amidst a great heap, or put into a sack, it will ferment to such a degree, in a few days, that the greatest part of it will lose its vegetative quality. During that fermentation, it will be very hot, and smell sour. Spreading it upon a barn floor, though but seven or eight inches thick, will answer no end, unless it be frequently and regularly turned both day and night, until the heating is over: but even this will not make its colour keep so bright as that which is well housed, well dried, and threshed in the winter. This last, laid up and unthreshed, will keep without any danger of spoiling, because it does not lie close enough to heat. The best way to preserve the seed threshed in the field is to lay a layer of straw upon a barn floor, and upon that a thin layer of seed, then another layer of straw, and another layer of seed, and so on alternately. By this means the seed mixing with the straw will be kept cool, and come out in the spring with as green a colour as when it was put in.

The following method is followed in cultivating saintfoin in the Isle of Thanet.

Though the lands in general here are very rich and fruitful, owing to the good tillage, and the quantity of manure they enjoy, yet at some distance from the sea, they have land which is very barren and thin by nature; nevertheless, even this indifferent land they farm to the greatest advantage. In these soils the farmers sow saintfoin or French grass with great success, having sometimes two loads of hay on an acre.

This grass thrives best in these parts, on a thin coat of earth with a chalky bottom; it pushes its long tap-root deep into the chalk, and extracts thence a nourishment, which is out of the reach almost of any other plant.

The land must always be exceedingly well prepared, before they attempt to put the seed in the ground; it has frequent plowings, and every the least appearance of a weed or root of grass is diligently picked off: grass in particular is a very great enemy to this plant; without the utmost care it soon chokes and destroys it. They sow this seed in April, either at the beginning, middle, or latter end of the month, according to the season: dry weather is best, provided it does not long continue: however, a little rain in these light soils does no great hurt. The quantity of seed they allow to an acre is five bushels; of course it is sown very thick. It does not lie any great length of time in the ground: when it is come up, they carefully hoe and weed it to keep down the roguery and grass: this puts the plants forward, and makes them so vigorous and strong, that they will of themselves keep down the grass, especially in these chalky bottoms, where grass does not thrive well, and is not apt to coat land with turf.

Saintfoin used formerly to hold good in these parts for twenty years together, but it does not now of late years last so long: this is probably owing to their want of care in choosing their seed, which surprises me, considering what good farmers they in general are. They get, it is true, when they can, the best seed the island affords: but it would certainly be a much better way were they now and then to procure some of a finer growth from France: for it was from that country, as far as I can understand, it first came hither, about the latter end of Charles the Second's reign; and I do not hear from the inhabitants that they ever remember the importing any more since.

The climate of France is more natural to it; of course the seed comes to greater perfection there, whilst, on the contrary, in England, that, as well as many other crops, is apt to degenerate after a certain number of years.

Where this crops takes, it is very advantageous to the farmer; it yields him for many years plenty of excellent fodder, and that upon land which would otherwise, perhaps, scarcely yield him any profit at all; and besides all this, when the saintfoin begins to fail, if proper care is taken, the land when broken up will be found greatly refreshed, and in a better condition to bear tillage and a succession of other crops.

The farmers here, when they intend breaking up a saintfoin lay, feed it the last three or four years: mowing it at this time, they think, hurts and exhausts the land too much; and besides, the dung and urine of the cattle are of great service.

They observe here, as well as in other places where saintfoin is cultivated, that after land has been once sown with it, it will not for some years, to any advantage, bear saintfoin again. *Museum Rusticum*, vol. I. p. 109.

The reader is obliged to Mr. Holdway, an old experienced farmer at Marlborough in Wiltshire, for the following account of cultivating saintfoin in that county:

"About one hundred years ago, says he, the culture of saintfoin was first introduced into Wiltshire, and was soon preferred to clover-grass: and there was indeed some reason for this preference, for it thrives much better, and yields a much larger increase on poor hungry soils, than clover can do.

"Another very good reason may be assigned why saintfoin was so well received. The sowing it at all was considered as a new husbandry, and the timorous farmers were very unwilling to hazard the trial of any new method on lands which would any other way yield them any considerable advantage: it was chiefly in corners of fields, of very little use to the farmer, that this pasture was first tried, and that on poor lands, as, should it not have succeeded, the only loss would have been the seed; yet many occupiers of land would not, at first hazard even this trifling loss.

"But the sentiments of these farmers were soon altered in this matter: clover wears out in a few years, whereas many, who sowed saintfoin on poor land, not worth above six shillings an acre, found their land so much improved as to be very speedily worth thirty shillings the acre, and at the end of twenty years it continued yet in good proof.

"In fact, it will thrive, and be a very considerable improvement, on the poorest, and seemingly on the barrenest land; but it must be remembered, that sheer and slight sands, and all clays and other cold and wet soils, are to be excepted: on rich lands the weeds soon destroy it. Besides, as it sends its roots very deep in search of nourishment, the longer it occupies land, the more good it does it; whereas this is far from being the case with shallow-rooting plants.

"A saintfoin lay may at any time be broke up, when it will be sure to yield several good crops of corn, and may afterwards again with good success be sown with saintfoin; and one principal reason why it thrives so well on poor lands must be the length of the roots by which it is enabled to resist the parching heat of the sun better than most other grasses are.

"One thing I must notify, which is, that I am by long experience convinced that the land cannot be made too fine for saintfoin; it thrives the better for it, and is the more certain to take.

"I have very often with good success, sown it with oats and barley in the manner clover is sown, the proportion much about equal to the grain it is sown with; for as the seed of saintfoin is much larger and lighter than clover seed, of course a larger quantity should be sown: it is much best for the plants to come up thick; the ground is thereby sooner stocked, and the weeds are easier kept under.

"Some in this county have sown it in rows with intervals, to afford a better opportunity of destroying the weeds; and I have heard that on the tolerable rich land, apt to produce weeds, it has done very well in this way; but as I never experienced it, I shall not enlarge on that head.

"It is best not to feed it the first year; but whether it is sown by itself, or with any other crop, it may be mowed the first year.

"It is much best, if a good crop is desired, and it is to continue any time to the land, to sow it in autumn by itself, the earlier the better; the proper season is from the beginning of August to the end of September; but if you mix it with other grain, let it be sown from the beginning of

February to the end of March ; the earlier in either season, the better.

" I have, I think, before observed, that the land cannot be made too fine for this plant ; and it should be well harrowed before sowing, and again harrowed afterwards to cover the seed.

" I must once more repeat, that it must not be fed the first year ; for the sweetness of the grass will cause the cattle to bite it too near the ground, which will greatly injure your crop : in fact, it is our practice not to let great cattle feed it till the third year, particularly in grounds that are inclinable to moisture : for the roots are tender, and much treading is very injurious to it.

" When the ground is well covered, suppose in the third year after sowing, if you intend to mow your faintfoin, it is best to lay it up by the middle of April at farthest : but it is better done three or four weeks sooner. The time for cutting it is when it begins to flower, as it is then fullest of sap : this will sometimes be about the middle of May, but often later, according as the spring is cold or warm.

" In feeding it, some necessary rules are to be observed. In the spring, turn in your great cattle, and you may be pretty certain the buds will not be cropped too near. Oxen thrive well on it, without the danger, at their first grazing, that is to be apprehended from clover, &c. yet even this danger chiefly arises from the negligence or ignorance of the hinds.

" In the autumn, and part of the winter, you may feed your sheep on it, which, if in health, will thereby be very suddenly fattened.

" Saintfoin hay is excellent food for horses, and they are uncommonly fond of it.

" If you turn in your cows in the spring in your faintfoin lay, you will find it will breed in them abundance of milk ; and all my acquaintance know that the butter made of it is excellent.

" When it is intended to save the seed of faintfoin, it is best to roll it in the spring, that the stones may be pressed down, and the scythe go close to the ground ; or else the best seeds, which grow on the lowermost joints, will be lost.

" When land is inclined to moisture, faintfoin may thrive very well on it till a wet winter comes ; but it is then a great chance if it is not destroyed.

" In this country it has long been the opinion of the ablest farmers, that it is best not to dung our faintfoin ; for the dung serves only to encourage weeds, and seldom reaches deep enough to give any supply of nourishment to the roots of the faintfoin.

" I have, if I mistake not, before observed, that the treading of great cattle, particularly in winter, is hurtful to this grass : I would therefore by no means advise the farmer to fodder his cattle on it, as the field will thereby be poached full of holes, in which the wet lodging, it is a chance but the roots of the faintfoin are rotted by it.

" I have often fed my sheep in winter with faintfoin hay ; but whenever I intended this, I always cut my faintfoin some little time before it flowered : it is very easy to observe when the flower cup is forming : the sheep will eat it very clean, and thrive well on it, provided it is not old and stinky.

" When I say that sheep in autumn will fatten very suddenly on faintfoin grass, it must be observed, that I did not mean the aftermath of such as had been mowed that season ; but the second growth, when the field had been for some time shut up after the great cattle had fed it in the spring. The aftermath is, it is true, good for sheep ; but, I think, not quite so good as the aftermath of natural grass ; at least, this I am certain of, that turn some sheep into a field where there is a mixture of natural grass and faintfoin, both of which have been mowed, they will to chuse eat up the first, before they touch the other with any degree of appetite.

" Saintfoin shoots very early in the spring, and to nip it in the bud is very injurious : I would therefore advise that the sheep be taken out about Christmas, soon after which time it often begins to grow.

" Some of our Wiltshire farmers have had a custom of sowing their faintfoin seed under furrow ; but I do not much approve of this practice, though they say in light land it cannot be buried." *Azusum Rusticum*, vol. I. p. 463.

The following method of cultivating faintfoin in Swit-

zerland was written by an experienced husbandman of that country.

" You have bought, you say, a little estate, at no great distance from the metropolis, and have thought of improving some of the lands by sowing faintfoin : you request me to let you know what are the methods in practice in this country relative to that grass, as when you left Switzerland to go to our uncle in London, you were too young to gain the necessary knowledge in farming. I shall oblige you with pleasure, and the rather, as I have had very good success myself in this particular article.

" The roots of faintfoin, says he, penetrate very deep into the earth, by which means they do not exhaust the surface so much as one would imagine, the vigour of the plant considered : the roots are perennial, and consist of a white woody substance within, covered by a black outward coat or bark : from the crown of the root proceed several leaves, and some branches about two feet long, which incline on all sides. Our fodder is furnished from these branches and leaves. Saintfoin is a very vigorous plant, and yields a most excellent fodder.

" It is not nice with respect to soil, but grows in almost any, if we except such as are clayey, very damp, and low, or stoney : the crop is in proportion to the goodness of the land, but the faintfoin that grows on poor land, though less in quantity, is most nourishing and heartening for cattle : the virtues of it seem concentrated, and the cattle thrive much better on it than on such as grows in greater quantities on rich mellow land.

" When we have it in our power to chuse our situation and soil for faintfoin, we ought to prefer a light land, gently sloping on the south-side of an eminence : here it prospers to admiration.

" This plant does not thrive in the shade : for this reason we should avoid having any trees in the fields that bear faintfoin : and it is subject to be sometimes chilled, by having snow lie too long on it in winter ; it should not therefore be sown on flat level land.

" To have a good crop, the land should be properly prepared, by having two or three good ploughings between harvest and barley feed-time : the stones must be very carefully picked off the field ; and it must be cleaned from all kinds of weeds, and other such trash.

" If it is likely that there will be a wet season, the spring is the best time for sowing faintfoin, as it will be much forwarder than that sown in autumn : but if the spring is too dry, the sowing will best be deferred till about August, as by that means the plants will have time to acquire strength in their roots, and make vigorous shoots in the spring.

" The farmers may take it for granted, that if the soil will admit of it, he cannot well plough his land too deep, or make it too fine : he will reap all the benefit of it in his succeeding crops.

" In Switzerland we sow it three times as thick as we do wheat : or which amounts to the same thing, we use the same weight of seed, the faintfoin seed being so much smaller as to make that difference.

" Good seed should be heavy, plump, bright, and of a yellowish red colour : if, on opening the pods, you find the seeds black and shrivelled, reject it as of no value : for it has been heated in the heap and will not grow : if it appears white and shrivelled, the plant was cut before the seed was ripe : from this you are to expect only starved, meagre, short-lived plants ; you must therefore by no means sow it. The pods inclosing good seed should be plump, large, and armed on one side with small prickles ; and they should also be of a deep brown colour : but it is best not to depend on the appearance of the pods, but open them, and examine the seed.

" The weather should be mild at the time of sowing the seed of faintfoin ; and it should be harrowed in, and not covered with above two inches of the earth at most : some sow it in the spring with oats : but this I by no means approve of ; it is much better sown alone, especially if you would have a strong vigorous plant, that shall last for years.

" In our very poor lands in Switzerland we sometimes pursue the following method :

" Immediately after harvest we give the land intended for faintfoin a good deep ploughing, laying it in high ridges ; in this manner it is left to be mellowed by the frost and snow ; we take advantage of the first hard frost to carry on our dung, and manure it well.

" When

"When the frost breaks in the spring, we spread the dung, and turn it in with the plough: we afterwards bestow at least two more ploughings on the land, not only to keep down the weeds, but to make the land as fine as possible: in autumn we sow wheat, and have reason to expect a tolerable good crop.

"When the wheat is got in, the land is again ploughed, and left to meliorate and pulverise by the winter frosts: early in the spring it is ploughed and laid level, the stones are all picked off, and the weeds cleared away: if rain is expected, it is now sown pretty thick with the saintfoin, otherwise the sowing is deferred till autumn. When poor land is managed in this manner, it will yield tolerable good crops of saintfoin for several years: it should not, however, be fed the first year, as the treading of the cattle will destroy the crown of the plant, and prevent its shooting the succeeding year: and sheep should never be turned in to feed on it, as they will crop it so close as to prevent its budding.

"Saintfoin comes up about a fortnight after sowing it, and if the weather is moist, something sooner. When the plants come up, they should be set out at a proper distance with a hoe that they may have room to spread. The young plants are very apt to be choked by weeds; they must on that account be kept very clear of weeds; till, by their branches, stalks, and leaves, they cover the land; after which there will be no danger of the weeds getting ahead.

"As saintfoin feed is often faulty, it will not be amiss to make a trial of it, by sowing some of it in a detached bed of a garden, counting the seeds before they are put into the ground: by this means it may easily be known how many of them fail, and the quantity of seed to be sown may be proportioned accordingly.

"Some have asserted, that saintfoin should not be mowed the first year: but this is an ideal precaution; for in Switzerland we think it rather does it good than harm to mow it in autumn; and experience every day convinces us we are right in our opinion. The first crop is not, it is true, very large, but the mowing causes the plants to branch, and gives strength to the roots.

"No cattle, as I said before, should be turned on saintfoin the first year: and indeed, it is best, if possible, always to mow it. We have three crops of green fodder or two of hay from it, in one season in this country.

"When we intend to save the saintfoin seed, we leave a part of it standing, and do not cut it till we observe, by the colour of the pods, which will then be of a deep brown, that the principal part of the seed is ripe: we then either gather the heads by hand, or reap them with a sickle, and lay them carefully on a cloth. The heads must be dried in layers three or four inches thick: if they were laid thicker, they would be apt to heat and spoil: when dry, we gently thresh them with sticks; flails would be too heavy; for if the seed is the least bruised, it does not come up. The stubble that remains after the heads are cut off may be mowed, and given either dry or green to the cattle; for though a little sticky, they will not refuse to eat it.

"I generally use my saintfoin green, foddering the cattle with it as soon as it is cut; and this I the rather do, because the making it into hay is such critical work: but when there is a likelihood of my being short of winter-fodder, I have no choice to make.

"The weather should be very fine when it is cut; for as it is full of sap, it requires great heat to dry it; and if it happens to rain, it takes more damage than common grass; and it is best not to cock it, as it is subject to heat in a very small space of time: if it is much wetted, it grows black, and loses all its sweetness.

"Even when saintfoin is seemingly quite dry, it is apt to heat in the stack; but this is easily prevented by spreading alternately a layer of good oat or barley straw, and another, of saintfoin; when it comes to be used all together, it makes an excellent winter fodder.

"Great care must be taken both in turning the swarths of saintfoin, and in loading it on the waggons, as a very little stirring will, when it is dry, shake off all the leaves; and this greatly lessens its value: for this reason I make my men turn the swarths with the handles of their forks, which is easily done; and I never cart it, but either early in a morning, or late in the evening, when it is somewhat moistened by the dews.

"Saintfoin is a very hardy plant, and bears, without being sensibly affected, the extremes of heat and cold; but

the bottom of the land where it is sown must not be wet, and there must be room for the roots to spread.

"A field of saintfoin on a good soil will last from sixteen to twenty years in prime, and even longer with care; for if, after seven or eight years, some well-rotted dung is laid on it, the future crops, as well as its duration, will be greatly increased. When it is sown on light land, marling it is of very great service.

"But if after all a piece of saintfoin falls off, our method is to plough it up in autumn as deep as possible; give it another ploughing in spring, sow it with oats, plough it again immediately after harvest, dung it, sow it with wheat; and when the wheat is off, plough it again, and giving it another ploughing, sow saintfoin in it about the end of August; and this in general succeeds as well as that which was first sown on the land.

"Before I conclude, I must give you a few cautions relative to this excellent fodder, which has of late so much improved this neighbourhood.

"It is so very sweet, and cattle are so fond of it, that without great care they are apt to eat too much of it; whence often proceeds a surfeit, and sometimes a corruption of the mass of blood, and cutaneous eruptions: they should at first have but a little at a time given them, that they may be by degrees habituated to it: by this management the danger vanishes.

"It is much more proper for slow draught horses than for such as are used for berlins, or for riding; for it is apt to make horses thick-winded, foggy, and somewhat sluggish: for farmers horses nothing can be better, or more nourishing; speed is not required in them.

"When saintfoin is intended to be made into hay for horses, it is best not to cut it till the seed is formed in the pod, as by that means the hay will be much more nourishing; and when the dried seed itself is plenty, nothing better can be given to the horses by way of corn; for I can assure you from experience, that one bushel of it will go as far as two of oats.

"When saintfoin is cut to be given green to cattle, it is best to mow it when it is in full bloom, as it is then most juicy, and fullest of sap, and it will consequently afford most nourishment to the cattle. The best way of managing it is to cut no more than will serve for the day; and by properly apportioning, or parcelling out the field, there will be, during the whole summer, some of it in order to cut for green fodder.

"If this green fodder is intended for sheep, it may with great propriety be cut just before it flowers: the stalks are then in a tender state and very nourishing, and good either for wethers or ewes. When it is to be made into hay for sheep the same rule should be observed.

"I have very little more to say on the subject of saintfoin, except that, as when a saintfoin lay is brought into tillage, it prepares land very well for wheat or rye, and bears good crops; there is seldom occasion among the good farmers to try how long it will continue in heart, as they generally break up these lays in turn, and find it advantageous so to do." *Museum Rusticum, vol. I. p. 37.*

Experiments on Saintfoin.

The following judicious series of experiments were communicated by a gentleman of distinguished rank and fortune in Yorkshire:

"From an entire conviction, (says this excellent husbandman), that it is the duty of every subject to contribute all in his power to the good of society, I have endeavoured, during several years that I have resided in the country, to promote and encourage the advancement of agriculture. To this end I have made variety of experiments, on different soils, to prove and ascertain the most beneficial methods of husbandry, or how to employ land to the most advantage.

"A great part of my estate, consisting of waste and uncultivated heath, which did not let for more than a shilling an acre, I judged it to be a matter of importance to try, if it was not possible, by culture, or by applying this ground to a different purpose, to increase the value of it. Happy would it be, could pleasure be made to coincide with profit! and it is certain, that whoever succeeds in the improvement of his own estate, may enjoy the inward satisfaction of rendering some service to his country: for the example of a landlord may be thought to have some weight with his tenants; and if, amidst a great number of experiments made for the sake of truth, some have proved

proved successful, one may expect that the farmer will at last adopt a method which he has for many years seen repeated with advantage: for however the common farmer may have been accused of an obstinate adherence to old customs, many instances might be produced of his quitting the paths of his ancestors in favour of modern improvements; but then he must be thoroughly satisfied, that the new way is indeed preferable to the old, not in theory only, but in practice, confirmed by actual experiments often repeated before his eyes. And can we justly blame the illiterate peasant for refusing to forsake a method he is well acquainted with, and can depend on for the support of himself and family, upon other terms? It is the province of the landlord to adopt a theory, and to try it by experiment; for if it fails, as is often the case, his ruin is by no means the consequence, and the loss is amply made up to him, by the secret pleasure always accompanying a good intention. But whatever service a gentleman may be of in encouraging researches of this nature, or by his influence in his own neighbourhood; yet ought his benevolence to extend farther, so as to be of use, if possible, to his country and mankind. It is the desire of communicating the little knowledge I may have gained from the experience of a few years, that has prompted me to address this letter to you, who are engaged in an useful and public undertaking: and you are at full liberty to make use of it, together with the detail of the experiments. They were begun without the least design of making them public, and may therefore be deficient in point of method and order: but they are strictly true.

"On the third of April, 1759, two acres of very sandy land (which had a hundred loads of red marle laid on it the year before, and had borne a good crop of oats in 1758) were drilled with faintfoin, on four feet ridges in double rows: eleven inch partitions, the intervals three feet one inch wide, and took four pecks and a half of seed. This was intended to be horse-hoed, as Tull directs: but the land was in such bad tilth, and abounded so with the natural grass, that, after once or twice attempting to destroy it, by ploughing the intervals, the horse-hoeing scheme was given up, and the faintfoin left to take its chance. However, a few plants remained thinly scattered in the rows (whether this thinness was owing to the badness of the seed, or to its being sown too deep, I know not, though I rather impute it to the latter cause, as, in sandy land, the shares of the drill are very apt to penetrate too far into the ground.) These remaining plants flourished exceedingly from the time of their being sown; many were in flower the following June, and afforded a tolerable crop, viz. about a load. The after-crop was very good. In 1760, these plants seemed to have arrived at their perfection, and the product was two waggon loads, or about two tons. In 1761, and 1762, this small close, having had some manure laid on it yearly, yielded nearly the same quantity of hay: and it is now let for forty shillings a year: a much higher rent than any land is let for in this neighbourhood, and four times the rent paid for it before the improvement."

The shares of the drill, as this gentleman, observes may be apt to penetrate too deep in light sandy land, unless the driller is careful to regulate the depth, by the chain fastened to the shafts, which should have some small links at one end of it, for that purpose. The shares may be also prevented from going too deep, by a foot, or small wheel, in the fore part of the drill plough; or by putting a triangular piece of wood in the trunk of the share, very thin at top, and gradually thicker downwards; this throws the seed at such a distance behind the share, that it falls into the channel made by the share, after it is almost filled by the dry earth, and then the seed lies shallow, or is not covered with much earth, though the channels are made deep by the shares.—But in whatever manner the seed is covered shallow, it should not be by making broad channels for the seed, as proposed below, because in that case the plants will come up in a broad row, which will not only obstruct the hoeing, but will also harbour weeds, which cannot be got out of a broad row as they may out of a narrow one; and for this reason the drill shares for all sorts of seeds should be made as thin, and the channels as narrow as is consistent with the necessary strength of the shares. For sowing wheat, faintfoin, and other seeds about that size, shares of an inch thick, or somewhat less, are sufficient; and for turneps, cab-bages, or seeds about that size, it is not necessary that the shares (so much of them as go in the ground) should be above half an inch in thickness, or very little more.

"N. B. This close of two acres was separated from another of twenty-seven acres, of so sandy and dry a nature, that, unless in a wet summer, the hay upon it was scarce ever worth mowing: and this experiment was made in order to determine what improvement the adjoining large close was capable of, and to experience whether or no the common opinion, that faintfoin is improper for all sandy and deep soils, be founded on truth, or only the result of prejudices: for the reason given for its disagreeing with this kind of soil, did not appear to me satisfactory; and great part of my estate consisting of such sandy land, it seemed a matter of importance, to know, whether the great advantage derived from faintfoin, on some soils, might not also be applicable to sandy soils.

"Encouraged by the flourishing condition of the faintfoin on this small close, I determined to extend the improvement to the larger one also, as soon as it could be brought into sufficiently fine order to be laid down with this grass. Accordingly, in the winter of 1759, twenty-five acres were ploughed with the five-coultered plough, as recommended by M. Duhamel, in his treatise on the cultivation of land, in order thereby to prepare the ground for turneps the ensuing summer; for I look upon this as one of the best methods of destroying the natural grass, and preparing the land for any of the artificial grasses; especially if the turneps are drilled in rows, and cultivated with the horse-hoe. The land was ploughed level in the spring of 1760, and into ridges of about five feet broad in June, and a single row of turneps was drilled on the middle of each ridge in July. It is to be observed, that the natural grass was far from being destroyed by these three ploughings; nor could it be entirely so by the subsequent hoeings of the turneps; so that it certainly was a great prejudice to the faintfoin. The same ground is now sown again with the same plant: but I would strongly recommend to those who are inclined to follow this method on such a soil as I have described, to continue the culture of turneps, with the horse-hoe two years instead of one: for by this means the natural grass, and weeds may probably be effectually destroyed. But to return to the experiment: the turneps succeeded as well as could be expected on such a soil, and without manure: they were eaten off by sheep, and Scotch cattle, foddered on the land.

"About four acres, on which the turneps were the first sown, were ploughed level, and afterwards, viz. in November, drilled with faintfoin in equally distant rows, one foot asunder. They took about a bushel to an acre. This was an uncommon, and may be thought an improper season for the sowing of faintfoin: but I chose to sow part of the field before winter, and part in the spring, part with faintfoin mixed with corn, and part with faintfoin alone; in order to see which method would succeed best, that I might make it my guide in other places more likely to yield good crops.

"Five or six acres of land were drilled in the beginning of April 1761, with faintfoin seed, in rows, at the same distance, and with the same proportion of seed as the four acres spoken of before: about three acres were sowed soon after with faintfoin and oats both drilled; and about twelve acres were drilled with faintfoin and barley; each in rows about a foot asunder. The whole of this field, which contained twenty-five acres, had been ploughed but once since the turneps; whereas two ploughings might have been better: but on account of eating them off with sheep and cattle, there was not any time for it.

"The three acres sowed with oats in rows a foot asunder, took four bushels and a half of seed, and produced a very good crop; by computation, five quarters to an acre: but the exact quantity, neither of the oats, nor of the barley, could be known, on account of its being mixed in the barn with corn that grew in other places. The twelve acres sowed with barley took seventeen bushels of seed, and produced a much greater crop than any land in the neighbourhood; though this was a great year for barley. All the farmers who observed this crop, allowed that they had never seen finer barley; and it may be said, without the least exaggeration, to have yielded above five quarters to an acre. I am convinced that this computation of five quarters to an acre is a very moderate one: not only from the number of sheaves, and the judgment of all who saw it, but likewise because I had no more than twenty-six acres and an half of land drilled with barley this year: and the whole produce when threshed, amounted to one hundred and twenty-eight quarters and two bushels; which is very near five quarters to an acre, taking one part with another: but these

twelve acres bore by much the greatest crop in proportion, and seven acres of the twenty-six were sown on beds five feet broad and horse-hoed, which never produces so large a crop.

"The summer of 1762 was remarkably dry, and bad for grass: many fields hereabouts, of ten acres, did not produce above a load or two of hay; but this of twenty-five acres produced twelve tons of good hay: which, considering that the saintfoin was not nearly arrived at its perfection, may be said to be considerable.

"It was now easy to see in what parts of the field the saintfoin had succeeded best.

"The four acres sowed before winter had the smallest number of plants of saintfoin of any; perhaps not more than one or two in ten yards: but this ground abounded so with natural grass, that this alone furnished a tolerable crop. The five acres sown in the spring, without corn, did not abound much less with natural grass, or more with saintfoin, than the preceding: but there being a great mixture of the seeds of rye grass with all the saintfoin sowed in the field, the rye grass appeared distinctly in tufts all along the rows; and, together with the natural grass, seemed completely to have covered the surface of the ground. The rows were much better stocked with saintfoin plants in the twelve acres sown with it and barley: but the rye-grass abounded here likewise.

"It is remarkable that the saintfoin flourishes best in those parts of the field where the land is most barren; the reason of which undoubtedly is, that, as scarce any natural grass or weeds arise to choke it there, its young and tender shoots have the benefit of the whole pasture, and its roots are not obstructed in their progress by the growth of other plants.

"Though the greatest part of this field is much understocked with saintfoin plants, yet it is in a very promising condition for a good crop of hay this year.

"I attribute the bad success of the saintfoin on the first four acres partly to its being sowed too late, whereby the plants could not acquire much strength before winter, which destroyed many of them; partly to some violent hurricanes of wind, which blew clouds of sand from one part of the field to another, and overwhelmed many plants; and partly to the shares going too deep, by which the seed was covered at least two inches. The bad condition of the five acres sowed alone in the spring, I believe to be owing, in some measure, to the causes already assigned, and also to the want of protection and shelter from drought, which corn would have afforded in that very dry soil. Barley does also help to stifle the natural grass, saintfoin's greatest enemy. The saintfoin which was drilled with barley, looked, as was before observed, by much the best: but, indeed, some precautions were used to sow the seed somewhat shallower on these twelve acres; and this may, in some degree, have contributed to its success.

"Upon the whole, from the experiments made in this field (and several others made since have strengthened my opinion on that head) I conclude, first, that saintfoin is very suitable to any sandy or deep soils provided they are dry, and that the natural grass and weeds can by any means be completely destroyed: secondly, that it is better to sow saintfoin in the spring, and with barley, than in the autumn, or spring alone; thirdly, that the seed should not be covered above an inch deep: but I believe half an inch the more proper depth. One foot may be a very proper distance for drilling the rows; and from a bushel to a bushel and an half, a proper allowance of seed for an acre of ground, provided the seed be good.

"I have tried the horse-hoeing of saintfoin sown on beds three or four feet broad; but though the plants do by that means certainly grow more vigorous, I do not think the crop so great; and when the stalks are strong and pipy, I have observed that cattle will not eat them.

"Saintfoin and other plants grow large when well nourished; for which reason, hoed saintfoin has larger stalks than the thick sown: but the large saintfoin is not harder than the small; on the contrary, the large is more succulent, and richer food than the small; the reason of this gentleman's cattle refusing to eat his large vigorous saintfoin, was, because it had stood too long before it was cut for them; and then it will grow hard and woody. It should be cut when in full sap, which is before it blows, or even before it begins to blossom, and then it is tender, full of rich juice, and very agreeable to cattle.

"The sowing in equally distant rows seems preferable, especially where a large extent of ground is to be sowed.

But my experience is very insufficient to decide this point absolutely. I could wish that gentlemen would make trials of the horse-hoeing of saintfoin in different soils and situations.

"Experiments carefully made, and often varied, by persons void of prejudice, may, in time, decide that important question in agriculture, viz. whether the common, or the horse-hoeing husbandry be, upon the whole, most advantageous to the English farmer.

"If saintfoin be drilled on a sandy soil, or on one that is in very fine order, the shares of the drill ought to be two inches thick, or they will grow too deep; and a small wooden roller should be fixed to, and follow the drill, instead of a harrow with teeth, which would bring too much earth upon the seed. Such a roller will lay the ground smooth, and fitter for mowing. A spring made of three pieces of ash, as described by M. Chateauvieux, is of great use, and may easily be added to Mr. Tull's drill plough. It may be fastened underneath the middle of the plank, by four screws, and made to press more or less on the roller, or harrow, which ever is made use of, by a wedge put in betwixt the spring and the hinder edge of the plank. If a harrow is used, iron teeth are much preferable to wooden ones.

"In the year 1757, I had a mind to try how much a soil naturally extremely bad, could be improved by art. Accordingly, I made choice of a piece of ground one acre and an half in extent, a barren sand, which produced only a few miserable weeds, and which the farmer who rented it did not think worth his while to cultivate. There happened to be a great quantity of red stony marle in an adjoining field, of which near three hundred loads were laid on this acre and an half. It was drilled with barley in 1758, and horse-hoed: but the crop proved a very bad one. In 1759, a load of lime, and about ten loads of dung were laid thereon, and it was drilled with turneps and horse-hoed: however, the crop still was but moderate; though a good deal better than could have been expected from such a soil. In 1760, it had turneps again, managed in the same manner as the former, but they were a great deal better. In 1761, it was drilled with oats, saintfoin, and rye-grass, mixed, in equally distant rows one foot asunder. It took two bushels and peck of oats, and two bushels of grass seeds. The oats were very good, and produced four quarters and four bushels. By continued horse-hoeing three years together, the land was got into perfectly fine order, the marle and sand were thoroughly incorporated, and the natural grass and weeds entirely destroyed: so that the saintfoin and rye grass grew and flourished exceedingly. In 1762, the summer being uncommonly dry, the produce was about half a load of hay; which was as much as one could expect the first year after sowing. It is very well stocked with plants, which now, in May 1763, seem as vigorous as in any of my other fields, though I have some which yield two tons of hay to an acre. This little piece of ground, which, before was not worth a shilling a year, is, by the labour and cost bestowed on it, now worth at least fifteen shillings an acre; which is a proof that, let land be ever so bad, it may be improved, and perhaps made equal to the best in the neighbourhood: but at the same time it must be confessed, that the expence is too great to be repeated at once on a large extent of ground. I calculate that three hundred loads of marle, dug and carried about three hundred yards, might cost about four-pence a load, or five pounds for three hundred loads, which has been the whole expence attending this acre and half: for the manure, ploughings, and horse-hoeings, were repaid by the crops of barley, oats, and turneps."

Mr. Duhamel has mentioned the following experiments relative to the culture of saintfoin:

In 1754, M. Eyma, near Bourdeaux, planted saintfoin, lucern, and clover, in rows eight feet asunder, with distances of sixteen inches between the plants in the rows, which yielded him an immense increase. The alleys were horse-hoed after each cutting.

In 1755, he planted a field, a little more than three roods square, with saintfoin, which he cultivated according to the rules of the New Husbandry; and this spot yielded him 10,000 pounds of dry hay. M. de Chateauvieux had 15,300 pounds of lucern, as we shall see, off somewhat more than an acre of ground, which he cut five times; but M. Eyma thinks that 14,445 pounds, Geneva weight, of saintfoin, which he had at another time, at one cutting, is a greater crop than M. de Chateauvieux's lucern; besides the after-crop, which indeed was but inconsiderable,

ble, on account of the dryness of the season. He says he cuts his saintfoin three times in good years, and that the two last cuttings produce nearly as much as the first: but he allows, that such years are not to be expected often.

Mr. Young observes, that many have a notion, that cutting saintfoin twice in a summer is an injury to it, and makes it bleed. But says, he has often cut his saintfoin twice; and three times, and once or twice he cut it four times in the season, without perceiving it was at all hurt by it. If cutting it often does it any damage, it must be by cutting it too young; but when it arrives to such maturity, as to come near blossoming, nature then points out the time to cut it, and it will then receive no more damage to cut it a second or third time, than cutting it at first.

M. Eyma doubts whether the preference be due to saintfoin or to lucern: but he is confident that either of them, properly cultivated, will produce surprising crops.

He thinks that one row of saintfoin, or lucern, planted in the middle of a bed three feet wide, will profit more by the different hoeings, and consequently produce more grass, than double or triple rows, though these last be planted on broader beds; because the single rows have the earth loosened on each side of them.

M. Diancourt sowed saintfoin, each plant of which in 1753, had a head of two feet diameter. They throve so well, that, in 1755, one plant, and that not the largest in the field, yielded twenty-three ounces of hay.

The following instructions were given by an ingenious gentleman in Lincolnshire:

"Mr. Tull says, that a deep soil is best for saintfoin. I believe every thing grows better, in a better soil: but by what I have seen of this plant, I shall always prefer for it a shallow soil, where there is a rock, or some hard substance, within six inches, or a foot, of the surface, to stop the roots of the plants, and make them spread horizontally. This has not only the good effects proposed in M. de Chateaufieux's manner of transplanting lucern, but, it is said, occasions its filling the ground with more shoots by their striking up from the knots of the roots. This fact I cannot verify: but certain it is, that, in such soils as I here speak of, a crop of saintfoin which at first appears very thin, will afterwards fill the ground perfectly well, and the plants of it will appear in much greater quantities than at first.

"I have several times broke off a root of saintfoin four or five inches within ground, and it always sprang up again. This is a small argument for the fact I mentioned.

"Saintfoin is much cultivated in Lincolnshire. The common allowance of seed is five bushels to an acre. A gentleman south of Lincoln advised me always to sow a small quantity of trefoil with it (about four pounds on an acre). The reason is, that in this exposed country, the young plants suffered more by the sun in summer, than by the frost in winter. Now the trefoil, coming to perfection the first year, and living only three, will be a shelter for the young plants, during the first year or two, and die off when the saintfoin wants its room. This system is well supported by practice: but rye grass should on no account be sowed with it; that being, when left for fodder, a great impoverisher of ground.

"Saintfoin is observed to get to perfection in three years, lasts good four or five, and then dwindles during four or five more. Its first crops are from one or two loads; its second stage, from three to four loads, and it dwindles down again to one.—Last summer, which was remarkably dry, did very well with this grass.

"I have sown saintfoin with barley, with wheat, without corn in the spring, and now" (this gentleman's letter is dated September 4th, 1763) "am sowing some more at this present writing; but can form no judgment as yet.

"Three years ago I drilled some, according to Mr. Tull's directions, in beds, with treble rows, and some at equi-distant rows. The horse-hoed beds were good, as far as they went: the others, drilled at a foot distance, gave so much room for weeds to come up, that the success was very moderate; which indeed would have been the case with the former, had not the horse-hoe cleared them. On the whole, as far as my small experience and observations reach, I would never chuse any one to drill his seed, but to sow it in the broad cast-way, on land very fine, with a good quantity of seed.

Mr. Marshall, in his Rural Economy of Gloucester, gives the following account of saintfoin on the Cotswold Hills: "The entire wolds are productive of this princely herb. The calcareous rubble, which has been mentioned as forming the subsoil, is in some places two or three feet deep; and the rock, below, mostly open. The roots have been traced, in stone quarters, to ten; some will say twenty feet. Here the saintfoin flourishes luxuriantly. But in other places the rock rises, in flat horizontal seams, too near the surface: there the saintfoin is weaker, and goes off sooner. It is said to have been cultivated upon these hills upwards of one hundred and fifty years.

"In the established practice, saintfoin is generally sown with barley after turneps.

"But it has lately been discovered, in one of those incidents of practice, to which every farmer ought to be attentive, that it is more eligible to sow it with oats after wheat: that is, when the soil is foul; even with couch-grass.

"Saintfoin, sown on a soil which is clean and in tilth, is liable, on the Cotswold Hills, to be choked with bents (bromus mollis) which, feeding before saintfoin is cut, annually encreases. The weaker plants of saintfoin are, by this means, smothered or kept under, and the quality of the hay proportionally injured.

"In laying down land, which had been inclosed from intermixed common field, and which was, of course, in various states as to tilth and foulness, it was observed, in more instances than one, that where the land happened to be foul, the bents were few, while that which was clean and fine, at the time of sowing, was, in a few years, over-run with them.

"This incident was caught at; not, however, by slovens, for the purpose of saving trouble or expence; but by men, whose activity and spirit, in matters of husbandry, are indisputable. Saintfoin has now been repeatedly sown, on a large scale, on a soil worn out and fouled by a succession of corn crops: and the event has been invariably what the incidents pointed out. The couch occupying the surface prevents the bents from gaining a footing; while the saintfoin, feeding in the subsoil, has little occasion for the surface.

"It has ever struck me, that saintfoin ought to be sown when the soil is poor; that is, out of heart as to manure; in order that it may be induced to strike downward, and feed below; as well as to prevent the grasses and weeds from luxuriating above, to its annoyance: but I had no conception of its being able to work its way in a bed of couch. The plants are, it seems, checked during the first two or three years; but, at length, the couch dwindling, or in its nature growing weak for want of the ground being stirred, the saintfoin gains full possession: and although it may be then thinner than saintfoin sown on a clean surface, this is thought to be no disadvantage to its productiveness. It is allowed, however, that the land, on breaking up saintfoin cultivated in this manner, is still foul. But even this circumstance has its attendant advantage, in this country; it affords an eligible turf for sodburning; and although this operation may not clean it thoroughly, it is to be remembered, that its foulness was caused by a succession of corn crops, previous to the sowing of the saintfoin; and that had it not been sown, the soil would have required a fallow to cleanse it.

"Nevertheless, upon the whole, it does not strike me as a practice to be universally recommended to the cultivators of saintfoin: circumstances vary in different districts; and the same judicious cultivator, who has struck out, and indeed may be said to have established, this novel practice, has found, that the bents may, in a clean soil, be overcome by handweeding, the first and second years; for although every bent may not be extirpated, the surface afterward become too stale for the seeds to strike in; and it appears to me more than probable, that the expence of handweeding is not equivalent to the loss of produce, by the new practice, in the crops of the three first years.

"My observations are the fuller on this subject, as it appears to me interesting; and, notwithstanding the practice, which has been struck out, may be in some respects objectionable, it has already been adopted, by some principal farmers; and will, probably, in a short time, become the prevailing practice of the Cotswold Hills.

"The time of sowing saintfoin, here, is the middle of March; or from that time to the latter end of the month.

"The quantity of seed is proportioned to the state of the soil.

foil. A foul foil requires more seed than one which is clean : from one bushel to three bushels an acre. The advocates for thin saintfoin think a bushel of seed sufficient ; provided the foil be clean.

" This is another interesting particular, in the cultivation of saintfoin. It is remarked by men of observation, that where the plants of saintfoin stand at some distance from each other, they grow taller, stronger, and afford more herbage, than where they stand thick upon the ground ; in which case, the plants are not only weaker ; but the crop is shorter and less productive. The strength of the plants may, perhaps, be the only cause of difference : a strong plant, in all probability, strikes deeper than a weak one ; by which means its pasture is proportionally enlarged.

" Price of saintfoin seed, three to six shillings a bushel, four shillings and sixpence a medium price. Chiefly raised in the neighbourhood.

" But if thin saintfoin be advantageous, why not set out the plants, and keep them clean the second year, with the hoe ? With this, and a small addition of handweeding when the bents run up to head, these troublesome weeds might, perhaps, be wholly overcome.

" It is invariably mown every year. If it be once suffered to be eaten with stock during the summer season, its productiveness is in a manner destroyed ; it is said that it will not, in this country, ever afterward rise to the scythe.

" It is a principle here laid down, by men, who seem to have paid singular attention to the culture of this plant, that it ought never to be eaten upon the ground when in a growing state. They have reduced their ideas to still greater accuracy ; they are clearly of opinion, that saintfoin cannot, on a par of seasons, be fed with safety in more than two months of the year : namely the months of October and November : in a mild December, it will frequently make a shoot ; which being crot is said to be nearly fatal to the plant. Pasturing in spring is observed to have a similar effect. Even mowing too early is considered as very prejudicial : and what appears extraordinary, (being contrary to the general nature of the plants) suffering the plants of saintfoin to mature their seed is believed to prolong their duration !

" It is well known, that cutting trees while in a state of growth, is injurious to their future progress ; being, it is understood, prejudicial to their roots, and cutting this strong, deep-rooting plant, in a similar state, may have a similar effect. If the injury be done to the root, and take place in the lower extremities of it, the damage, which follows, is easily conceived ; for whatever portion of the length of the root is destroyed, in such proportion will the pasturage of the plant be contracted ; and, until it has had sufficient time to re-extend its roots, in the same ratio will be its productiveness. These reflections are offered incidentally ; in order to excite a spirit of enquiry, which may lead to more accurate ideas concerning the nature of most useful plant.

" The expenditure of saintfoin hay is chiefly on turnep-sheep and horses. The produce one to two tons an acre.

" The expenditure of the aftergrass is principally on lambs, which are newly weaned : also on grown sheep, as well as on cattle ; but is seldom, I understand, eaten with horses.

" The duration of saintfoin on the Cotswold Hills is short. Seldom more than ten years : not even with the management abovementioned, on land which has never borne saintfoin before. This, however, may be difficult to ascertain. It has been cultivated on these hills, it seems, the major part of two centuries. It is not likely, however, that every patch should have been hit : the shortness of its duration must therefore be given to the nature of the soil, or subsoil.

" The general idea seems to be, that land ought not to be recrot with saintfoin, under twenty years. But, it is probable, that it cannot be cultivated, with success, after so short an interval. There is an instance of a piece of land on these hills being crot three times with saintfoin, within memory ; but the last crop was of little value : it went off in about three years. Therefore, notwithstanding what has been said above, the present proportion of saintfoin ley to the arable crops may be sufficient. In the present course of crops, each piece will come round for saintfoin in seventy years : and it appears doubtful whether, even after that interval of rest, the substrata will be sufficiently recharged to send up ten more crops, equal to those at least

which it afforded the first time. The food of saintfoin it then contained might have been some thousand years in forming."

SALLENDERS, a disease in horses, consisting in cracks in the bending of the hough, and occasions a lameness behind. This disease is cured in the same manner as the mallenders. See MALLENDERS.

SALT-MARSHES, pasture-lands lying near the sea, and sometimes overflowed by the sea-water.

" It has been observed, says an ingenious writer in the Museum Rusticum, that horses and black cattle thrive better, and get flesh and fat sooner, in salt marshes, than in fresh water meadows or upland pasture ; yet I do not remember ever to have heard any good reason assigned for it.

" Some will tell you that the air of the sea whets their appetites : that the pasture is rich and nourishing ; and that the herbs produced by the lands near the sea are more conducive to the health of herbaceous animals, than such as grow on upland pastures, whether natural or artificial.

" But may we not rather attribute the thriving of cattle on these marshes, to the saline particles with which the earth as well as its produce, is, when near the sea, strongly impregnated ? Perhaps even the dews have their portion of salt ; but of this I have made no experiment, therefore mention it only as a probable conjecture ; for as they fall soon after they are exhaled from the sea, without passing through the secretions necessary to separate their saline parts, why should not this be the case ?

" But to return to my first subject : I am fully of opinion, that the saline particles only, with which the grass is impregnated in the above-mentioned marshes, cause cattle to thrive in them in the manner they are known to do. These salts purge away the foul humours which the beasts have contracted, either by idleness, or by being overheated in labour ; by which means they are better disposed to be nourished by the aliment they receive.

" It may perhaps, be objected, that if the grass of these marshes is apt to purge cattle, this very purging, by being long continued, will be a means of preventing their growing fat. To this I answer, that the cattle take with their food every day nearly the same quantity of these purgative particles : but that the quantity of salt, which at their being first put into the marsh will have that effect, will cease producing it when they are, by custom, habituated to take a daily portion of it : this must be allowed, as we all know, that a few grains of rhubarb will operate as a cathartic to a person that is not accustomed to take it ; yet it is as well known that a man may take many grains daily, if he uses himself to it, without its being sensibly purgative to him.

" It is not convenient to every one to send their cattle to a salt marsh : would it not, therefore, be happy, if we could substitute a method that would nearly answer the same purpose ? I do not think this impossible : perhaps, if common salt water was to be laid in the fields for the horses to lick as often as they pleased, they would thrive much better : were I to say I know it would have that effect, it would be no presumption.

" Cattle are naturally fond of salt, and if left at their liberty, will take no more of it than what does them good. With this help, our fresh-water meadows, and upland natural artificial and pastures, would yield us a greater profit, and of course be worth more both to the land-owner and farmer.

" Some will not allow a thing to have merit, unless it is supported by what they call a proper authority ; and they do not allow the experiments of a particular person to be sufficient. To satisfy such I can assure you, that in the inland parts of Switzerland, when their horses and cattle have endured the hardships of a long and severe winter, they turn them in the spring loose into the mountains, laying salt here and there upon the rocks, for them to resort to when they please ; and of this they are so fond, that when the farmers went to catch their horses, they take some salt in their hats, as we do oats in a sieve, to allure them.

" Experience has long convinced them, that the salt thus laid in their way answers every good purpose : their cattle are more healthy in general than ours are in England ; and almost to this alone do they attribute it.

" In the province of Munster and Connaught, in Ireland, they very frequently lay salt on slates, for the benefit of their horses when at grass : this, they find, does the

cattle great service : and in this should we imitate them, and not be too proud to learn of them, because in Ireland agriculture is not in so flourishing a state as in England.

"Some few farmers have (to do them justice) practised this method in our own country ; but contenting themselves with the profit resulting from it, they have not propagated the knowledge of the many advantages they are sensible may be derived from this practice of giving salt to cattle.

"The farmers and horse-jockeys know well the use of salt ; they mix it often in their medicines, and find, by experience, that nothing proves so powerful a stomachic to horses, as a little salt thrown into their oats.

"I must farther observe, that the use of salt is very proper when cattle are turned into clover, lucerne, or coleseed to feed : it is well known, that, on these occasions, they are very apt, unless great care is taken, to be surfeited ; the salt would prevent this accident, and thereby greatly accelerate the fattening of the cattle, and make it much safer to the farmer.

"Salt has also been found to be of great service in fattening hogs, by causing them to drink more plentifully than otherwise they would."

Lucerne cut green and given to horses, has the same effect upon them as a salt marsh. The lucerne at first, and for several days, is in a great degree diuretic to them ; after which they thrive upon it surprisingly, and in a very short time they get in high order.

For the uses of salt in rendering hay more grateful to cattle, See the article BRINING of HAY-RICKS.

SAMPHIRE. A plant which grows on cultivated sea-mud.

SAND, a genus of fossils found in minute concretions, forming together a kind of powder, the genuine particles of which are all of a tendency to one determinate shape, and appear regular, though more or less complete concretions ; not to be dissolved or disunited by water, or formed into a coherent mass by means of it, but retaining the figure in it ; transparent, vitrifiable by extreme heat, and not dissoluble in, nor effervescing with acids.

These are subject to be variously blended and intermixed either with homogeneous, or heterogeneous particles, particularly with flakes of talc ; and according to these, and their different colours, are to be subdivided into several kinds, as red, white, &c.

Dr. Lister divides the English sands into two classes ; the first, sharp or rag sand, consisting of small transparent pebbles, naturally found on the mountains, and not calcinable : these he farther divides into fine and coarse, and subdivides each, according to the colours, into white, grey, reddish, brown, &c.

The second, soft or smooth, which he subdivides into that with flat particles broken from lime-stones, that with silver-like particles, and that with gold-like particles.

As to sand, its use is to make the clayey earth fertile, and fit to feed vegetables, &c. for earth alone, we find, is liable to coalesce, and gather into an hard coherent mass, as is apparent in clay : and earth thus embodied, and, as it were, glued together, is no ways disposed to nourish vegetables : but if with such earth, sand, &c. i. e. hard crystals, which are not dissolvable in water, and still retain their figures, be intermixed, they will keep the pores of the earth open, and the earth itself loose and incompact, and by that means give room for the juices to ascend, and for plants to be nourished thereby.

Thus a vegetable, planted either in sand alone, or in a fat glebe, or earth alone, receives no growth in increment at all, but is either starved or suffocated ; but mix the two, and the mass becomes fertile. In effect, by means of sand, the earth is rendered, in some manner, organical ; pores and interstices being hereby maintained, something analogous to vessels, by which the juices may be conveyed, prepared, digested, circulated, and at length excreted, and thrown off into the roots of plants.

Grounds that are sandy and gravelly, easily admit both of heat and moisture ; but then they are liable to these inconveniences, that they let them pass too soon, and so contract no ligature, or else retain it too long, especially where there is a clay bottom ; and by that means it either parches, or chills too much, and produces nothing but moss and cankerous infirmities : but if the sand happens to have a surface of good mould, and a bottom of gravel, or loose stone, though it do not hold the water, it may produce a forward sweet grass ; and, though it may be

subject to burn, yet it quickly recovers with the least rain.

Sea sand is accounted a very good compost for stiff ground ; for it effects the two things following, viz. it makes way for the tree of seed to root in stiff ground, and makes a fume to feed it.

Sand indeed is apt to push the plants, that grow upon it, early in the spring, and makes them germinate near a month sooner than those that grow upon clay, because the salts in the sand are at full liberty to be raised, and put into motion, upon the least approach of the warmth of the sun ; but then, as they are hasty, they are soon exhaled and lost.

It is remarkable that sand, though it appears a very hard, dense, and indissoluble body, yet is contained invisibly in the brine, or salt water of our salt springs ; and even on the shooting of the salt, after evaporation, there still remain the particles of it in the clear pellucid salt ; and this, though wholly soluble in water, yet when a brine, made by such a solution, is boiled, deposits as much of the sand as the common brine of the pits, or sea water.

Dr. Plot, who was very curious to know the true history of this singular effect, procured experiments to be made in the following manner : eight folds of fine holland, and as many of much finer cambric, were put together, and, a quantity of the brine of the Staffordshire salt pits being strained through this, there was nothing separated from it but a small quantity of black dust, which seemed to have fallen in by accident, and which was not at all like sand ; yet, on evaporating this brine, it was found to contain no less than one fourth part as much sand as salt ; the quantity of brine yielded a bushel of salt, yielding also a peck of sand.

Some have supposed from these, and the like observations, that the sand was generated during the time of the boiling the liquor, but the more careful examiners think otherwise ; it appearing to them, that the particles of this sand may be seen in the brine, by the help of a microscope, before the boiling, in form of rectangular oblong plates, some nearly square ; these were so small, as readily to pass the strainer with the water ; and appearing as numerous in it after, as before the straining, shew that they are no more to be kept, by such means, than the salt.

The pores of the finest strainers, examined by the microscope, appear twenty times bigger than these plates, or particles of the sand, and therefore it is not to be wondered at, that they let them through. There requires, therefore, no more to the formation of the sand, than the coalescing of several of these particles into one larger granule, and soon ; and this is very likely to be done by means of the evaporation of a part of the fluid which kept them separate, and of the motion given to them in boiling, which naturally and necessarily brought them into the spheres of their own mutual attractions, at a time when their attraction with the fluid they swam in, was also much diminished with its quantity. This attraction seems even evidently to increase between the particles, as the water becomes evaporated, and, when finally the salt is drawn from it, and it is examined, as it drops from the baskets, in which the salt is put to drain, it is seen to contain more numerous particles of this sandy matter than before ; and these are found to coalesce into yet larger concretions, by degrees, as the remainder of the fluid evaporates from them on the glass.

The particles of this stony matter, when once thus united, are no more to be separated by water, nor is the matter any longer soluble in that fluid. The common spar found in form of stalactites and incrustations on the roofs, walls, and floors of old caverns, shews that it was once dissolved in water, and by that means brought to those places, and made into those forms : and it should seem, that this sand, as it is called, was only this sort of spar, which is contained more or less in all water ; and which, on the evaporating of that water and separation of the salt, which might help in making the water a menstruum proper for the retaining it, shoots out into its own natural concretions ; for the figure of these thin plates is the true and natural thin parallelopiped or rhomboidal figure of the smaller concretions of that matter, and even of those pieces into which it falls on breaking. *Phil. Trans.* No. 145.

Common sand is a very good addition by way of manure to all sorts of clay lands ; it warms them, and makes them more open and loose. The best sand for the far-

mers use is that which is washed by rains from roads, or hills, or that which is taken from the beds of rivers; the common sand that is dug in pits never answers nearly so well. Sand mixed with dung is much better than laid on alone: and very fine manure is made by covering the bottom of sheep folds with several loads of sand every week, which are to be taken away, and laid on cold stiff lands, impregnated as they are with the dung and urine of the sheep.

Besides clay land there is another sort of ground very improveable by sand; this is that sort of black foggy land on which bushes and sedge grow naturally, and which they cut into turf, in some places. Six hundred loads of sand being laid upon an acre of this land, according to the Cheshire measure, which is near double the statute acre, meliorate it so much, that without ploughing, it will yield good crops of oats or tares, though before it would have produced scarce any thing. If after this crop is taken off, the land be well dunged, and laid down for grass, it will yield a large crop of sweet hay.

Once sanding this land will improve it for a vast number of years, that it will yield two crops of hay in the year, if there be weather to make it in. Some land in Cheshire has been, by this means, rendered of twelve times its former value to the owner. The bogs of Ireland, when drained, have been rendered very fruitful land, by mixing sand in this manner among the earth, of which they consist. Add to this, that in all these boggy lands, the burning them, or firing their own turf upon them, is also a great advantage. The common peat, or turf ashes, mixed with the sand for these purposes, add greatly to its virtue.

Sea sand, which is thrown up in creeks and other places, is by much the richest of all sand for manuring the earth, partly its saltness, and partly the fat and unctuous filth that is mixed among it, give it this great virtue. In the western parts of England, that lie upon the sea coasts, they make very great advantages of it. The fragments of sea shells also, which are always in great abundance in this sand, add to its virtues; and it is always the more esteemed by the farmers, the more of these fragments there are among it.

The sea sand used as manure in different parts of the kingdom is of three kinds: that about Plymouth, and some other of the southern coasts, is of a blue grey colour like ashes, which is probably owing to the shells of muscles, and other fish of that or the like colour, being broken and mixed upon it in great quantity. Westward, near the Land's-end, the sea sand is very white, and about the isles of Scilly it is very glittering, with small particles of talc; on the coasts of the North-sea the sand is yellowish, brown, or reddish, and contains so great a quantity of fragments of cockle shells, that it seems to be chiefly composed of them. That sea sand is accounted best, which is of a reddish colour: the next in value to this is the bluish, and the white is the worst of all.

Sea sand is best when taken up from under the water, or from sand banks, which are covered by every tide.

The small grained sand is the most sudden in its operation, and is therefore best for the tenant who is only to take three or four crops; but the coarse or large-grained sand is much better for the landlord, as the good it does lasts many years.

Where sand is dredged out of the sea, it is usually twice as dear as where it is taken from the sand banks.

When the land has been well manured with the large sand, they take four crops of corn from it, and then lay it down for pasture for six or seven years before they plough it again. The grass is so good, that they commonly mow it for hay the first year; it always abounds very much with the white-flowered clover. If the grass grows but short, it is the farmer's interest to feed his cattle upon it, and it will turn to as good account this way, being very sweet and rich, and making the cattle fat, and the cows yield a very large quantity of milk. *Mortimer's Husbandry. See CLAY.*

SAND-FLOOD, a terrible disaster incident to the lands of Suffolk, and some other parts of England, which are frequently covered with vast quantities of sand, rolling upon them like a deluge of water, from sandy hills in their neighbourhood.

Violent winds break through the turf that covers these hills, and then the sand, lying loose and naked, is soon carried down upon the plains, where it covers and buries the grass, and in a very little time eats through the light turf, and

mixing itself with the sand underneath, becomes one bed of this dry matter never to be covered with turf again. A large body of sand being thus got together, nothing stops its progress; but it, at every storm, rolls over more and more ground, so that in a few years it extends itself a vast way, especially where the ground, over which it passes, is of the same sandy nature, and only covered with a thin turf.

In some parts of Suffolk the ground encourages this change so greatly, that a bed of sand broke loose from a neighbouring hill, and covering only a few acres, perhaps eight or ten, will, before it has travelled four miles forward, which it does in a small course of years, deluge a thousand acres. It travels down hills faster than any way else, but will not be stopped by ascent, but will move up the steepest hill, only that it requires more time. The making of fences, in the common way, to keep it out, is in vain. It runs through the hedges, and flies over the tops of the banks; and when it reaches a village, in its course, will bury the cottages, unless preserved at more charge than they are worth. It will in a very little time beat up to the eaves of a house, of the low kind, that are usually built in a country village, and has often weight enough to break down walls in its passage.

The best way of stopping its progress is by hedges of furze, planted one over the other, as they become levelled; these, if well kept up, will by degrees, stop or divert the progress; and some who have tried this, with resolution, after they have had the sand raised twenty feet high, have found it stop its increase, and then, having manured this adventitious soil with dung, found it as good ground as that which made the surface before.

About Thetford, the villages were wholly destroyed by this about ninety years ago, and the branch of the river Ouse, called then Thetford river, so blocked up by it, that very small vessels only could go up it, where very large ones used before. The river has been of great service in stopping its progress into Norfolk, where otherwise its course would have carried it, and its vast spreading sideways, in proportion to its going forward, would have made it bury vast quantities of land in a few years.

The most probable conjecture, as to the cause of this strange sort of deluge in these parts of England, is, that this portion of the country of Suffolk lies east north east of a part of the great level of the fens, and is by this exposed to very impetuous winds which acquire more than ordinary force by their passing through so large a tract of country uninterrupted; the storms seem to be one great cause of the mischief, and the sandy nature of the soil the other. There are old stories, in the country, of suits at law commenced among the farmers, for grounds blown out of the owners possession; but the people who gain this sort of wandering land are the greatest sufferers. A little sand sprinkled by the winds over a tract of land, where there is a bed of sand under the turf, soon eats through that obstacle; and what was at first only a thin coat of sand, becomes then a deep plain of it, capable of being blown away to the depth of eight, ten, twenty, or more feet, and is carried over every thing in its progress before the winds, when once taken up by them. *Philosophical Transactions, N^o. 37.*

SAND-lands, or Sandy lands, a term used by our farmers to express such grounds as consist wholly of a pure-sheer sand.

This is of different colours, as white, blackish, reddish, or yellowish, and is very different in its nature, and in the size of its particles, some being harsher and some milder, and some very light, seeming only to be mere dust. The grey, black, and ash-coloured sand-lands are the worst of all, and generally are found on heaths and commons. Gravelly lands approach much to the nature of these, and those which consist of the largest stones, and are mixed with the hardest sands, are of all the most barren.

The properest plants for arable land, of this kind, are white oats, rye, buck wheat, and turneps. The natural produce, in weeds, is quick grass, sorrel, broom, furze, fern and heath.

The best manure for them is either marle, or such clay as will break with the frosts. Cow dung is also a good manure for these lands, and many use with success chalk, mud, and the half rotten straw from dung-hills.

When the farmer has a mind to raise corn on these lands, he must order them the same as they do the clays; but where they are over-run with broom, furze, and such sort of weeds, marle is to be laid on in great quantities. This is

the

the practice in Staffordshire, and by it they rid themselves of these troublesome weeds, and procure good crops of corn, though at some expence.

The first sowing of this land is with buck-wheat, and for this they make three fallowings in winter and stir them in the May following; at this time they sow them, allowing one bushel of seed to an acre, which yields them sixty again. Then once plowing these lands after this crop is off, they are fit to sow rye on.

In Oxfordshire, they seldom give these lands more than two fallowing for wheat, except they are very much over-run with weeds; and they esteem the white and Lammas wheat the most agreeable for this sort of land, and then after a allow rath-ripe barley. They afterwards generally fallow them every other year, and reckon them unfit for beans and peas though they sometimes sow them with winter vetches. If they sow peas on them, they esteem the rath-ripe kinds the best.

In Herefordshire, they are much subject to moss growing upon their sandy lands, and they make a great improvement by burning it on the ground, and mixing the ashes with lime, which they plough in.

They generally sow them with rye after this manure, and that yields a very great increase upon them, and brings on a very good kind of grass, if they are laid down after a crop or two. *Mortimer's Husbandry.*

SAP, a juice furnished by the earth, and changed into the plant, consisting of fossil, saline, aerial, and other particles from putrefied animals, vegetables, &c.

This juice enters the plant in form of a fine and subtile water: which the nearer it is to the root, the more it retains of its proper nature; and, the farther from the root, the more action it has sustained, and the nearer it approaches to the nature of the vegetable.

Consequently when the juice enters the root, the bark whereof is furnished with excretory vessels, fitted to discharge the excrementitious part, it is earthy, watery, poor, acid, and scarce oleaginous at all.

In the trunk and branches it is further prepared, though it still continues acid; as we see by tapping or perforating of a tree in the month of February, when it distils a watery juice apparently acid.

The juice being here carried to the germs or buds is more concocted; and here having unfolded the leaves, these come to serve as lungs for the circulation and further preparation of the juice.

For these tender leaves, being exposed to the alternate action of heat and cold, moist nights, and hot scorching days are alternately expanded and contracted, and the more on account of their reticular texture.

By such means is the juice still further altered and digested as it is further in the petala or leaves of the flowers which transmit the juice, now brought to a further subtilty, to the stamina: these communicate it to the farina or dust in the apices, which is, as it were, the male seed of the plant, where having undergone a further maturation, it is shed into the pistil, which performs the office of an uterus or womb; and, thus having acquired its last perfection, it gives rise to a new fruit or plant.

The root or part whereby vegetables are connected to their matrix, and by which they receive their nutritious juice, consists of an infinite number of vasa absorbentia, which being dispersed through the interstices of the earth, attract or imbibe the juices of the same: consequently, every thing in the earth that is dissoluble in water, is liable to be imbibed: as air, salt, oil, fumes of minerals, metal, &c. and of these do plants really consist.

These juices are drawn from the earth very crude; but by the structure and fabric of the plant, and the various vessels they are strained through, become changed, further elaborated, secreted, and assimilated to the substance of the plant.

SCAB, a disease incident to sheep, chiefly occasioned by a tedious length of wet weather.

"I imagine, says Mr. Vesey, your readers will not be displeased if I should, with your assistance, communicate to them a remedy for this disorder, which I have several times tried, and almost always found to answer extremely well.

"Some men, whom I have known to breed and feed a great number of sheep, have been grossly mistaken in their comprehension of the nature of this distemper, which they rashly judged to be merely cutaneous; whereas, when a sheep has the scab, the blood is always more or less affected by it: therefore the outward applications, which are in gene-

ral alone resorted to for a cure, do for the most part more hurt than good, by driving in the eruption, and making it fix on the internals, thereby often occasioning the death of the animal.

"Now the true way to treat this disorder is, first to give the animal something inwardly to drive out the eruption; then comes, with propriety, the outward application, which completes the cure by killing the scab.

"When a farmer has any of his flock afflicted with the scab, let him attend to the directions which follow:

"Take a gallon of soft well or pond water, which divide into two equal parts: in one of these parts dissolve eight ounces of old hard soap; to which when it is dissolved, add two ounces of spirits of hartshorn, and seven ounces of common salt, with four ounces of roll brimstone, beat to a fine powder and sifted: then take the other part of the water, in which put two ounces of tobacco leaf, and one of white hellebore root: boil this second part till you have a strong infusion, after which strain it clear from the leaves and roots.

"When you have got thus far in the process, take that part of the water, first mentioned, and set it over the fire; let it boil for about half an hour, keeping it continually stirring with a wooden ladle during that time: in the mean time heat again the other part, in which the tobacco and hellebore were infused; and when it is hot, mix the two parts gradually together over the fire, keeping the mixture continually stirring till it is taken off the fire, which should be in about a quarter of an hour: when it is quite cold, let it be put into a stone bottle, in order to its being kept in a cool place for use.

"Then take four quarts of new ale or beer: put into it twelve ounces of common salt, two ounces of bay salt, and eight ounces of pounded nitre, together with twelve ounces of pounded roll brimstone: set them over a gentle fire, and when the ale boils, take off the scum; let it boil for about half an hour; after which set by till it is cold, and put it into a stone bottle for use.

"When you are so far prepared, take one quart of ale, set it on the fire: mix into it by degrees, three ounces of flour of brimstone: when it is just ready to boil, take it off the fire, and let it stand to cool; and when it is only blood-warm, give this quantity inwardly to three sheep, which is to be repeated every second day till they have had three doses. This will drive out the disorder, when the first mixture is to be rubbed on the distempered part: and two days afterwards the second, and so alternately for about eight or ten days, till the cure is affected: sometimes two rubbings will be sufficient.

"I must observe that all these mixtures will be best boiled in well glazed earthen or iron pots." *Museum Rusticum*, vol. II. p. 173.

"The two greatest enemies the sheep, says another ingenious gentleman, or at least their wool (which is the most valuable part of them) have, are the scab and fly. I believe they destroy more wool than all the other diseases incident to that animal.

"Mr. Vesey has given us an approved remedy for the scab, and at the same time enters somewhat into the nature of that distemper. For my own part, I have not presumption enough to look into first causes: secondary ones are all I aim at: I always took nature to be an instructor, and the surest guide; but if we will hobble out of the way ourselves, she is not to blame.

"I agree with Mr. Vesey, that in this, and every other distemper a sheep labours under, the blood is more or less affected and disturbed: which disturbance, if I am not mistaken, the faculty call a fever; therefore it must be always considered, that a fever is [no more than a struggle of nature to get rid of some enemy in the blood, by throwing it out by some of the outlets of the body, namely by sweat, urine, or stool; or upon the surface of the skin; and then she seems to say, I have thrown the distemper out to your view, and there destroy it by proper applications.

"It surely is no scab until it is thrown out upon the skin: and when it is thrown out, what avails it giving internal remedies, to do that which nature has done before? If it be out, there's your ailment; and I think, gentlemen, it is an axiom in physic, that when a distemper is once known, it is half cured: if it is only coming out, my advice would be, not to disturb nature, who is always acting for our good in a wiser and better manner than we can do ourselves: she sometimes indeed is too weak for her office, and sometimes too strong; in the one case she is to be properly

perly afflicted, and in the other, prudently restrained: and when we do more or less, the effects are generally fatal. I hope this will satisfy Mr. Vesey, that he is not altogether in the right any more than his neighbours.

"To cure an illness with a few medicines, is as commendable as to say a great deal in a few words. One great obstacle to Mr. Vesey's treatment of sheep with scab, is its being too compound, troublesome, and laborious, setting aside the expence; and, where there are a great number of sheep, hardly to be practised. I would have all remedies for the ailments of sheep be as simple as possible; and to be obtained and prepared with as little trouble; for certain I am, gentlemen, when it is otherwise, many will let their flocks go neglected, or at best leave them to a slovenly shepherd, who knows very little of the matter: and when clip-day comes, when the poor creatures are out of their wool, (if they had any on before) what a sight presents itself to view! most parts of their skins being one continued scab, and other parts eat quite through, and deep into the flesh, by the maggot: this I have seen at clip-day, and may speak it; but what must I alledge it was owing to? sorry am I to say, to the over credulity of the master, who thought he had a shepherd who knew every thing; but the event proved the contrary.

"You must not be surprised when I say, what will destroy the fly will also cure the scab, with little or no alterations: mercury is a mortal foe to both; and the remedy for the fly is as follows:

"Take of good corrosive sublimate half an ounce: dissolve it in two quarts of rain water: to which add a gill of spirits of turpentine: this is the whole of it, which must be used in the following manner:

"When the sheep is struck, the shepherd must make a circle round the maggots with some of the water, by dropping it out of a bottle: this prevents them getting away, for they will not come near the water: then he must shred or open the wool within the circle, and drop a few drops of the water amongst them, and rub them about with his finger, and there leave them, for they will all die presently.

"I speak this from my own certain knowledge, and many others in this part of the country (Isle of Ely) can do the same.

"To a quart of the above water I add a pint of the simple lime water of the London Dispensatory; and I declare it from experience, there is no more certain cure for the scab than it: I am sure it is the cleanest, the soonest prepared, and when so, the cheapest; which are inducements, I think, sufficient to have every countryman make use of it." *Museum Rusticum, vol. II. p. 369.*

SCAB, or ITCH, a distemper in horses, proceeding from their being over-heated, and corrupt blood; to cure which you must let him bleed and purge him: for this take of the root of wild cucumber, and reduce it to powder; infuse it in a pint and a half of white wine for three hours, and give it him to drink, and he will soon be well.

If the distemper appears outwardly, rub all the parts of the horse's-body that are affected with ointment, called *Ægyptiacum*, or *Unguentum Apostolorum*.

SCABBARD, is the skin that serves for a sheath or case to a horse's yard.

SCABBED HEELS in HORSES, a distemper called also the frush.

Sometimes the frush falls away by degrees, by reason of an eating scab which penetrates to the quick, and causes so great an itching that the horse cannot walk without halting; but these sores are not so dangerous as they are troublesome.

Before the horse grows lame, his feet will stink like old rotten cheese, so that you easily discover the nature of the grief, since you cannot possibly come into the stable without smelling it; and besides the horse will sometimes beat the ground with his feet, by reason of the intenseness of the itching.

To begin the cure, you must pare the frush as near as you can with a buttress, and having quenched a good quantity of unslaked lime in vinegar, and strained it, boil it, and throw it boiling hot upon the frush: after you have done this, apply a restraining charge of powder of unslaked lime, mixt with the second water, or the black restraining, made of foot, vinegar, and whites of eggs.

The following ointment, called the countess's ointment, is also very useful in these cases: in half a pint of aqua-vitæ boil a pound of honey in a clean glazed pot, over a gentle

fire, stirring it till the honey is thoroughly heated and incorporated with the aqua-vitæ; then add verdigris, Venetian borax, and gall, of each two ounces, searfed through a fine searse, with two ounces of white vitriol pounded.

Boil these all together over a small-coal fire, stirring them till they be well incorporated; and keep the ointment for use; this will cure in three or four applications; but the dressing must be kept on with splents.

If the disease return after the sore has been cleansed, then apply the following ointment, which is called the neat-herd's ointment:

Take burnt allum and borax in fine powder, of each two ounces; white vitriol and verdigris, of each four ounces, very finely powdered; put these into a very clean pot, with two pounds of honey, and boil them over a clear fire, stirring all well together, till they be well incorporated; when the ointment is cool, stir two ounces of strong aqua-fortis; keep it well covered for use, and stir it once a day, for the first six days.

This ointment will heal them, though the internal cause can hardly be removed; and besides the horse may be let bleed in the toe, from time to time.

For preservation, the frush ought to be paired often, and the place rubbed once or twice with the second water, which will waste away part of the corruption, and dry up the roots of the scabs so effectually, that they will not break forth again for a long time; then bathe the feet daily with the following water:

Boil allum and white vitriol, of each a pound and a half, in a gallon of water, till it be wasted to two quarts at least; when you perceive the itching to be gone, melt tar, or black pitch, upon the scabs, and keep the horse's feet well picked, and free from dust or any other filth that may dry them.

Or take of rectified spirits of wine, and the sharpest vinegar, each two ounces: tincture of myrrh and aloes, one ounce; of *Ægyptiac* ointment, half an ounce; mix them well together.

After washing the part with this mixture, dip a pledgit of tow into it, and secure it in the best manner you can.

During the use of this, it will be necessary to give a purge once in six or eight days, and in the intermediate days the diuretic medicines proposed for the grease; which see.

SCIATICA, or RHEUMATISM. A disorder horses are liable to: to cure which, take half an ounce of oil of turpentine, and two ounces of camphorated spirits of wine, with which rub the part well, and let the horse have rest for a fortnight, and the complaint will be removed.

SCOWRINGS for HORSES; are those gentle, wholesome, and natural medicines, which, not stirring up any great flux of humours, only keep the body clean from such as are apt to rise or grow, being every way as wholesome in health and sickness, and may most properly be termed preparatives or preparers of the body, to entertain stronger remedies.

There are several kind of them prescribed, but the most gentle and natural is grafs, which you should give him for fifteen days together, after which time it will fatten him.

The best grafs for this purpose, is that of a new-mown meadow, for that will rake his guts very well, and not fatten: but if you would have him fatten, you must put him into some other pasture, which has not been mown, next to this forage, i. e. only the blades of green corn, as wheat, rye, barley, &c. given him for seven days and no more, will cleanse and cool his body; the like also will the leaves of fallow, the elm, or green thistle, do.

A mash of malt, taken in a larger proportion than is directed under that head, mixed with a handful or more of beaten hemp-seed is also a gentle medicine in this case.

Other sorts of scowrings there are; particularly after sweat, take half an ounce of rosin, or jalap in powder; as much of cream of tartar powdered, as also of liquorice in powder; make them into balls with fresh butter, of about the bigness of a small walnut, and give him four or five at a time in a hornful of beer, one after another.

One of a stronger nature is to mix a handful or two of hempseed with oats, or take a handful of the powder of dried box-leaves, and as much of brimstone, and mix it amongst his provender; these two purge the head, stomach,

and entrails, will kill all kind of worms, and dry up phlegm.

Another prescription is, to take fallad-oil half a pint; a pint of new milk from the cow; brew it together, and give it him lukewarm; or else take a pint of muscadine, and half a pint of fallad oil, and give it him to drink; or the same quantity of oil and sack, mixed together, and give it lukewarm; this has much the same effect as the others, and is good for any manner of cold, stopping the wind-pipe; and if you add a quantity of sugarcandy thereto, it will be the better.

But for such horses, whose grease must necessarily be melted, as running, hunting-horses, and the like, first take twenty raisins of the sun, with the stones picked out of them, ten figs split round-wise, boil them in two quarts of running water, till the water be consumed and thickened: then take powder of liquorise, aniseed, and sugarcandy, finely searfed, and mix it with the raisins and figs, stamping and working them together till they become a stiff paste, then making round balls thereof, of a tolerable bigness, roll and cover them all over with fresh butter, and give as many of them to the horse as you shall think suits his strength, provided the day before you give him such exercise as will raise his grease, and that immediately before you give him the medicine, you also warm him thoroughly, that the humours being again stirred up, it may the more effectually work.

Another very good receipt to purge a horse from all grease, glut, or filthiness within his body, is to take three ounces of aniseed, six drams of cummin-seed, a dram and an half of cathamus, an ounce and two drams of fenugreek seed, an ounce and a half of brimstone, all which beat to a fine powder, and searfe them: then take a pint or two of fallad oil, a pound and a half of honey, and of white wine two quarts; and this with as much fine wheat flour as is sufficient: make all into a stiff paste, and knead and work it well, which you are to keep in a galley-pot, close covered, for your use.

Now when the horse has been hunted, and is at night or in the morning very thirsty, take a ball of it as big as a man's fist, and dissolve it in a gallon or two of cold water, and it will make the water look as white as milk; then give it him in the dark, lest the colour displease him; if he drinks it, then feed him; if he does not, let him fast till he takes it, which certainly he will do at twice or thrice offering, and when he has once taken it, he will refuse all other drink for it, and you cannot give him too much nor too often of it, if he has exercise.

SCRATCHES, a distemper incident to the heels of horses.

It has so much affinity with the grease, and is so often a concomitant of that disease, that the method of curing the scratches may be selected from that article.

The parts affected should be first covered with the linseed and turnep poultice, having a little common turpentine added to relax the vessels; the green ointment may then be applied to promote the discharge, when the scratches may be dried up with the ointments and washes recommended in that article. See GREASE.

It is best afterwards to keep the heels supple, and softened with curriers dubbing, which is made of oil and tallow. This will keep the hide from cracking, and be as good a preservative as it is to leather; and by using it often before exercise, will prevent the scratches, if care is taken to wash the heels with warm water, when the horse comes in. When they prove obstinate, and the sores are deep, use the following; but if any cavities or hollow places are formed, they should first be laid open, for no foundation can be laid for healing, till you can dress to the bottom.

Take Venice turpentine four ounces, quicksilver one ounce; incorporate well together by rubbing some time, and then add honey and sheeps suet, of each two ounces.

Anoint with this once or twice a day; and if the horse is full of fleshy, you must bleed and purge; and if the blood is in a bad state, the alteratives must be given to rectify it. *Bartlett's Farriery*, p. 294.

There are a multitude of receipts for this purpose, but I shall prescribe only some of the chief.

Take brimstone finely powdered, mix it with sweet butter, and anoint the part with this once a day.

Take a handful of the tender tops of elder-buds, and as many bramble-berries, before they are ripe, and when they are red, bake them in two quarts of wort, and about the quantity of an egg-shell of allum, with which water, very hot, wash the sores twice a day.

Let the horse bleed in the shackle-veins, spur-veins, and the fore-toe veins, only let it be three days between the bleeding of the one toe and the other; then rub the sores till they be raw and bleed, with a thin hay rope.

Having boiled half a pound of allum in a quart of stale urine, and a quart of strong brine, till they come to a quart, wash the sores well with the liquor; afterwards having procured the sperm of frogs, in the month of March, put them into a pot, and let it stand for a week, in that time it will look like oil: spread this, with what round things appear in it, on a cloth, and bind it on the sores, repeating this several times. This has cured, when the disease has been thought incurable.

But the best of all medicines, and which scarcely ever fails to cure the scratches, is, if the horse be of a strong body and good stature, give him an ounce and a half of the best aloes you can get, pound it to a very fine powder, and mix it with very good butter, working and mixing it very well with a knife, then divide it into three parts, every one of which cover again with fresh butter, and make them as big as a good middling wash-ball; give the horse one of these in the morning fasting, upon the point of a stick, and a little while after ride him to warm his body, which will cause them to work the better: then bring him into the stable and keep him warm, and let him fast two or three hours; when you are to give him a mash of malt, let him eat a little hay, and then ride him softly for two or three hours.

After the balls pour down a horn or two of warm beer, and if you find him purge too much, so that it takes his stomach quite away, give him two wild briar-balls pounded to powder, in a quart of warm beer, and it will soon stop it; or if you have not the briar-balls, boil some cinnamon, pepper, nutmeg, ginger and bay-berries in the beer.

But if the horse does not purge at all, ride him to some green corn that is not cut, or for want of that, to some four grafs, and let him feed on it for about a quarter of an hour, then ride him gently home, set him up warm, and he will purge very kindly without danger.

SCYTHE, **SITHE**, or **SYTHE**, the instrument used in mowing, being a crooked blade joined at right-angles to a long pole. See the article MOWING.

SEAGRIM. See RAGWORT.

SEAM, tallow, grease, hogs-lard.

SEAM of Corn, a quarter, or eight bushels.

SEAM of Wood, a horse load of wood.

SEAR, dry; opposed to green; spoken of wood.

SEARCHER. See the article BORER.

SEAVES, rushes.

SEAVY Ground, ground over-run with rushes.

SEED, the product of a plant, whereby the species is propagated.

The choice of the seed intended to be sowed is an object of greater importance than many farmers seem to imagine. It is not sufficient that the finest grains be chosen for this purpose, unless they are likewise very clean. Such wheat is not difficult to be had from land cultivated according to the principles of the New Husbandry; but we seldom find corn entirely free from seeds of weeds when it has been raised in the common way.

It is natural to suppose, that the grains of flinted and sickly corn necessarily partake of the weakly disposition of the plant which produced them, and that their productions cannot be so fine as those which grow from the seeds of strong and healthy plants. For this reason Mr. Tull advises to take the seed corn from a richer soil than that in which it is to be sowed, and rather from ground in perfect tilth, than from land which has been less carefully cultivated. This seems to be very right (though the contrary opinion is almost generally received), because more may reasonably be expected from the productions of a fine good seed, which are full of vigour and well conditioned, than from a poor weak plant.

M. de Chateaubieux, who often sowed with no other intention than merely to try, for the benefit of mankind, at what time, in what manner, and in what condition, it is best

best to sow wheat, found that this corn sprouted pretty well even when sowed so green that it had not yet lost its milky quality; but thinks it much more advisable to sow none but what is thoroughly ripe; because the seed has then attained its full perfection, from whence we may most certainly expect the best and strongest plants.

"The wheat, says he, which has been reaped in a warm dry year, seems to me fitter for sowing, than that which has been gathered in a cold wet season: for in such a time as this last, all the productions of the earth are less good; their taste is less savoury; and as that corn in particular in which there is most moisture, is most difficult to keep, I infer from thence that the formation of its grain must be less perfect. I should therefore prefer wheat a year old, provided the year it was gathered in was warm and dry, to that which may have just been gathered in too rainy a season: for the same reason, I always choose for sowing, wheat of the growth of my high grounds, rather than that which has been produced in flats. The benefit accruing from all this care, may, perhaps, not be extremely great: but at the same time it does not cost any thing. Let us do in agriculture what is done in all manufactures, where the very smallest profits, the very least savings, are not neglected. Those small articles, often repeated, make large sums in the long run, and are a real gain.

"Another thing, of greater consequence, first made known to me by chance, but since confirmed by repeated experiments, always attended with the same success, I strongly recommended as extremely serviceable to the first sprouting of the seed. In my experimental sowings, I commonly used wheat taken from the heap in the granary; and likewise, frequently, corn picked out of the ears the moment before I sowed it. I counted exactly the grains of both sorts, and suppose that few will think there could be any difference in their productions. Yet I found a considerable one. What was picked out of the ears always rose extremely well; scarce a grain of it ever missed; whereas numbers of those which were taken from the heap, never sprouted at all. I did not perceive this difference at first; but at last it struck me. I relate the fact as it is, without pretending to account for the cause of this difference, which would lead me into too long a digression. The experiment itself may be of real use, by shewing us, that instead of threshing the wheat intended for seed at any time, without distinction, it ought not to be threshed till a very few days, at most two or three, before it is sowed. A few hands will be able to supply the seeds-men with as much as they will want: nor will this method, which may be a means of saving somewhat in the seed, be attended with any extraordinary expence.

"Perhaps too this practice may be attended with a very valuable advantage. I have not indeed yet made the trials necessary to satisfy myself of what I imagine; but my desire to be of service to the public induces me to mention it, that the lovers of agriculture may reflect upon it, and try such experiments as will clear up my conjectures.

"Threshing the seed only just before it is sowed may possibly, in some measure, or perhaps intirely, prevent the cause of smut in wheat. By this I mean, that the seed which has not been mixed with smutty corn, or any way infected by its black powder, will be exempt from that distemper. Not that I take black powder to be absolutely the original cause of this distemper in corn; but I believe it is very capable of communicating it to grains which are sound.

"That nothing may be neglected which can be of any service to the seed, great care ought to be taken in threshing the corn, especially in the manner that business is commonly performed, with flails, upon the barn floor: for a great number of grains are frequently so much bruised thereby, that it is impossible they should ever grow. If the wheat thus threshed for seed is not thoroughly dry and hard, the mischief is still greater; much more of it being then absolutely crushed by the flail.

"As sowing in drills requires less seed than is used in the common method, it will be easier to execute there an operation which might be too long and troublesome for so great a quantity as is used in the old way. The method which I advise, and which I have practised, is this. Let one or two beams, two feet and a half, or three feet thick, be laid across the barn floor; let the threshers stand on each side of the beam, and take out of loose sheafs of wheat, one of

which should be placed behind every man, a handful at a time, and give it two or three strokes against the beam. This will bring out a great deal of grain, which is to be reserved for seed. The ears thus shaken may be bundled up again, and afterwards threshed out with the flail, for other uses. This method is not so tedious as some may imagine: we are sure that not a grain is bruised; and those are the most perfect which drop out thus. I think I may compare this operation with what is done in the making of wine, where the first running is always the highest flavoured and best.

"Another excellent way to separate the fullest, and consequently heaviest grains, which are undoubtedly the fittest for seed, from those which are of less value for that purpose, and at the same time to clear them from many seeds of weeds, is, to make a stout man, with a broad wooden shovel, throw the corn with all his force towards an opposite corner of the barn, or rather of a large boarded hail, which generally is the fittest for the work. All the light, small, shrivelled grain, unfit for sowing, and the seeds of cockle, darnel, &c. not being so heavy as the solid corn, will fall short, and lie nearest to the man who throws them; while such as are large, plump, and weighty, out flying all the rest, are separated widely, and may easily be gathered up. Experience will shew the vast advantages of sowing seed thus chosen.

"The use of steepes was introduced very early into husbandry, not only as a means of preserving corn from several distempers to which it is subject, but also with a view to render the seed more fruitful. That some of them have sometimes answered the former of these instances is undeniable: but with regard to the latter, much stronger and oftener repeated evidences than any that have yet been produced, are still wanted to confirm their boasted efficacy. I shall, however, give a concise account of some of the most famous of both kinds; with this previous observation, that even such of them as have not succeeded in some cases, through causes perhaps unknown to us, may possibly do well in others, when tried with proper judgment and attention. Experiments of this kind should by all means be continued on a double account; first, to take off a prejudice which seems to gain ground, though it be not founded on any rational principle; and next to be well assured whether these preparations do or do not produce any sensible effect. Experiments seldom prove useless to careful and accurate observers. If they do not always answer the end proposed, they at least sometimes lead the way to other important discoveries.

"The Romans had their lees of oil, decoction of cypress leaves, juice of house-leek, &c. on which they have bestowed full as much commendation as they merit. Lord Bacon seems to be the first who has paid any attention to this subject in England: but he has only pointed out the path to others: nor do I know any author who has yet given us a set of experiments with this view, long enough continued absolutely to determine what effects some kind of steepes may have towards rendering grain more fruitful."

Van Helmont, and, since him, the authors of the *Maisons Rustiques*, having given many receipts for steepes, which they vaunt exceedingly, as increasing the fruitfulness of the seed steeped in them. But at the same time that they recommend these receipts, they advise sowing the corn thinner than usual; generally one third less; a circumstance which, alone, will add greatly to the crop, as very many experiments, and particularly all the good trials of the new husbandry, have evidently demonstrated. That the comparison may be just, all circumstances should be alike, as to the goodness of the soil, the quantity and quality of the seed, &c.

M. Duhamel, to satisfy himself whether any benefit does arise from the use of steepes, by way of giving the seed a greater degree of fruitfulness, tried the following experiment. He infused some good wheat in a lye of dung, mixed with lixivial salts, nitre, and sal ammoniac, and sowed with this grain two beds in his kitchen garden, dug with a spade. One of the beds was sowed very thick, and the other very thin. At the same time he sowed two other beds, exactly like the former, with some of the same seed, not steeped, one thick, and the other thin. At harvest time the beds sowed with the steeped seed were so exactly like the others, that it was impossible for the eye to distinguish between them.

A gentleman in his neighbourhood followed exactly the directions given in the *Maisons Rustiques*, in the use of one

one of their boasted receipts, which is there said to be of such efficacy, that the land need be plowed but once for wheat prepared with it. He did so; and his crop was scarce worth reaping.

On the other hand, M. Duhamel mentions his being informed by M. Peirol, many years secretary to the intendant of Auvergne, that he had made several experiments in imitation of those mentioned in abbé de Vallemont's famous book. In the month of May 1755, he planted in his garden (an indifferent soil in a hot exposition) four small cabbages, which then had only four leaves. In September following, the same cabbages were six feet and a half in circumference. Some plants of red wheat, transplanted into a bed dug very fine in his garden, bore one hundred and thirty ears a piece, each of which contained from forty to eighty grains. Some plants of white wheat, transplanted at the same time, produced an hundred and twenty ears, each of which had from thirty to forty grains. Two grains of red wheat, sowed in the same bed, and not transplanted, produced each of them one hundred and forty ears, which contained six thousand grains. Five plants of red wheat, distant from one another six inches, did not branch so well, being too close together: but each of them produced from forty to fifty ears, which contained from forty to sixty grains. Rye, which branches less than wheat, produced from thirty to thirty-five ears, each containing from sixty to seventy grains: and the barley of that country, which branches but little, produced however from sixty to eighty stalks, though the seed of this last had not been steeped in any liquor before it was sowed.

The author of these experiments judiciously observes, that they must be repeated and varied, before it can be made to appear that the extraordinary increase is owing to the steep.

This celebrated liquor of the abbé de Vallemont is made as follows:

Put into a tub, exposed to the south, one bushel of horse-dung, the same quantity of cow-dung, half a bushel of pigeon's-dung, as much sheep's-dung, as much ashes, three gallons of small pricked wine, two pounds of saltpetre, and as much water as will sufficiently dilute the whole, so as to make it thin enough for use. Every time that any of this liquor is taken out to sprinkle the plants, it is filled up again with water; and as it may be too strong at first, it may be weakened accordingly.

It is essential to observe, that M. Peyrol added to this infusion frequent digging; for the ground was dug five times between the plants of wheat: and he observed that each digging sensibly gave fresh vigour to the plants, which grew to the height of six feet.

M. Donat, another of M. Duhamel's judicious correspondents, made trials of these mixtures, from the use of which so much is promised: but says he thinks them of no other service, than to amuse the curious, who do not regret expence. As the authors of them boast that all kinds of soils, whether good, bad, or indifferent, well or ill ploughed, rested or not rested, will produce ten times more than in the common way; this gentleman sowed a large extent of ground, some good, some bad, some well, and some ill ploughed, &c. He made the steep himself, was present when the seed was sowed, and took care that no circumstance was neglected. But notwithstanding all his care, his crop was far from answering their promises. The good, well cultivated soil, produced fine wheat; but not extraordinary in point of quantity. The only advantage was in the saving of the seed. The poor ill cultivated land, and that which had not been rested, produced very little grain: and the very bad soil, none at all. These experiments convinced M. Donat, that the surest means of obtaining good crops, is, to have the ground in good condition. This is the principle on which the New Husbandry is founded: nor indeed does it offer any thing marvellous, or contrary to the most ancient precepts of good husbandry.

If there be in any of these steeps, or preparations, a more than common virtue, by which the grain infused in them is rendered more prolific than it would otherwise be, possibly some such benefit may accrue from the following practice, which is recommended by the author of the New System of Agriculture.

"Take, says he, the corn which is intended for sowing, and throw it, by a bushel at a time, into a large vessel full of water; let a man stir it with a staff, as violently as he can, for a considerable while together, and then giving it a little time to settle, skim off all that swims on the surface: repeat this till no more rises; then take out the corn which

has sunk to the bottom; and lay it by for seed; proceeding in the same manner till you have your intended quantity. After this, make a brine of bay-salt and rain-water, strong enough to bear an egg. Steep the seed corn in this liquor during thirty hours; for less time will not have any effect: then take it out, spread it upon a smooth floor, strew over it a good quantity of fine-ground powder of slaked lime, and sweep the whole up and down till each grain leaves clinging to another, and becomes, as it were, perfectly candied with the lime. It is then fit for sowing; and will infallibly produce a very abundant crop." Some farmers vary this steep, by adding to it a mixture of pigeons or other dung; and in most parts of France, where this receipt is known, they omit the salt; perhaps because it is too dear in that country, and steep the wheat in lime-water. For this purpose they put it into baskets, and carefully skim off all that swims on the top, most of which would not sprout, and is only fit to feed fowls.

The society of improvers in the knowledge of agriculture in Scotland, call the following a very promising receipt for multiplying corn: but as no experiment that we know of, duly attended to, has yet confirmed that surmise, we can only say, that it may not be wrong to give it such farther trials as will not hurt the experimenter, whether they do or do not succeed: a rule which should be constantly observed in all experiments.

"Take as much water as will fully cover the quantity of grain you intend to use; add thereto a reasonable quantity of a mixture of horse, cow, and such other dung as you can conveniently get, so as not to make the water too thick: add likewise for every boll (four bushels) you are to steep, about a peck or a sixteenth part of the same sort of grain as you are to steep. Boil all these till the grain is reduced to a pulp; keeping the kettle or cauldron close covered, to retain the steam. When the boiling is over, pour off the water, and dissolve in it a pound of nitre, or salt petre, to every four bushels of corn: then, while it is lukewarm, infuse your corn for three days; after which, drain off the water, spread the grain on the floor, mix it with a sufficient quantity of sea-sand (if such can be conveniently had), and lastly, with lime, to dry it, as is usually done in other cases."

"It seems reasonable to think," say the abovementioned society, "that nothing can be more natural for impregnating grain, than the strength and essence of itself. But, since nitre is added, it is best to be cautious; for it has been found by experience, that salts, though they have the virtues mentioned, kill or destroy the vegetative powers, when the application is immoderate, either with respect to the quantity, or the time the grain is steeped; so that there has often been a necessity to sow over again with the same, or some other grain. To make the better judgment concerning this critical affair, the nature and condition of different grains are carefully to be considered; but the most certain knowledge and direction are to be obtained by a course of observations and experience. Mean while, it is better to observe the maxim, avoid extremes."

In Mr. Houghton's collection of papers relative to husbandry and trade, are several experiments on the steeping of wheat and barley in a liquor which is there said to have occasioned a very great increase, and is thus made: "Take a quantity of rain-water, and dissolve in every gallon of it two pounds of stone-lime: let it stand two or three days, stirring it three times a day: then pour off the water into another vessel, and add to every gallon of it about four ounces of saltpetre, and one pound of pigeon's dung: mix them well together, by stirring them three or four times a day, and then strain off the liquor to keep for use." Mr. Everard, who communicated this receipt to Mr. Houghton, steeped a handful of wheat in a quart of this liquor, where he let it infuse eighteen hours: he then took it out, and laid it to dry in the air for the space of one day; and then steeped it again in the same liquor for about twelve hours, dried it as before, and steeped it again a third time, about six hours, after which he planted it in his garden, which was but common earth, setting it by single grains, about ten inches asunder, and a finger's length in depth. He could not remember whether every grain sprouted, but thought that very few failed. Those which did grow, produced an extraordinary increase, several of them yielding from sixty to seventy, some of them eighty stalks with very large ears full of fine plump corn: many of the ears were six inches long, and contained sixty grains: none had less than forty.

He also steeped peas and beans in the same liquor; but could not say whether their having been steeped too long was the cause that none of them came up: but he took the thick sediment which remained after the liquor was strained off, mixed it with four times the quantity of earth, let it lie all winter in a gravel walk, south of a codling-hedge, then made a row of holes, about four inches distant, put a handful of the mixed earth into each hole, with a pea upon it, and covered it with common mould. The peas sprouted well, ran up the codling-hedge to the height of about nine feet, shot out branches in several places, like vines, and bore so many well filled pods, that he judged he had above a bushel from about three or fourscore seeds.

He tried also an experiment on wheat infused in lime-water alone, some in brandy alone, and some in brandy and lime-water mixed, and had a great increase from each grain. With some of the liquor made with salt-petre, lime, and pigeons dung, he watered several trees in his garden, and found them grow and flourish much faster than any other of the same kind which were not watered in that manner. He also steeped barley in the same liquor, and found its increase equal to that of wheat.

Whether there be, or be not, any kind of prolific efficacy in these, or any other steeps, of which great numbers are pompously recommended, and which proper experiments can best determine; they are at least so far serviceable to the seed corn, that they clear it from filth, from many seeds of weeds, and from such poor, light and distempered grains as are not fit for sowing, and prepare it in such a manner, that, being already well moistened, it will shift much better than absolutely dry grain, in case a drought should ensue after it is sowed.

This thorough cleansing of the seed may probably be, in a great measure, the reason why corn so prepared is least apt to produce smutty ears. All the lyes generally made use of, certainly preserve the plants from mouldiness, and that in which lime is a principal ingredient seems to be one of the most effectual. But as this part naturally leads to the distempers of corn, another very intricate, but highly interesting subject, we shall resume it under that head, to which it properly belongs; and give in the mean time M. Duhamel's farther opinion concerning the pretended prolific virtues of infusions, with some late experiments relative thereto, as delivered in the sixth volume of his excellent *Treatise on the Culture of Land*, published last year.

We listen readily to the marvellous, especially when it promises any great and singular advantage. Such was the abbe de Vallemont's prolific liquor, by means of which the husbandman was to reap vast crops, without manuring, or scarcely ploughing his land. He was only to soak his seed in this admirable liquid, which was to open, strengthen, and amazingly fertilize the germ. Improbable as this doctrine is, it was greedily received.—It is known, that a seed contains in that part of it which is called the germ or bud, the embryo of a plant, that is to say, a plant in miniature, and that the rest of the seed serves to feed the young plant, or plantule, till it acquires roots which draw its farther nourishment from the earth. As soon as these roots spread, the seed is exhausted, and there remains only its then useless husk. What benefit then can be derived from prolific liquors? Perhaps they may render the nutritive substance of the seed fitter to support the young plant, which in consequence thereof may appear somewhat more vigorous at first, and till it has struck out roots: but from the time of its producing those roots, it ceases to subsist upon the lobes of the seed. Can it be imagined that a single atom of any prolific liquor exists at the distance of four or six inches from the plants in the earth, where its roots are spread, and from whence they draw their subsistence? Yet, such is the fondness of men for projects of this kind, de Vallemont's mixture was extolled as a wonderful discovery, indued with a magnetic virtue, capable of attracting from the bosom of the air certain principles, which probably do not exist in it, and numbers of receipts have been devised for making prolific liquors. Writers upon agriculture have stuffed their books with them, and vaunted their miraculous effects. A desire to see these mighty promises fulfilled, paved the way for their reception, and ill-made experiments have given a sanction to the error.

A little corn, impregnated with these pretended prolific liquors, has been planted grain by grain in a garden, and

its extraordinary increase has immediately been imputed to the steep. I myself was deceived by such trials: but when I extended them to three or four acres of ground, this great fertility no longer took place, and I began to doubt the efficacy of these boasted specifics. About the same time, I saw a single grain of barley produce 230 stalks, without any preparation; and was informed by the Rev. Dr. Hales, that another grain of barley had in like manner produced one hundred and fifty-four ears. From hence I concluded, that the prodigies of vegetation so much vaunted by some writers, as the effect of their favourite infusions, have in fact been owing to the nature of the soil, to good culture, and to the grains being at such distances from each other, that their roots have had room to spread, and thereby collect a great quantity of food. I then had recourse to new experiments, which confirmed me in this opinion.

We see in the Political State of England, that a grain of wheat which grew by chance on a bed of onions, and had not received any preparation, produced 5600 grains. Upon which the author of that work remarks (as indeed I had done before in regard to the former of the above-mentioned productions) that we must not from thence infer that the country where such a thing happens is naturally more fertile than another, or the method of agriculture commonly practised in it better than elsewhere; for that the cause of these prodigious growths is, that the grains stand single and in a good soil; that the only consequence which can be drawn from thence, is that the New Husbandry comes nearest to that state in which these surprising growths are produced; that it certainly must increase the product of the crops; and that it will probably require less seed than is used in the common way.

Though it was pretty well proved by our experiments, that good culture and proper manures contribute more effectually to the increase of crops, than all the boasted prolific liquors; yet several persons, out of zeal for the public good, have published, some of the advantages which they think arise from the use of certain fertilising steeps, and others, receipts for making them.

In this spirit, M. de la Jutais has given us a little tract, entitled. *The true Philosopher's Stone*; according to which, an admirable prolific liquor is to be thus made. Fuse some nitre in an iron vessel; and when it is hot enough to burn the substances which are to be added, throw in a small quantity of the same kind of seed as you intend to sow: for example, if you would have a prolific liquor for wheat, throw a little wheat upon the nitre; if turneps, put in turnep seed, and so on. These seeds take fire, are consumed, and incorporate with the melted nitre. Your prolific liquor is then made, and you have only to mix the nitre with water. What results from this operation? Nothing more, than that there is in this prolific liquor a great deal of nitre with a small portion of fixed nitre, or alkaline salt: whether this nitre be mixed with wheat, barley, turnep seed, or powder of coal, all chymists allow that the result will be the same, and that the same liquor might be made by mixing a little alkaline salt with a strong solution of salt-petre. The question is, what effect it will have upon vegetables. To try this fairly, two exactly similar fields should be sowed, the one with wheat prepared with the prolific elixir, and the other with wheat only limed in the usual way; taking care to sow an equal quantity in each field: for the single circumstance of diminishing the quantity of the seed, may increase the crops in years when the corn does not tiller much, and in good soils. Many have been deceived by not attending to this circumstance. The following are well made experiments:

“M. Delu, after trying M. de la Jutais's essence three times, with the most scrupulous care and exactness, thinks it of no sort of service.

“M. Peirol, whom I mentioned before, communicated to me in 1755, several experiments which he had made with great care, in order to satisfy himself whether these prolific liquors have any virtue; and those trials made him then hope for success. I thanked him for his obliging letters, and exhorted him to repeat the same experiments with some new precautions which I thought important. He did so, with all possible care; and it is with real pleasure that I shall give a just account of them, because they seem to me extremely fit to dissuade those who wish well to agriculture, from putting their trust in such illusions. In-

stead of running after an empty shadow, they may employ their time in useful perquisitions, by which the public will be benefited.

" M. Peirol sowed, both in his own garden, and in that of the intendant Auvergne, 1. many-eared wheat; 2. rath-ripe barley; 3. the common red wheat of the country; and had from each of them an amazing increase.

" Each plant of the many-eared wheat, had from fifty to ninety-two stalks, and these last yielded 13800 grains.

" Some of the rath-ripe barley had two hundred and forty-four stalks of each plant, and yielded 14640 grains.

" Several plants of the red wheat had three hundred stalks; but the grains were eaten by birds.

" These were fine productions: but the most important thing to be observed here, is that M. Peirol sowed all these different kinds of grain, as well in his own garden, as in that of the intendant, on the same day, viz. the 8th of September 1756; part of this corn having been steeped in the abbé de Vallemont's fertilizing liquor, while the rest had not been infused at all: yet their productions were quite alike, the ground had been prepared exactly in the same manner for the steeped and the unsteeped grain, and both were equally watered from time to time with that prolific wash. This last circumstance spoils the whole experiment: for who can doubt but that this watering of the plants with impregnations of dung, must give them great vigour; even more than a considerable quantity of dung itself would have done? However, the following experiment is, luckily, without the fault.

" On the 4th of April 1755, M. Peirol divided a pretty large field into five equal parts. The ground was in good tilth, and he sowed it with barley.

" The first part was sowed with unsteeped barley in rows a foot asunder.

" The second was sowed with the same kind of barley steeped in de Vallemont's liquor, and likewise in rows a foot asunder. Both had a ploughing between the rows, towards the end of April.

" The third was sowed in broad-cast, according to the custom of the country, excepting the quarter part of the usual quantity of seed was retrenched: but still it was the same sort of barley, and this had been steeped in de Vallemont's liquor.

" The fourth division was also sowed in broad-cast, like the former; with this only difference, that the seed was steeped in a prolific liquor invented by M. Robineau.

" Lastly, the fifth part was sowed entirely in the common way, with the usual quantity of the same kind of seed, unsteeped.

" The following was the state of these five divisions at harvest time.

" The first and second, which had been sowed in rows, with only a quarter part of the quantity of seed generally used in the common way, but prepared for the one by being infused in de Vallemont's liquor, and sowed in the other without any impregnation, were both very fine, and yielded a great deal of grain.

" The third and fourth, which had been sowed in broad-cast, with an abatement of only a quarter part of the usual quantity of seed, and where the grain for one had been steeped in de Vallemont's liquor, and that for the other in M. Robineau's, were middling, and not visibly different in any respect.

" The fifth spot, which had been sowed entirely in the common way, and with the usual quantity of seed, was the worst of all.

" Though M. Peirol was prejudiced in favour of prolific essences, he nevertheless concludes from this experiment, 1. That the unsteeped grain used for the first mentioned portion of the field, having yielded as fine a crop as that of the second which was steeped, infusing the seed does not contribute much to make the plants tiller.

" 2. That the products of the third and fourth divisions being quite alike, M. Robineau's sleep is not better than de Vallemont's.

" 3. That the difference between the crop of the fifth, and those of the third and fourth pieces of ground, was probably owing to the different quantity of seed.

" 4. That the superior beauty of the first and second, which surpassed all the rest, was occasioned by the grains being so far distant from each other, that the roots of the plants had sufficient room to collect their food, and that

the husbandman was enabled to stir the ground between the rows, in the spring, by which the vigour of the plants was considerably increased. All this confirms the advantages of the New Husbandry; and M. Peirol is so convinced of it, that he has sowed a very large tract of land, near Riom, in the same manner as the two first parts of the above-mentioned experiment.

" He has likewise made another trial of de Vallemont's specific, by planting vines in two different places. In one of these, where the soil was good, the common practice was followed, and the cuttings sprouted soon: in the other, where the ground was less good, each cutting was watered with two quarts of de Vallemont's liquor. These last shot out later, but then grew with great strength, and retained their leaves a long while. It cannot be doubted but that an infusion of dung will invigorate plants, and make them grow faster than they would otherwise. The owners of vineyards are here to consider, whether the expence of people to do this business may not be greater than the advantages accruing from it will repay: but it is certain that by thus watering their newly planted cuttings, especially with a strong infusion of dung, they will secure their taking root.

" To satisfy myself in regard to M. Robineau's pretended prolific liquor, I chose a piece of ground laid out for wheat, and divided it into three equal parts. One of these was sowed in the common way, with seeds only limed, and produced one hundred and ninety-two sheaves to the acre, which yielded sixty bushels of corn. Another was likewise sowed in the common way, with seed only limed, but two fifths less in quantity than is generally used, and produced one hundred and sixty-eight sheaves, which yielded fifty-four bushels. The third part was sowed with the same quantity of seed as the first, but prepared according to M. Robineau's direction. This produced one hundred and fifty-six sheaves, which yielded fifty-four bushels of grain. From whence it follows, that his method was not of any service to the crop.

" His liquor, when distilled over a very slow fire, yields a little brandy; what remains in the matras, yields a great quantity of salt-petre, and the residue is a bitter water which contains a small portion of alkaline salt. This is nearly what would be obtained from de la Jutais's liquor.

" M. Vandusfel has also tried M. Robineau's prolific liquor, and found it attended with no other effect, than that the field where it was used had somewhat fewer smutty ears than other grounds, for which the seed had not been so prepared. But other seed which he steeped in an infusion of dung, ashes, and lime, produced corn totally exempt from smut."

An ingenious correspondent of the editors of the Museum Rusticum, has given us the following improved method of breeding seed-wheat.

" I join, says this Essex farmer, with many others in opinion, that it is best every year to change one's seed-wheat, and this has been my constant practice: I have had many a weary ride to get seed that would please me, for I am, and always have been, very difficult in this matter.

" I have near two hundred acres of land in constant tillage: these I divide into three portions, so that I have every year about sixty acres in wheat, sixty more in barley and oats: and the remainder are either fallow, or in beans, peas, or turneps, &c.

" When I first came into my farm, I expended annually, of seed-wheat, thirty quarters; for after the example of my neighbours, I allowed four bushels of seed for every acre I sowed.

" These thirty quarters often cost me above seventy pounds; and God knows I could sometimes but little spare so much money, after the great annual expence of getting in my harvest.

" Some part of my land differs greatly in its nature from the other: near half my farm is a stiff deep clay; what bottom it has I know not, as I never could find it in digging my ditches, &c. the other half is a bed of light sandy loam; with a gravelly hard bottom.

" This difference in the soil of my farm is, on many accounts, a great advantage: particularly, my wheat does not all ripen at the same time; I have generally nearly got in that growing on my gravelly land, before that on my clay is fit to cut; and I can besides plough in all weathers, frost excepted.

" But

" But not to digress too much, I took it into my head that, with proper care, I could breed for myself, on my own land, as good seed-wheat as any I could buy, if not better; and I determined within myself to make the experiment.

" Before I made this experiment, I had reduced the quantity of seed I used on each acre, to three bushels, which was a great saving to me. I had still occasion for above twenty quarters.

" My first step was to select ten acres of the best land I had; five from the heavy, and as many from the light part of my farm; this land was by nature rich and good; it lay on the gentle southern declivity of a hill, and required very little manure: it lay in two little detached fields, at some distance one from the other.

" When I had prepared this land by a winter and summer fallowing, in which time the clayey part was ploughed seven times, and the light land five times, I had both fields sown with some of the best wheat I could procure; that for the heavy land I got from Hertfordshire, the other from a particular friend who holds a farm in Cambridgehire.

" When the season for sowing approached, I was mightily pleased with the appearance of my two little plots; for they resembled the best-kept gardens, not a weed to be seen, and the earth as fine as garden-mould.

" On this occasion I did not brine my seed, but had it put into a large tub; some water was then poured on it, and I made a stout labourer, with a stiff half-worn birchen-broom, stir it very briskly about for near half an hour; this I imagined would wash off the smut, if any there happened to be: the light seeds, which were very few, were skimmed off.

" I let the wheat afterwards lie three hours soaking, when my man again stirred it briskly with the same broom, and immediately poured the water off.

" Whilst yet wet, the seed was sprinkled in the usual manner with slacked lime, in order to prepare it for sowing.

" My reason for not brining it was, that I thought it would bring it too forward; and I rather chose to sow it early, which is, I know, in general, a very good practice.

" In sowing this land, I, in some measure, followed Mr. Tull's directions: that is, I sowed my wheat in rows with large intervals in the following manner.

" I had a furrow opened about a rod from the hedge: in this furrow some seed was by a careful hand very thinly scattered, not sowed in the common way with a sling of the arm.

" It took up time; so I had two sowers to each plough. When the ploughman had drawn the first furrow, he then opened another, at about ten feet distance from the first in the land; and seed was in the same manner thinly scattered in this also: after this, he returned to the first furrow, and drawing another close to it, covered the seed; the same thing he did by the second furrow: he afterwards went two bouts without any seed being sown in the furrows; but the third bout, seed was thinly scattered, as before, to form the second row of corn in each bed: another bout was made to cover the seed when the two beds were finished, the middle of the interval being left unploughed.

" In this manner both my little fields were sown, in double rows with intervals about five or six feet wide betwixt the beds, and the rows about two feet asunder.

" The corn came up very well, and preserved a good wholesome appearance all the winter.

" Early in the spring, that is, in the month of February, I made a careful man sow the spaces betwixt the rows of corn on the heavy land with wood-ashes, and on the light land with foot: these were both soon washed in by the rain, and the effects were speedily to be seen in the new assumed vigour of the crops, and this vigour continued till the corn was ripe.

" As soon as any weeds appeared, the intervals which were left unploughed at seed-time were turned up, and the spaces betwixt the rows diligently hand-hoed: this hand-hoeing was several times repeated, to keep the crop quite clear from weeds, the intervals had also several other stirrings; but this work was chiefly done with a very light plough, without an earth-board in the heavy land, and without either earth-board or coulter in the other little field.

" Every thing came very well forward: and when the wheat began to spindle, I had the outsidies of the rows well

earthed up with a plough, and the insides with a hand-hoe; the insides were done first.

" At harvest the fields made a noble appearance: a fine well broke earth striped with rows of healthy wheat.

" The cutting this wheat was very easily performed, it stood so ready to the reapers hands; and when it was housed and threshed, it yielded me about four quarters on an acre, one with another, the first year, though I have since had sometimes more, sometimes a little less.

" My ten acres then yielded me about forty quarters; and I had occasion for only about twenty-two to sow my common wheat-lands: I therefore took only the first and prime part of this crop, getting the sheaves very lightly threshed; what remained made excellent bread-corn.

" I never saw finer seed-wheat than mine was this year: my heavy lands I sowed with the seed produced by the light field, and my light lands with that produced by the heavy field.

" As soon as I had got in this select crop, I got the intervals in order for sowing with a second crop, in most respects continuing the practice of the year before: I had the like success, and might, perhaps, with equal advantage, have continued cropping the fields every year in the same manner; but, not to depend too much on Mr. Tull, my next crop was a full crop of barley on them, which succeeded well: and I selected two other plots of ground, of equal goodness, for my seed-corn husbandry, as I call it.

" In this manner I have now for several years past managed growing my own seed; and, if any thing, my crops have since increased; but I have again reduced the quantity from three to two bushels of seed for each acre of my wheat-land in common: that is, such as I sow in the ordinary way: on some of my rich, strong land, I do not use above six pecks, and find it answer very well.

" I could like to extend this New Husbandry, or this imitation at least of the New Husbandry, over all my lands that are in tillage: but in my method of practising, the expence would be too great; my sowers are well paid; I have enough to do to make my ploughmen go out of their ordinary way; and it cost me a great deal hoeing: yet all this I do not grudge to procure good seed.

" By introducing the drill-plough and the horse-hoe, I could save a great deal of labour on my light lands; and I may probably some time or other attempt it: but, at the same time, I am very sensible, I shall find great difficulty in getting men that will even try to do the work with these instruments. The common labourers in husbandry hate novelty: they pursue, without murmuring, the old beaten track; but put them out of it, and thought will become necessary: the fact is, they imagine it a very great hardship to be obliged to work and think too, and all for the same money.

" Without great resolution, and some kind of authority, a farmer will be obliged to let them even dig a ditch their own way: innovation they like not in any shape, often making use of the expression, that they are too old to learn.

" This, to a man who is very much disposed to lend a helping hand towards the improvement of agriculture, is a mortifying circumstance: there is scarcely any thing so difficult as to make an obstinate man useful: if, by dint of authority, you oblige him to go out of his way, he will rather contribute to the loss of your crop, than not to endeavour to convince you that he is in the right. I have often, to my sorrow, felt the truth of this observation.

" Several reasons, though I deal not much in them, may be assigned for the seed-wheat I raise in the above described manner, being so good.

" In the first place, I sow it on land that has not tasted any dung for some years, but is, in its own nature, rich and good: to this practice I ascribe a great deal of its goodness. In the next place, as the corn does not stand too thick, it enjoys all the benefit it can receive from the sun and air: by this means it attains a perfect maturity, and is certainly improved both in bulk and quality.

" This slight spring-dressing I give it, of foot or ashes, is of very great service: it warms the roots, and brings the corn forward; it loosens the earth, and either itself gives nourishment to the plants, or, at least, puts the earth in a disposition to afford it.

" Not

"Not a little is to be attributed to the frequent hoeing betwixt the rows and the stirrings of the intervals; and I find one very particular and great advantage result from it, which is, that it is an excellent means of clearing my land of weeds; for they no sooner attain a part of their growth, but they are destroyed long before they seed.

"Farmers in general think their fields cannot in the spring be so full of wheat-plants: the ground seems covered with verdure, and the blades are, as it were, crowded for want of room: when the weeds begin to get up, they send in a parcel of men and women with weeding-hooks, not letting a hoe come near the land to cut them up: they are sadly afraid they should not have plants enough at harvest; whereas, if they were to measure and mark off a rod square of land in February, and count the plants growing on it then, and afterwards count them in the beginning of August, it would almost always be found, that four parts in five of them had perished in the intermediate months, and that what remained were, by far too much crowded still, and had each but few stalks.

"I never weed my corn of late years; for as I allow only two bushels of seed, and often less, to an acre, the plants come up thin; and there is of course room for a moderate-sized hoe, which is the instrument I clean my land with; and so far from being fearful of having my crop injured by this means, I order the workmen, where the plants stand too close, to cut them up without mercy, as they would do the most pernicious weeds: if there happens by any accident to be a vacant spot, they easily remove some plants to it, with earth about their roots, by the help of their hoe.

"By this management, I in some measure, reap the benefit of the advantages promised in the New Husbandry; though I have not such opportunities of so often giving the plants a fresh supply of nourishment, nor of earthing them up when the grain is forming in the ear; for, after the corn has put forth its stalks to any considerable length, it would not be so proper to send in the hoers: but all the loss is the want of earthing up the plants so late as I could wish: for the weeds will, before this time, be pretty well got under, and but a few of them will be able to ripen their seeds before harvest, when they will of course be destroyed by turning in the stubble, which I always do as soon as possible; though many of my neighbours let their stubbles lie rough all the winter, for the sake of feeding a few score of ewes.

"Every farmer has methods peculiar to himself; and they are, for the most part, such as were practised by their fathers, grandfathers, &c. whom they succeed, in the culture of their farms.

"My method, as you must now be sensible, differs from most of those used by other occupiers of land; and if I cannot so well defend them by arguments, an experience of several years has convinced me that I ought still to persist in the practice of them: they have answered all the ends I could wish from them: what could I desire more?

"I am enabled to raise my own seed without the trouble of procuring it from a great distance, at a large expence, and with a deal of trouble.

"My crops are to the full as good as ever they were, and I use less seed by above one half: my manure goes a great deal farther than it used to do, because I bestow more ploughing and other tillage on my land; and I am not so much pestered as I formerly was with weeds, for they now very seldom are suffered to seed on my land.

"Of this last evil, I mean that of weeds, I have not, however, yet got quite rid; for such of my fields as border on my neighbour's lands are still often infested; some of these same neighbours, I have several times mentioned, are but slovenly farmers, and the weeds which have winged or downy seeds, are constantly waisted by the wind from their land to mine; so that I, in some measure, am punished for their neglects: thistles are this way particularly troublesome, as the seeds of them will sometimes be carried a very considerable way by the wind.

"I have very little more to say at this time, except that I never thresh the sheaves that are to supply me with seed-corn, till just when I want to make use of it. I have a notion, that the seed keeps better in the covering nature has given it, I mean the chaff, than it would do without it; and I am pretty certain it sprouts sooner in the ground, the husk or bran of the grain being preserved in a tenderer

and more yielding state; than it would be were it exposed to the open air."

The choice of seed-corn is undoubtedly very material in husbandry, and it would seem that the largest, plump, full-bodied corn was the most proper for seed, as being the most vigorous, maturest, and fullest of flour, and therefore capable of furnishing the young plant with the most plentiful share of nourishment: but however plausible this may appear, experience does not confirm it: but on the contrary, it is abundantly proved by experience, that small thin seed, as of wheat, produces as large ears of full-bodied corn, as the full-bodied seed, selected with the greatest care.

This is certain, from the common practice of the best farmers, who, by choice, buy for seed the wheat produced upon burn-baked land, the grains whereof are known to be in general smaller and thinner, than those of wheat raised upon good land cultivated.

"Some have thought, says Mr. Tull, p. 55, that a large grain of wheat would produce a larger plant than a small grain, but I have full experience to the contrary. The small grain, indeed, sends up its first single blade in proportion to its own bulk; but afterwards becomes as large a plant as the largest grain can produce. Farmers, says he, p. 233, in general know this, and choose the thinnest, smallest grained wheat for seed, and therefore prefer that which is blighted and lodged, and that which grows on new broke ground, and is not fit for bread; not only because this thin wheat has more grains in a bushel, but also because such seed is least liable to produce a smutty crop, and yet brings grains as large as any. I myself have had as full proofs of this as can possibly be made, in both respects. It was from such small seed that my drilled Lammas wheat produced the ears of that monstrous length described in this article [eight inches long]. I never saw the like, except in that one year, and the grains were large also. And as full proofs have I seen of thin seed wheat escaping the smut, when plump large grained seed, of the same sort, have been smutty."

Here we see plainly, that the quality of wheat for seed, does not consist in the fullness, plumpness, and largeness of the grain, as by many has been supposed, but principally in the soundness of it, of whatever size it happens to be, whether large or small.

Secondly, the most material circumstance, next to the soundness of the grain, seems to be in the nourishment that the seed receives in the ground. This is a remarkable circumstance, and shews the great advantage of good land, and of preparing it well for the seed. It shews also the great benefit of good hoeing, that can, without the assistance of manure, improve the puny plants arising from small seed, to so great perfection as in this case, and produce large well filled grain, and ears of Lammas wheat of such a surprising length as eight inches, which is near twice the length that good ears of sown Lammas wheat commonly attain to.

It may appear unaccountable in regard to seed wheat, that the quality of it is not discoverable either from its size or appearance, but these in other cases are not to be relied on. The gardeners direct those who would save prime carrot seed, to take up these roots, in order to see that they are fair and straight, and then to replant them, not doubting but the finest carrots will produce the best seed: and in this they seem to be right. Yet in some cases that appear similar, this rule is erroneous. "I should not have believed it, says Mr. Weston, had I not been told it by others, and since experienced it myself, that a very large onion is not the best to plant for seed." Traacts, p. 10. Hence it appears, that we cannot safely reason, in such cases, from analogy; but in tracing the operations of nature, we should depend chiefly upon experiments.

SEED-LIP, SEED-LEAF, or SEED-LOP, a seed-basket, or the vessel in which the sower carries his seed, in order to sow it.

SEEING, a term used by horse-dealers to imply the times when a horse begins to have white eye-brows; that is, when there grows on that part about the breadth of a farthing, a parcel of white hair, mixed with those of his natural colour. This is a mark of oldage, a horse never seeing before he is fourteen, and always before he is sixteen years old.

SELANDERS. See SALENDERS.

SEMBRADOR, an instrument used in Spain for sowing corn. *See the article* **DRILL-PLOUGH**.

SEMIFISTULAR Flowers, are those whose upper part resembles a pipe cut off obliquely.

SEMIFLOSCULOUS Flowers, are those whose petals are hollow in the lower part; but in their upper flat, and continued in the shape of a tongue.

SERVANTS. Mr. Marshall, in his Minutes of Agriculture, says, that on the maturest calculation, he found the yearly expence of a man servant in the house to be 35*l.* and that of a boy 23*l.* supposing the man's yearly wages to be 10*l.* and the boy's 3*l.* Now the expence of a day-labouring man for a whole year, (if he works every day) is but 27*l.* 10*s.* which is 7*l.* 10*s.* difference against keeping a man in the house by the year. But that of a boy is still more in proportion, viz. the expence of a day-labouring boy for a whole year, (if he works every day) is but 7*l.* 10*s.* which makes a difference of 10*l.* more than $\frac{3}{4}$ of a boy's day-wages. In the above account, no deduction in the daily pay is made for rainy days. The impropriety, therefore of keeping plough-boys in the house is very visible: and though it may be convenient to have the carters about the house, the conveniency is not worth 7*l.* 10*s.* a year. Mr. Marshall therefore recommends putting a woman into a cottage, within about two hundred paces of the farm yard, to take in lodgers; and to keep in the house no more farming servants than a butler and a yard-man. Indeed he says it is absolutely necessary to have somebody about a farm-yard, in cases of emergency; but the above two are sufficient, as the carters in the adjoining cottage will be nearly as handy as if they were in the house. (This measure like many others is merely local, but the hint is universal.)

Perhaps the farmer who keeps no accounts, imagines he saves money by boarding his servants in the house; but if he keeps them in the luxurious manner which farming-servants in general expect to be kept, he will be mistaken. A farmer, indeed, who sits at the head of his kitchen-table, may no doubt feed his men considerably cheaper, than a person who eats in a separate apartment. It is a just observation, that one fed by his master costs the community as much as two who provide for themselves; for discharge a grumbler, one who pretends to be dissatisfied, though in fact only satiated, and he will return to his bread and cheese with, perhaps, equal health and equal happiness. He sits down to his master's table with a resolution to eat voraciously of the best, to do himself justice; but at his own table, eats sparingly of the meanest, to save his money. His motive in both cases is the same: self-interest.

Mr. Marshall observes, that in some counties, particularly in Surry, it is an established custom for every man, in harvest, to work by the acre, or by the month, not by the day. If a labourer be constantly employed through the year, he expects during harvest to be constantly employed in mowing, reaping, &c. by the acre, or to have his harvest-month; that is to have an advance of wages certain, wet or dry, during one month; which month commences when it best suits his employer. This Mr. Marshall says is very convenient; they are always at command, in cases of emergency; and nothing but a continuance of rains while the barns are empty can make them burdensome. He strongly recommends the employing of active young men; for one invalid or sluggish fellow will spoil the whole set; and this holds generally. Mix two or three old women, or two or three boys, with a company of men, and the effect will be very soon visible; for the men will soon conform to the ways of either the old women or the playfulness of the boys. It is not prudent to employ many women with the men; and nothing but necessity can excuse it. Two women after the first or second day, will do as much work as half a dozen alone. If it be necessary or convenient to employ a number of both men and women, it is but common good management to keep them separate; with this exception, which may be laid down as a maxim, viz. one man among women, and one woman among men. A crusty conceited old fellow will check the gossiping of the women, and it has been remarked that raking after a young wench has animated more than a gallon of ale. Two are dangerous; they breed contention, and rather retard than accelerate. The most valuable servant in harvest is a good carter. It is necessary to common management that it should be able, willing, and careful. Every pitch of hay and corn, generally speaking, passes twice through his hands; he loads and unloads, which are the two most labourious tasks of harvest; he drives the team backwards and forwards; if he loiters by the way, the field-

men or stackmen must stand idle; if he spill or overturn his load, or if he breaks his waggon, or set his horses, the arrangement of the day is broken; and, perhaps, the damage done by the loss of time rendered irreparable by the next day's rain. A good carter will not suffer his waggon to be overloaded. The fieldmen too, that is the pitchers and assistant loader, should be young and active, and well matched with the carter.

SETTER, a kind of seton or issue, made by cutting a hole in the dewlap of an ox or cow, and putting into the wound a sort of tent formed out of the root of hellebore, by which the ill humours vent themselves.

To SEW, or go SEW, to go dry; spoken of a cow.

SHAKING, a disease incident to sheep, consisting of a weakness in their hinder quarters, so that they cannot rise up when they are down. No cure is yet known for it.

SHARD, a fragment of an earthen vessel.

SHARE of a plough, that part which cuts the ground, the extremity forward being covered with a sharp-pointed iron, called the point of the share: and the end of the wood behind, the tail of the share. *See the article* **PLOUGH**.

The length of the whole share from point to tail, according to Tull, should be three feet nine inches; at the top of the iron it has an upright piece called the fin; and near the iron at the other end, there is an oblong squared hollow, called the socket, the use of which is to receive the bottom of the sheat. Near the tail there is a thin plate of iron, well rivetted to the wood; by means of this plate, the tail of the share is held firmly to the hinder sheet of the plough by a small iron pin, with a screw at the end, and a nut screwed on it, on the inner or right side of the sheet.

The point of the share is that part in which it does not run up to the fin; this point is generally made three inches and a half in length, and should be flat underneath, and round at the top, and the lower part of it must be of hard steel. The edge of the fin should also be well steeled, and should make an acute angle with the share.

The socket is a sort of mortise: it should be a foot long, and about two inches deep: the fore-end of it must not be perpendicular, but oblique, conformable to the end of the sheat which enters into it. The upper edge of the fore-part must be always made to bear against the sheat; but if this end of the socket should not be quite so oblique as the sheat, it may be helped by paring off a small part of the wood at the point.

SHAW, a wood that encompasses a close.

SHAWLE, a shovel used in winnowing corn.

SHEARING of sheep, the operation of cutting off the fleece or coat of wool with a pair of shears. *See the article* **SHEEP**.

SHEAT of a Plough, that part of the plough which passes through the beam, and is fastened to the share.

The sheat, or as it is sometimes called, the fore-sheat, there being another piece of timber behind it called the hinder-sheat, should be seven inches wide, and fastened to the beam by a retch (a piece of iron with two legs), and by a wedge driven by it into the hole of the beam. The angle contained between the sheat and the beam of the plough should be about forty-two degrees.

SHEAVES, bundles of corn bound up in the field. *See the article* **HARVEST**.

SHED, a slight temporary covering.

SHEDDING of the seed, in horses, proceeds sometimes from the abundance and rankness of it, and also from strains, or being over-loaded, and sometimes from an infirmity in the stones and seed-vessels not being able to retain the seed till it be digested and thickened.

When there is a discharge of seed dribbling frequently from the yard, plunge him every morning into cold water, and give him the following ball every night and morning:

Take Venice turpentine, one ounce; make it into a ball with a sufficient quantity of a bole armoniac.

If this suffice not, and ulcers in the urethra are suspected, inject a little of the following up into it, two or three times a day:

Take balsam capivi, one ounce, dissolve it with the yolk of an egg, then gradually add to it a pint of lime-water.

Some colts get a habit of rubbing their yard against their belly until they shed their seed; for this there is no cure but castrating.

Or take a pound of Venice or common turpentine, and the same quantity of bole armoniac finely powdered, and as much wheat flour as will suffice to make it up into a stiff paste; roll it out between your two hands, and break it off about the quantity of a small wash-ball, and give the horse three of them morning and evening, upon the end of a stick, or in a horn full of strong beer, till the flux of seed stop, which will be effected once in ten days, or at most in a fortnight: but before you give him the balls, it will be proper to purge his reins very well, for this will not hasten, but perfect the cure.

For the shedding of seed, or colt evil; mix Venice turpentine and sugar together, and give the horse every morning a ball, until the flux be stopped.

If you add a little of the inner bark of oak, or the powder of an acorn, they will be very good.

This distemper happens commonly in August, and in very hot weather in May.

For the cure, take the powder of aniseeds and leaves of betony in equal proportion; stamp them with white wine, till they come to be a very thick paste; anoint the part with this, and it will cure that imperfection in the yard of the colt.

SHEEP, *ovis*, in zoology, a well known species of cattle, and which are kept at the least expence of any to the farmer. They will thrive upon almost any ground, and for that reason are preferred by many before the larger cattle.

The best sort of sheep for fine wool are those bred in Herefordshire and Worcestershire, but they are small and black-faced, and bear but a small quantity.

Warwick, Leicester, Buckingham, and Northamptonshire, breed a large-boned sheep, of the best shape, and deepest wool we have got. The marshes of Lincolnshire breed a very large kind of sheep, but their wool is not good, unless the breed be mended by bringing in sheep of other countries among them, which is a scheme of late very profitably followed there.

The northern counties in general breed sheep with long, but hairy wool: and Wales breed a small hardy kind of sheep which has the best tasted flesh, but the worst wool of all.

The farmer should always buy his sheep from a worse land than his own, and they should be big-boned, and have a long greasy wool curling close and well. These sheep always breed the finest wool, and also are the most approved of by the butcher for sale in the market.

For the choice of sheep to breed, the ram must be young, and his skin of the same colour with his wool, for the lambs will be of the same colour with his skin. He should have a large long body, a broad fore-head, round and well rising large eyes, and straight and short nostrils. The polled sheep, that is, those which have no horns, are found to be the best breeders. The ewe should have a broad back, a large bending neck, but short; clean and nimble legs, and a thick deep wool covering her all over. To know whether they be sound or not, the farmer should examine the wool that none of it be wanting, and see that the gums be red, the teeth white and even, and the brisket-skin red, the wool firm, the breath sweet, and the feet not hot. Two years old is the best time for beginning to breed, and their first lambs should not be kept too long, to weaken them by suckling, but be sold as soon as conveniently may be. They will breed advantageously till they are seven years old.

The farmers have a method of knowing the age of a sheep, as a horse's is known, by the mouth. When a sheep is one shear, as they express it, it has two broad teeth before; when it is two shear, it will have four; when three, six; when four, eight; after this their mouths begin to break. The difference of land makes a very great difference in the sheep.

The fat pastures breed straight tall sheep, and the barren hills and downs breed square short ones: woods and mountains breed tall and slender sheep, but the best of all are those bred upon new ploughed land, and dry grounds. On the contrary, all wet and moist lands are bad for sheep, especially such as are subject to be overflowed, and to have sand and dirt left on them. The salt-marshes are, however, an exception to this general rule, for their saltiness makes

amends for their moisture; any thing of salt, by reason of its drying quality, being of great advantage to sheep.

As to the time of putting rams to the ewes, the farmer must consider at what time of the spring his grass will be fit to maintain them and their lambs, and whether he has turneps to do it till the grass comes; for very often both the ewes and lambs are destroyed by the want of food; or, if this does not happen, if the lambs are only stunted in their growth by it, it is an accident that they never recover. The ewe goes twenty weeks with lamb, and according to this it is easy to calculate the proper time. The best time for them to yearn is in April, unless the owner has very forward grass, or turneps, or the sheep are field sheep, where you have not inclosures to keep them in, then it may be proper they should yearn in January, that the lambs may be strong by May-day, and be able to follow the dam over the fallows and water-furrows; but then the lambs that come so early must have a great deal of care taken of them, and so indeed should all other lambs at their first falling, else, while they are weak, the crows and magpies will peck their eyes out.

When sheep are turned into fields of wheat or rye to feed, it must not be too rank first, for if it be; it generally throws them into scowings. Ewes that are big should be kept but bare, for it is very dangerous to them to be fat at the time of their bringing forth their young. They may be well fed indeed, like cows, a fortnight before hand, to put them in heart. *Mortimer's Husbandry*.

The feeding of sheep with turneps is one great advantage to the farmers, from the crops they raise of them; they soon fatten upon them, but there is some difficulty in getting them to feed on them; the old ones always refuse them at first, and will sometimes fast three or four days, till almost famished; but the young lambs fall to at once.

The common way, in some places, of turning a flock of sheep at large into a field of turneps, is very disadvantageous, for they will thus destroy as many in a fortnight, as would have kept them a whole winter. There are three other ways of feeding them on this food, all of which have their several advantages.

The first way is to divide the land by hurdles, and allow the sheep to come upon such a portion only at a time as they can eat in one day, and to advance the hurdles farther into the ground daily, till all be eaten. This is infinitely better than the former random method, but they never eat them clean even this way, but leave the bottoms and outsides scooped in the ground; the people pull up these indeed with iron crooks, and lay them before the sheep again, but they are commonly so fouled with the creatures dung and urine, and with the dirt from their feet, that they do not care for them; they eat but little of them, and what they do, does not nourish them like the fresh roots.

The second way is by inclosing the sheep in hurdles, as in the former, but in this they pull up all the turneps they suppose the sheep can eat in one day, and daily remove the hurdles over the ground, whence they have pulled up the turneps: by this means there is no waste, and less expence, for a person may in two hours pull up those turneps; the remaining shells of which would have employed three or four labourers a day to get up with their crooks out of ground, trodden hard by the feet of the sheep; and the worst is, that as, in the method of pulling up first, the turneps are eat up clean; in this way, by the hook, they are wasted, the sheep do not eat any great part of them, and when the ground comes to be tilled afterwards for a crop of corn, the fragments of the turneps are seen in such quantities on the surface, that half the crop at least seems to have been wasted.

The third manner is to pull up the turneps, and remove them in a cart or waggon to some other place, spreading them on a fresh place every day; by this means the sheep will eat them up clean, both roots and leaves. The great advantage of this method is, when there is land not far off which wants dung more than that where the turneps grow, which perhaps is also too wet for the sheep in winter, and then the turneps will by the too great moisture and dirt of the soil, sometimes spoil the sheep, and give them the rot. Yet such ground will often bring forth more and larger turneps than dryland: and when they are carried off, and eaten by the sheep on ploughed land in dry weather, and on green sward in wet weather, the sheep will succeed much the better; and the moist soil, where the turneps grow, not being trodden by the sheep will be much fitter for a crop of corn, than if

if they had been fed with the turneps on it. The expence of hurdles and the trouble of moving them is saved in this case, and this will counterbalance at least the expence of pulling the turneps, and carrying them to the places where they are to be eaten. They must always be carried off for oxen. *Tull's Horse-Hoeing Husbandry.*

"It can hardly be doubted, says M. de Buffon, but that those animals which are at present tame and domestic, were formerly wild. Yet the weakness and stupidity of the sheep being considered, and likewise that this defenceless animal cannot save itself by flight; that all carnivorous animals are his enemies, singling it out in preference to others, and devouring it for the fineness of its flesh: at the same time we must remember that this species is not very prolific, and that each individual is but short-lived: when these particulars are considered, we should be inclined to think that from the beginning of things, the sheep has been committed to the care of man; that his protection is necessary to its subsistence, and his care to its multiplying; nor are any defects known to afford wild sheep; but in all places where man does not govern, the lion, the tyger, and the wolf, reign by violence and cruelty; these voracious animals live longer, and multiply much faster than the sheep: and were we even now to forsake the numerous flocks fed in the pastures, and on the hills, they would soon be destroyed before our eyes, and the whole species extirpated by the number and voracious appetites of carnivorous animals.

"Thus it appears that this species is indebted to our assistance and care for its continuance; for it could not subsist of itself. The sheep is absolutely without defence or resource; the weapons of the ram are but weak; his courage nothing more than a petulance, troublesome to others, useless to himself, and destroyed by castration. The wethers are still more timorous than the ewes. It is from fear that they so often assemble in flocks; the least uncommon noise causes them to leap over each other, or gather close together: while this fear is attended with the grossest stupidity: they have not sense to avoid danger: they even appear not to feel their disagreeable situation; they stay wherever they happen to be, whether it rain or snow; and such is their obstinacy, that in order to make them change their place, or follow any road, they must have a leader, trained to walk before them, whose motions they readily follow step by step. This leader himself would stir no more than the rest of the flock, were he not driven by the shepherd, or hunted by the guardian dog, which is taught to protect and defend them; to guide, separate, gather them together, and direct them in their motions.

"Sheep, therefore, of all quadruped animals, are the most stupid, and have the least instinct and contrivance. The goats, which in so many respects resemble them, have much more sagacity: they stand in need of no guide, they shun dangers: new objects soon become familiar to them; whereas the stupid sheep neither shuns nor approaches: though under the greatest want of assistance, they do not approach man so freely as the goat: and what in animals seem the lowest degree either of fear or insensibility, they see their lambs taken away without anger, without resistance, and without expressing their grief by any cry different from their common bleating.

"But this animal, in itself so despicable, so destitute of sentiment and internal qualities, is to man the most valuable; its utility the most immediate and extensive: it alone satisfies wants of the greatest necessity; it furnishes both food and apparel, besides the advantages arising from the skin, milk, tallow, bones, and dung of this creature, to which nature seems to have given nothing as its property; all is to be delivered up to man.

"Love, the most general and active sentiment, is alone able to impart some vivacity to the ram: he becomes wanton, fights, rushes against the other rams, and sometimes even attacks his shepherd; but the ewe, when in heat, seems not at all the more affected, or the more animated; her instinct reaches no farther than not to refuse the ram's approaches; to chuse her food, and know her lamb. The instinct of this animal is the surer, as it is more mechanical; and, if I may be allowed the expression, the more innate. A young lamb will, amidst a numerous flock, find its dam and seize the dug, without ever being mistaken. Sheep are also said to be impressed by modulated sounds, to feed more assiduously, to be in better health, and to fatten sooner by the sound of a pipe; and that they are evidently sensible of the charms

of music. But it is also said, and I believe with more truth, that music rather serves to amuse the shepherd's tedious hours, and that to this supine and solitary life the origin of that science is owing.

"These animals, whose instinct is so simple, are also of a very weak constitution: they cannot bear walking any length of time: travelling exhausts them; running soon puts them out of breath: the scorching rays of the sun hurt them equally with the rain and snow. Their diseases are many, and most of them contagious. The superabundance of their fat often proves fatal to them, and always hinders their fruitfulness; they yearn with difficulty; they frequently cast their lambs, and require more care than any other domestic animal.

"When a ewe is near yearning, she must be separated from the flock, and watched in order to be assisted; the lambs often presents itself a-thwart, or with its feet first; and in this case, without assistance, the ewe's life would be in danger. After yearning, the lamb is raised on his feet; at the same time all the milk in the ewe's udder is milked out, it being vitiated, and very noxious to the lamb, which is kept from sucking till the udder is filled with fresh milk: the lamb is kept warm, and for three or four days shut up with the ewe, that it may learn to know her, during which time the ewe is fed with good hay, barley-meal, or bran mixed with a little salt; and water, whose chill is taken off, and mixed with a little quantity of flour, bean-meal, or ground millet, given her to drink. At the end of four or five days she may be gradually fed like the rest, and sent with the flock, taking care that she be not driven too far, lest her milk be heated. Some time after, when the sucking lamb shall have gathered strength, and begins to play, no farther care is requisite; it may be left to follow its dam to the pastures.

"All the lambs of a weakly appearance are generally disposed of to the butcher; those intended to be kept being the largest, most vigorous, and having the thickest fleece. Lambs of the first yearning are never so good as the following. To bring up lambs yearned in the months of October, November, December, January, and February, they must be kept in the house during the winter, going out only in the morning and evening to suck; but in the beginning of April they may be turned into the open fields. Some time before this, a little grass is daily given them, in order to habituate them by degrees to this new food. They may be weaned at the end of one month; but it is better to delay it for six weeks or two months. White lambs, without spots, are always preferred to the black or mottled; white wool being more valuable than the black or mixed.

"The proper age for castration is at the end of five or six months, or even a little later in spring or autumn, when the weather is mild. This operation is performed by two different methods: the most common is by incision, when the testicles, which are easily separated, are drawn out through the wound: the other is performed without incision, by tying a string very tight round the scrotum above the testicles: for this compression destroys the vessels which supplies them with blood and juices. The lamb, on castration, becomes sickish and dull, so that it would not be improper to give him, for two or three days, a little bran mixed with a small quantity of salt, to prevent a loss of appetite, which this operation often causes.

"At the end of the year, rams, sheep, and wethers lose the two fore-teeth of the lower jaw; and they are known to want the incisive teeth in the upper jaw. At eighteen months the two teeth joining to the former also fall out; and at three years, being all re-placed, they are even and pretty white: but as the creature advances in age they become loose, blunt, and afterwards black. The age of the ram is also known by his horns, which shew themselves in the very first year, and, often at the birth, and continue to grow a ring annually to the very period of life. Though sheeps are often without horns, yet they have bony prominencies in the same places of the head, where the horns of rams appear. Some sheep however have two, and others four horns, five or six inches in length, but less twisted than those of the ram; when there are four, the two outward are shorter than the others.

"The ram is capable of generating at eighteen months, and a ewe may yearn at the end of a year; but it is better to delay it till the ewe be two, and the ram three years old. The produce of these animals, if too early, and even the first,

first, is always weak, and of a bad constitution. One ram will be sufficient for twenty-five or thirty ewes; but he should be remarkable for strength and comeliness. He must also have horns; for some have none, and such, in these climates, are very indifferent. In a good and comely ram, the head must be large and thick, the forehead broad, the eyes large and black, the nose short, the neck thick, the body long and raised, the back and rump broad, the testicles large, and the tail long. The best are white, with a large quantity of wool on the belly, tail, head, and ears, down to the eyes. The best sheep for propagation are those which have most wool, and that close, long, silky, and white; especially if at the same time they have a large body, a thick neck, and a light method of walking. And it has been already observed, that those which were rather lean than fat, bring forth more easily than others.

"The season of the ewe's heat is from the beginning of November to the end of April; but that they may be brought to conceive in any season, by giving them provocative foods, as salt water, and bread of hemp seed. Each ewe is covered three or four times, and then separated from the ram, which always prefers the older sheep, and neglects the younger. In the season of copulation they should not be exposed to the rain or bad weather, wet hindering their retention; and a clap of thunder often produces abortion. A day or two after being covered, they are put again to their common diet, without having any more salt water; the continual use of which, as well as that of hempseed bread, and other hot aliments, would infallibly cause abortion. They go five months and year at the beginning of the sixth; they seldom bring two lambs. In hot climates they year twice a year; but in France, and the colder countries, only once. Some have the ram given to them about the end of July or the beginning of August, in order to have lambs in the month of January; but the ram is given to a much greater number in the months of September, October, and November; and lambs are in great plenty in February, March, and April. They are also to be had in the months of May, June, July, August, and September, there being no scarcity of them but in October, November and December. The ewe yields, during seven or eight months, plenty of milk, which is a good food for children and peasants. It also makes good cheese, especially if mixed with that of cows. The time for milking ewes is immediately on their going out to pasture, or on their return; twice a day in summer, and once in winter.

"Ewes fatten very fast during their pregnancy, as they then eat more than at other times. As they often hurt themselves, and frequently miscarry, so they sometimes become barren; and it is not very extraordinary for them to bring forth monstrous productions. However, when properly tended, they are capable of yearning during their whole life; that is, to the age of ten or twelve years; but generally, when they are turned of seven or eight, they break, and become sickly. A ram lives to twelve or fourteen years; but after eight is no longer fit for propagation: he should then be knit and fattened with the old sheep. The flesh of the ram, though nit and fattened, is but of a bad taste; that of the old ewe flabby and insipid; whereas that of the wether is the most succulent, and the best of all common meats.

"To form a flock, from which a reasonable profit may be expected, sheep and wethers must be purchased, of about eighteen months or two years old; and one shepherd, if careful, and assisted by a good dog, may take care of a hundred. In leading them out to pasture, he should go before them, and accustom them to know his voice to follow him without stopping, or straying among the corn, woods, and fallow lands, where they would do damage. The places that best agree with them are downs and small eminences; low, wet, and marshy grounds should be avoided.

"During the winter, they are fed at home with bran, turneps, hay, straw, lucern, saintfoin, the leaves of elm, ash, &c. They are, however, led out every day, unless the weather be very bad; though it is rather to walk than feed them; and in this inclement season, it is always near ten in the morning before they are led out; and after staying four or five hours, they are watered, and brought back about three in the afternoon; whereas in spring and autumn they are led to the field as soon as the sun has dispersed the frost or humidity on the grass, and continue there till sun-set. It is also sufficient for them in the seasons, to drink once a day, just before they are brought back to the sheep-house,

where they must always find fodder, though in less quantity than in winter. It is only in summer that they are to live entirely on the pastures, whither they are led twice a day, and also made to drink twice. They are led out very early in the morning to feed, as soon as the dew is down, where they continue four or five hours; after which, and being had to the water, they are brought back to the fold, sheep-house, or some other shady place; about three or four o'clock, when the extreme heat begins to abate, they are a second time led to the pasture, where they continue till the evening; and where it not for fear of wolves, they should pass the night in the open air, as they do in England, which would render them more vigorous, clean, and healthy. As too great a heat is remarkably troublesome, and the violence of the sun-beams disorders their heads, and throws them into vertigoes, it is proper to make choice of places shaded from the sun, and in the morning to lead them on eminences exposed to the east, and in the afternoon on those that are exposed to the west, that when they are feeding, their heads may be in the shadow of their body.

Lastly, in order to save their wool, they must not be led through any bushy places.

"In dry and high grounds, especially if the herbage abound in wild thyme, and other odoriferous plants, the mutton is of a much finer quality than that which is fed in moist vallies and low plains; unless these plains be sandy and near the sea, the herbage then being sprinkled with salt; and the sheep are no-where so good as on these salt plains. The ewes also fed in them, yield more milk, and of a better taste. These animals are remarkably fond of salt, and nothing is more healthful when given in moderation; and in some places it is customary to put into the sheep-house a bag of salt, or a saline-stone, which they all greedily lick one after another.

"Every year the stock should be examined, in order to find out such as begin to grow old, and are intended for fattening; for as they require a different management from the others, so they should also be formed into a separate flock. They should be let abroad in summer before sun-rising, in order to feed on the grass while moistened with the dew. Nothing forwards the fattening of wethers more than a great quantity of moisture; and nothing more obstructs it than the heat of the sun; so that about eight or nine in the morning, before the great heat begins, they should be brought back, and salt given them to excite thirst. About four in the afternoon they should be led a second time into cool and moist places; and after two or three months of these little cares, they will have all the appearance of being full of flesh: indeed they are generally fattened as much as they can be; but this fat proceeding only from the great quantity of water they have drank, may be said to be no more than oedema, or bloated humour, which would in a short time turn to the rot, and can be prevented only by killing them while in this state of fatness. Even their flesh, far from being firm and juicy, is extremely insipid and flabby: in order, therefore, to make good flesh, besides letting them feed on the dew, and giving them a great deal of water, they should have, at the same time more succulent food than grass. They may be fattened in every season, by only keeping them apart in a sheep-house, and feeding them with the meal of barley, oats, wheat, beans, &c. mixed with salt, for making them drink more copiously. But in whatever manner, and in whatever season they are fattened, they must be immediately disposed of; for they cannot be fattened, twice, and they will die by diseases of the liver.

"Worms are often found in the livers of animals; and a description of those found in the liver of sheep and oxen, may be seen in the *Journal de Sçavans*, for the year 1668, and *Ephemerides of Germany*, tom. v. 1675, 1676. These worms were thought to be peculiar to ruminant animals; but M. Daubenton has found the very same in the liver of the ass; and it is probable that the like may be found in the liver of other animals: but it is also affirmed, that moths have been found in the liver of sheep." M. Rouille, secretary of state for foreign affairs, was so kind as to communicate to me a letter to him, from a doctor of physic at Montiers, in the duchy of Tarantaise in Savoy, from whence I have made the following extract. "It has for a long time been observed, that the sheep of our Alps, which are the best in all Europe, sometimes fall away surprisingly. Their eyes become white, sunk, and blinded; their blood ferous, with scarce any redness to be seen in it; their tongue dry and shrivelled; their nose stuffed with a yellow, viscid, and putrid mucus; an extreme debility, though they eat

eat a great deal; and, in fine, the whole animal system visibly decaying. After several close enquiries, these animals were found to have in their liver white papilios, with proper wings; their heads of a semi-oval form, bilious, and of the bigness of those belonging to the silk-worm. I have been convinced of the reality of this fact, by squeezing above seventy out of the two lobes; and, at the same time, all the convex part of the liver became lacerated. They have been found in the veins only, without a single instance of their being in the arteries. In the cystic duct small ones have been found, together with small maggots. The vena porta, and the capsula of Douglas, which are visible there as in man, yielded to the softest touch. The lungs and other viscera were found." It were to be wished that the doctor had given us a more circumstantial description of these papilios; that these animals which he saw may not be suspected to be no other than the common worms found in the liver of a sheep, which are very flat and broad, and of so singular a figure, that they would rather be taken for leaves than worms.

"Every year the whole flock, wethers, ewes, and lambs, are sheared. In hot countries, where the creature may without danger be laid bare, the wool is not sheared, but plucked off; and often they yield two fleeces in a year. In France, and the colder climates, it is cut only once a year with large shears, still leaving the sheep part of their fleece, as some defence against the severity of the climate. The season for this operation is in the month of May, after thoroughly washing them, that the wool may be as clean as possible. In the month of April it is too cold, and it is delayed till June or July, the wool would not grow sufficiently during the remainder of the summer, to secure them from the winter's cold. The wethers have generally more wool than the ewes, and it is also better. That of the neck, and the top of the back, is the prime; that of the thighs, tail, belly, throat, &c. is not so good, and worst is that taken from dead beasts, or such as are sick. White wool is also preferred to the grey, brown, and black, as it may be dyed of any colour. Straight wool is better than curled; and it is even said that the wethers whose wool is too much curled, are not in so good a state of health as the others. A considerable advantage may also be drawn from sheep by folding them; that is, by leaving them for a proper time on lands intended for improvement. In order to this, the ground must be inclosed, and the flock shut up in it every night during the summer. By this means the dung, urine, and heat of the body of these creatures, will in a short time bring the ground into heart, whether exhausted, or naturally cold and barren. A hundred sheep will in one summer meliorate eight acres of ground, which will continue its fertility six years.

"We are told by the ancients, that all ruminant animals have suet, though this is strictly true only of the goat and sheep: and that of the sheep is in greater quantity, whiter, drier, finer, and of a better quality than any other. Fat differs from suet, as continuing always soft; whereas suet hardens as it grows cold. It is chiefly about the kidneys that the suet is found; and the left has always more of it than the right. There is also a great deal of it in the caul, and about the intestines; but this suet is far less firm and good than that of the kidneys, the tail, and other parts of the body. Wethers have no other fat than suet; and so predominant is this fat in their constitution, that all the extremities of their flesh are covered with it. Their very blood is not without it; and the seminal lymph is so saturated with it, as to appear of a different consistence from that of other animals. The lymph of the human species, that of the dog, the horse, the ass, and probably of all animals without suet, liquefies by cold, rarefies in the air, and becomes the mere fluid from the time it was ejected from the animal's body. On the contrary, the seminal liquor of the ram, as well as that of the goat, and probably other animals that have suet, instead of rarefying in the air, hardens like suet, and, with its heat, loses all its liquidity. This difference I have perceived by microscopical observations on these seminal lymphs. That of the ram coagulates in a few seconds after its leaving the body, and to perceive the living organical molecule, of which it contains a prodigious quantity, the object plate must be heated, in order to preserve it in a state of fluidity.

"The taste of the flesh, the fineness of the wool, the quantity of the suet, and even the size of these animals, differs very great in different countries. In France they

chiefly abound in the duchy of Berry; those in the neighbourhood of Beauvais, and some other parts of Normandy are the largest, and fullest of suet. In Burgundy they are very good; but the best are those that feed on the sandy coasts of our maritime provinces. The wools of Italy, Spain, and England, are finer than those of France. In Poitou, Provence, the neighbourhood of Bayonne, and some other parts of France, there are sheep which seem to be of a foreign breed; they are stronger, larger, and have a great deal more wool than those of the common breed. These sheep are also more prolific than the other, it being nothing extraordinary with them to have two lambs at a time, and year twice a year. The rams of this breed, engendering with the common ewes, produce an intermediate breed, partaking of the two from whom it proceeds. In Italy and Spain, the number and variety in the breeds of sheep is still greater: but all must be considered as forming one and the same species with our sheep; though this so numerous are diversified species hardly extends beyond Europe. Those long and broad tailed creatures so common in Africa and Asia, and by travellers called Barbary sheep, seem to be of a species different from ours, as well as the American, Vigonia, and Llama.

"White wool being much more esteemed than black, spotted or black lambs, are almost every where sold to the butcher; though in some places the far greater part of the sheep are black; and for black lambs to be produced by a white ram and ewe, is a phenomenon common in every country. In France there are only white, brown, black, and spotted sheep; Spain has dun sheep; in Scotland there are yellow; but all these differences and varieties in colour are no more fortuitous than the differences and varieties of the breeds, which are, however, only owing to the effects of the food, and the difference of the climate." *Buffon's Histoire Naturelle, tom. v.*

The reader is indebted to the ingenious Mr. Irwin for the following observations relating to the management of sheep in Ireland:

"Of all the quadrupeds, says he, the sheep perhaps is the animal best adapted by Providence to pay the rent. It requires great attention to it; but, at the same time, little bodily trouble. The chief care should consist in their cantonment for food, in which our Irish farmers are extremely negligent (I mean those of them that have abilities to be otherwise); for they station them promiscuously over the land, enclosing only the fattening grounds, which is done but badly, and other cattle suffered to mix with them; whereas sheep, in their rearing and fattening state, should be by no means suffered to perambulate a variety of pasture. For this reason,

"Most closes, or inclosed fields, have some herbage, besides the common grass, predominant in them; and where sheep are suffered to run over too many of these at once, the different mixtures in such extensive pastures have, I am convinced, from repeated experimental observations, very unfavourable effects on this tender and delicate animal, both as to the rearing and fattening, or as to bone and growth.

"It actually gives, or inclines them to a *scourer* (and other disorders well known to the shepherds), oftentimes not less prejudicial than that which they never fail getting in low swampy grounds, which always proves mortal to sheep that are suffered to remain ever so short a time in such places; for though the noxious insane effects of such pasture may not immediately appear, or operate on them, it never fails bringing on the rot in the end, which manifests itself by the scower, and other unhealthy symptoms.

"A gentleman in my neighbourhood, who occupies several thousand acres of deep rich soil, suffered a considerable loss of sheep, particularly ewes, in the spring of 1759, (I think it was); and that season was far from being inclement, especially wet, which is the most unfavourable weather to that kind of stock.

"I made close enquiry into the causes of this uncommon mortality; for such it appeared to me at that time.

"The common reasons for this destructive pestilence were indeed given; but from some observations I made from appearances, I did not judge them satisfactory.

"It seemed to me that a too extensive run of over fertile, luxuriant soil, little or no shelter, negligence in folding, and other care not difficult to be taken, but absolutely necessary to the well being of this delicate animal, had brought on a deadly and general rot.

"Many were with difficulty saved, only to languish away, in all probability, the succeeding winter; for though a sheep, the first time it is tainted with the rot, whether in winter or summer, may for that season, with great care and difficulty, be preserved, it nevertheless seldom happens that any amelioration of pasture will make it a long liver; for when it is once touched with this disorder, a cure may (as in many human chronical diseases) be patched up; but it will never get thoroughly clear of it. Hence the generality of our farmers, though they may think otherwise from their practice, appear to me to be in great error in this respect.

"But their stock is commonly too large, and they are continually buying in, or selling out; so that by not keeping them for any length of time, they have not proper opportunities to explore rightly the effects of the causes we are now investigating.

"The largeness of their stock, I say, prevents them from looking minutely into these necessary matters, which is not in general the case in England. Besides, from the great numbers they often times possess, they are so accustomed to losses in this way, and so little attendant to physical causes, that they are things of course with them; neglects I call them, that a little attention would easily remedy, were the flocks never so large: and in this respect indeed it must be admitted, custom erroneously commits too many to the care of one shepherd in a country not yet thoroughly improved.

"Through the laziness or inattention of the herdsman (for careless they almost all are) many casualties they pretend arise from the unimproved state of the farm, and easily impose them as such on their employers, whereas they solely proceed from their own neglect.

"To remove sheep often is an excellent temporary preventative against the rot, and most other disorders incident to them; but to fold them dry a-nights is still more infallible; that is, to keep them from rain; but the largeness of the flocks in Ireland, most people imagine, is an absolute bar against this salutary expedient.

"This is an ill-founded surmise. If they would divide their stock in smaller proportions, that is, to limit their sheep-walks to one or two hundred acres at most, under the care of one man; to allow to these proportions (the land being, we will suppose, of no more than a middling good sort) three sheep *per* acre in summer, and one and a half in winter, in the rearing or breeding way; and to erect on every such farm proportionable shelter-houses to a south, or south-by-east aspect, (but never to the north or west, the winds blowing, especially from the latter point too long and cold) there would not be one third of the annual dearth of sheep there is; and in this computation I fancy the proportion is exceeded.

"Those who hold very extensive tracts, may say this simple expedient is not practicable; but it certainly is, both to the considerable and inconsiderable farmer, even in parts where timber is not easily to be had, which seems to be the chief difficulty. Suppose now (to give a very feasible hint) a house made of turf (if no stone or brick could be conveniently had) one hundred feet long, about fourteen wide, and the wall about five feet high, with four large doors or openings to the aspects before-mentioned; slight and cheap timber girthing, easily carried from afar, would do for this business as well as the best; the thatch, whether straw out of the barn, or stubble, which last is far the best, we know, is of a trifling value in those parts, and ought to be well saved on with ropes, which makes it effectually resist stormy weather; and the erecting the wall of turf, or, which is much better, with clay mortar, well mixed with straw-rubbish, we also know, cannot cost much, where labour is but from a groat to six-pence a day.

"In short, I could erect one of these houses in this manner on every hundred acres, which is the quantity of land that ought to be allowed to each, for fifteen pounds, Irish money, or, at most, twenty. The land, spoiled by digging off the fods, would be soon restored by the treading of the sheep. The hay-yard, of course, to be adjoining this house.

"All the objection I think can be made is, the not being able to move these houses, thereby to ameliorate different spots of the farm, as they do in Switzerland their wooden houses that run on wheels.

"Conveniencies in countries are different: in Switzerland there is plenty of wood; in many parts of Ireland the length and difficulty of carriage renders a sufficiency of it

for this purpose impossible to be had: besides, moving houses, for aught I know, may do well in Switzerland, or in England; but such as I mention would answer extremely well in Ireland.

"In this way I am sensible the winter-mucking would be almost always on one spot; but it would make much dung, which might be removed to great advantage; and if it had not, is it not evident that it would be much more beneficial to lose the night-mucking, during the three or four most inclement months of the year, than treble the worth of it of one's stock? Moreover, I am not clear, but the dung being preserved from the frost would go farther than if scattered by the sheep about the land in hard weather: and though it is much the custom to turn out dung in that season, I am certain, (and many physical causes will demonstrate it) the sooner afterwards it is mixed with the land, the more of its virtue it will retain.

"But before I quit the article of sheep: as I said before, countries and circumstances differ; for though I do not approve of extensive uninclosed pastures in Ireland, it seems in Spain they do well enough: the flocks there are small, as in France; but they have a right of commonage in that country, perhaps not in any other civilised one that we know of.

"There it is a constant practice with the shepherds, soon after shearing time, to set out with their flocks, generally consisting of about a hundred each, and to pass from one province to another, feeding them promiscuously both on ley and corn lands, the meadows, and some other particular enclosed lands, as parks belonging to the nobility, and clergy especially, only excepted.

"These itinerant shepherds often travel three or four hundred miles from their habitation with their small flock: they sometimes take part of their family, a good deal of provisions, a tent, and some well-trained dogs, and are never stopped if they keep the sheep on the open lands, and often do not return home till after lambing-time.

"They generally have one third, or half the profit of the stocks for their hire." *Museum Rusticum*, vol. I. p. 449.

"I think, says another writer in the *Museum Rusticum*, that early shearing should be preferred on many accounts: some defer this work till at or after Midsummer; but this should be avoided, as very bad consequences often ensue. By this late shearing, the maggots have an opportunity of breeding in their skins; and this frets them in such a manner that they often pine away, and lose all their flesh.

"This is easily prevented by early shearing, and therefore if the weather be any thing tolerable, I generally do this work about the middle of May, and sometimes the beginning of that month: by this method the new growth of the wool has time to get a-head, so as to secure the sheep from the attack of the fly. It is true that at this time of the year the weather is often cold, and chilling rains fall which might endanger my new-shorn sheep, was no farther care taken of them: but this danger I always guard against, by washing my sheep, after shearing, with salt-water taken from the Medway: this is of great service in killing any vermin that may harbour close to their skins; and, besides this advantage, the penetrating quality of the salt so warms this animal's mass of blood, that it is a great means of preserving it from many disorders to which it is fatally subject: such as the gripes, scab, red-water, rot, &c. &c. This I say has been my practice ever since I have lived in Kent; but before that time, when I was not within distance of the sea or Medway, to get salt-water from thence, I always made a brine of proper strength with common salt and soft water, and applied it to the same use with equal benefit, though it cost me, to be sure, somewhat more. When my sheep have sores, either by the bite of flies, or by scratching, &c. I find the best remedy to be that which is commonly in use, viz. a little tar applied to the wound: many, if you ask their advice, will, by way of shewing their judgement, prescribe to you complicated mixtures, which have no other merit but being more expensive: but be assured, the more simple the remedy, the speedier the cure.

"Many farmers suffer great losses by buying sheep that are rotten; for which reason, every prudent man should, when he buys a lot of sheep, agree with the seller, that he should warrant them sound for a month at least; this would prevent many heavy losses, and be a means of guarding honest

neft men from being impofed on: If fheep are the leaft inclinable to the rot, the beft remedy is to drive them directly into a dry upland pafture.

"Though I fhear my fheep fooner than moft of my neighbours, I fhould alfo have obferved, that I always fhear my fat wethers firft, as they are beft able to bear the cold; and I referve my poor fheep till laft, as the cold and chilling rains pinch them more than the others." *Mufcum Rufficum*, vol. I. p. 210.

I never ufed, fays Mr. Lifle, "to fhear till the Monday before Midfummer day; but I now (anno 1714) find I was in an error in fo doing; and that, as my keeping is very good, by which means the wool grows the larger, and heats the fheep the more, and their flefhinefs being fuch as to bear the cold the earlier in parting with their fleeces, I ought to begin to fhear the firft week in June; and the fheep would not only thrive much the better, when the load of their wool was gone, but their new wool would alfo have more time to grow againft Wayhill fair, which would make the fheep look more burley." *Lifle's Husbandry*, vol. II. p. 275.

We cannot but in general approve of the early fhearing of fheep, beginning with the fatteft; but no certain day can, with reafon, be fixed for doing this work; for our feafons differ fo much in various years, that next year, in the beginning of May, the weather may be fo warm as to be very proper for the work; and in the following year, the middle of the fame month may, on account of the cold, be too foon to begin. The beft regulator for this work, as well as many others, would be the ftate of vegetation, from repeated obfervation of fome particular tree or plant, on a particular foil and expofure; for to bring plants to a certain ftate, requires always a certain degree of heat, and this is fooner or later, according to the feafon. Every work of husbandry, in fpring at leaft, might be regulated in the fame manner, and that to great advantage, for nature is an unerring guide.

The fheep of the Ardennes, a foreft in Lower Germany, are very where celebrated for the exquisite delicacy of their flefh; and from a particular method of fhearing them, their wool alfo is in no lefs efteem.

"Amidft all the accidents and diftempers to which fheep are liable, feldom any of them are known to die, certain innocent remedies foon reftoring them. I have obferved every where elfe there is a fixed feafon for fhearing fheep; and accordingly I have feen not a few, after being fhorn, fhivering with the fharpnefs of the air; whereas, in the Ardennes, if the month of April or May be too hot or too cold, the fhearing is delayed; and is not often they fet about it before the middle of fummer. If, when bared, they are found to have received any wound in the fhearing, it is rubbed over with a liquid pitch, and all the reft of the body well wafhed with wine or oil.

"In fome part of the Ardennes, the wine is mixed with oil-lees, or an ointment is made of wine, oil, and virgin-wax; and this precaution is faid not only to thicken their wool, but alfo preserves them from fores and the fcab. They are never fheared in the morning, it being a proverb in the country, that wool is to be fheared, as fruits defigned for keeping are to be gathered, when the dew and coolnefs have been exhauled by the heat of the fun. If fheep are fheared when fwetting, the wool, by imbibing the fweat, becomes the fofter and better coloured.

"Sheep are fubject to a kind of diftemper, which within two or three weeks, frequently fweeps away a whole flock; but, to prevent fuch a fatality, the Ardennes fheep, at the beginning of the fpring, have a certain potion given them.

"The flock is firft carefully examined, and the ailing fheep feparated from the found; an excellent method: yet is the Ardennes the only place where I ever faw it praftifed: after this, the juice of wild fage and horehound, well cleaned, is mixed in their drink, and this continued for a fortnight fucceffively. In autumn this medicament is repeated; and thofe which are fick likewise go through the fame courfe during a fortnight, and generally with a very happy effect.

"Upon being feized with the fcab, which the negligence of the fhepherds does but too often occasion, an ointment is prepared for them of the juice of any kind of fage, mixed up to a confiftency with pulverifed cerufs and frefh butter: with this the fheep are rubbed, and, three days after, wafhed with the urine of a fhe-aſs, which cures them.

"If the exceffive heats have fo affected them; that they grow fickly and faint, and even to a total lofs of appetite; the juice of wild beets is mixed in their drink, and endeavours are ufed that they fhould eat them; which if they can be brought to, they are the fooner upon their legs; but if any afthmatic fymptoms appear in the fheep, the tip of their ears is cut off, after which the paunch of a fheep, being thoroughly boiled in wine, a fpoonful of the liquor given to every fheep; and this never fails, in a very little time, to fet them to rights.

"The cough is fo common a diforder among fheep; that one feldom paffes near a flock without hearing it in feveral: yet in the Ardennes it is otherwife; for upon their firft coughing, a radical cure is wrought by fyringing; during fix or eight days, up the fheep's noſtrils, blanchd almonds pounded in wine.

"It fometimes happens that fheep feed in paftures intermixed with noxious herbs, which not feldom occasion their belly to fwell; and this, without a speedy remedy, proves fatal; but, upon the firft appearance of it, they are bled in the lip, and a fpoonful of man's urine adminiftered to them, which makes a perfect cure.

"If along with the grafs they have eaten any worms or leeches, olive-oil, mixed with warm vinegar, is poured down their throats: this not only cures them of the prefent evil, but preserves them from feveral other accidents.

"An abſcefs, or impoffthume, in the fheep, is cut, and falt, well pulverized and burnt with liquid pitch, ftrewed over the incifions.

"In order to make the fheep good nurfes, fo that they may be able plentifully to fuckle two lambs, all they do is to bind dittany (in fome places called pepper-wort) and trefoil to their bellies.

"Upon the lambs being fick, a few ivy-leaves are given them to eat, which after a week fo well reftores them, that they fuck very vigorously." *Mufcum Rufficum*, vol. IV. p. 420.

"There are, fays Mr. Mills, in this kingdom, vaſt tracts of ground, known by the name of Downs, on which are chiefly fed large flocks of fheep. Experience has abundantly evinced, that though the grafs there is naturally fhort, it is an excellent food for fheep; and as the welfare of thefe creatures is of the utmoſt confequence to one of the moſt eſſential branches of the commerce of England, very great caution ſhould be uſed in making any alteration in their diet, till it be well proved, by fair experiments, that a richer pafture does not injure their fleeces. I would therefore recommend, in the ſtrong-eſt manner, to gentlemen who have eſtates bordering on ſuch downs, particularly on that extenſive tract called Salifbury Plain, which reaches from the weſtward of Marlborough to the ſea, to bring ſome of their fheep into rich paftures, of different graſſes, as well natural as artificial, and to keep them there for ſome generations, in order to aſcertain with certainty, what the effect will be.—The word generations, may, perhaps, here terrify at firſt, as implying a long ſpace of time for theſe experiments, thoſe who do not immediately confider in how few years this ſucceſſion may take place.—A lamb reared from its birth on, for inſtance, burnet, will, in two years, bring a lamb, which, in two years more, brings young, and the ſixth year may ſee the third generation: ſo that by the end of ſeven or eight years the fact may be aſcertained.

"If fheep will be equally benefited by richer pafture, then the farther improvement of theſe downs muſt become a matter of great concern, both to individuals and to the public; becauſe, granting that they may be improved with ſafety, the number of our fheep may be greatly increaſed: but if ſuch improvement ſhould be found in the leaſt detrimental to the wool, inſtead of being encouraged, it ſhould be forbidden, even by law." *Mills's Husbandry*, vol. III. p. 379.

Mr. Young, in his *Annals of Agriculture*, vol. IV. inſerts the following:

"I keep a large flock of ewes for breeding, and which are commonable fheep. By an act of parliament which paſſed ſome years ago, I got a claufe into it, to prevent rams being turned on commons after the 20th of Auguſt, my reaſon for it was, that the breed might not be injured by the ewes communicating with paltry rams; and alſo, to prevent the ewes from taking the ram too early. To avoid theſe two evils, the farmers were obliged to take their ewes to pafture and ſtubbles early in September, when our ewes take the ram, which they ought not to do till the end of

October, and then the lambs will be dropped in the beginning of April. The consequence is, that farmers can, by keeping their ewes on the commons with safety from paltry rams, preserve their winter pastures near two months longer, which is of great advantage to their flocks. Before this act passed, I generally lost about 20 lambs in every hundred, by the severe weather and want of grass in February and March; and a lamb once stunted in its growth, like a stunted tree, never comes on well after. On the 25th October, I draw my ewes into flocks of 25 each, and put a ram to each. In a fortnight or three weeks after, they all go together. Thus every ram has his share of ewes without being harassed out of his life, and I lose very few lambs in consequence of it."

In *vol. XIII*, he says that "A farmer, of a considerable lordship in Bohemia, visiting the hot-wells of Carlsbad, related how he preserved his flocks of sheep, from the mortal distemper which raged in the wet year 1769, of which so many perished. His preservative was very simple, and very cheap: he fed them every night, when turned under a shed, cover, or stables, with hashed fodder straw, and eating it greedily they all escaped."

"This verbal information has since been confirmed by a gentleman, Mr. G. of S. a celebrated agriculturist, for his many judicious experiments, in a letter to a friend of his, who consulted him about it."

"Since you are pleased, says he, to inquire after my agronomical trials, to prevent the destruction of sheep, arising from wet damp weather, during their common pasture-walks, they are much at your service; I made them during all those late wet seasons, and have found them undeniably certain, and to be entirely depended on; though ever so cheap and easy. They consist in nothing more but giving the sheep at night, when turned in, some dry chopped barley or oat-straw, for their fodder, which they devour with eagerness. Their nature requires, it seems, and their instinct calls for this corrective, after having been fed all the day long with wet grass; and having gathered too much moisture in their bodies."

"Many shepherds erroneously pretend, that sheep spurn dry provender, after having tasted green vegetables. But it has been observed, that the flocks of such prejudiced shepherds, were the very flocks that suffered most: whereas those, who followed my example never lost a single sheep; though kept all the day long upon none but wet fallow fields."

In *vol. VIII*. of his Annals, he says, "The following record of the profit of sheep, deserves observation."

"Five Norfolk ewes were bought somewhat after Michaelmas 1783, for 16s. a head, and were kept in enclosed fields and pastures of much inferior quality to some. Early in the spring 1784, they produced seven lambs, which were all sold to the butcher in the month of May, for 16s. a head. They shorn in the summer about half a tod of wool, which was sold for 6d. per pound: the five sheep took the ram again, and in the month of August, in the same year, had seven lambs more, which, not long after Michaelmas, made 10s. each. Of the five ewes, four being tolerable meat, were sold at their original price, in the month of October, and the fifth, early in the next spring, fetched a pound. The total produce of these five sheep, in something more than the compass of a year, was 9l. 16s. 6d. and all this upon little more than an acre of ground; so copious and abundant was a crop of clover."

Mr. Marshall, in his Rural Economy of the Midland counties inserts the following:

"The method of destroying maggots, here, is effectual, and, if applied in time, simple and easy. Instead of cutting the wool off the part affected, and scraping off the maggots with the points of the shears, the wool is parted, and the maggots picked out with a knife, or otherwise dislodged, without breaking the coat; and a small quantity of white lead scraped, from a lump, among the wool; which being agitated, the powder is carried evenly down, to the wound. Too much discolours the wool; a little prevents any farther harm from the maggots, that may be left among the wool; driving them away from the wound; and, at the same time, is found to promote its healing. In well shepherded flocks, which are seen regularly twice a day, there is no such thing as a broken coat."

In his Rural Economy of Yorkshire, he says "The common time of putting ewes to the ram, in the Vale, is from old Michaelmas to the latter end of October; bringing them in the latter end of March, or the beginning of

April. In the Morelands, the latter end of November, or beginning of December, is chosen for the time of putting to, in order that the snows may be pretty well over before lambing-time."

"If twin lambs be preferred, the ewes are put to superior keep a few weeks before the ram be admitted. This likewise brings them in nearer together than when they are put to the ram in low condition."

"It is also understood by attentive shepherds, that ewes ought to have an increase of keep a few weeks previous to their lambing; but less judicious sheep-masters think it sufficient to put them into good keep as they drop their lambs."

"This, however, is a very faulty practice. If there be any mystery in the rearing of sheep, it lies in giving the ewes a flush of milk at the time of lambing. This cannot be done without putting them to good keep a fortnight or three weeks before that time. An additional supply of milk cannot be commanded in a few hours. The carcase of the ewe, as well as her udder, may require to be saturated at the time of lambing, lest, in the interim of preparation, the lamb be stunted or starved."

"Another practice to which attentive breeders pay due regard is, that of trimming provincially, docking, breeding-ewes, as early in the spring as the state of the weather will permit. I have seen the bags of ewes (of the modern breed) so heated with the dung and urine which hung about them, as to become chafed to running sores. The bag ought to be trimmed a few weeks before lambing (when the ewes are put to fresh keep), and the tail and buttocks as soon as warm weather come in."

"To render the breeding sheep profitable, much attendance and attention is requisite. A few ewes, therefore, cannot be worth the notice of any man except a small pains-taking farmer, who has little else to attend to. I have seen more labour and attention thrown away upon a score of ewes than their whole produce was worth. A ewe-flock large enough to employ a shepherd, is, in many situations, the most profitable flock."

"The only particular of management which is here entitled to notice is, that of dressing them in autumn with tar and grease, provincially salving; the tar and grease with which they are anointed being aptly enough termed salve."

"How the practice was first introduced into the district under survey does not appear to be at present known, though not of more than fifty years standing. It probably travelled from the north, where I find it is now in use; not from the south, where I have never met with the smallest traces of it."

"The intention of this practice is to kill lice, prevent the scab, and make the wool grow; and another idea, I believe, is, that it fortifies the skin against the severity of the winter's cold."

"Whether it answer all or any of these intentions I will not assert. Whatever may be its effects, it has now been the invariable practice of the district for near half a century. I have not at least met with more than one man who has deviated from it, through principle."

"This deviation, however, is made by one who seldom acts from caprice. He does not wholly deny its use, but thinks its effect is very transient. He has found tobacco-water more effectual against vermin; oil of tar, if cautiously used, a safe and certain remedy of the scab; and is of opinion, that salving is of little if any use to the growth of the wool: he allows that it may increase the weight of the wool in proportion to the quantity of dirt it contracts; but thinks it does not add to the quantity."

"Whether it does or does not may, nevertheless, be a moot point: ointment rubbed on a recent scar of a horse is believed to assist the hair in growing. Pomatum is allowed to encourage the growth of the human hair; and it is probable that salve may have some effect on the growth of wool: the only doubt in my mind is, whether the advantages, upon the whole, are adequate to the expence."

"This is a matter difficult to be ascertained: I can say, that the scab does not appear to be less prevalent in this than in other districts: and it appears probable to me that, notwithstanding the present prevalency of the practice, it will in time wear away. I will, nevertheless, here give a detail of the process; not to prolong its continuance, but to memorize a practice which at present gives cold and dirty employment to thousands, some weeks in every year."

"The mixture, is eight pounds of butter (of the second, third, or fourth quality, *see article DAIRYING*) to one gallon

gallon of tar. The butter being dissolved, the two ingredients are poured into a tub or other vessel, and stirred for some time with a long wooden spatula; agitating them violently, and uniting them intimately together. The general guide is to keep stirring until the butter has regained its stiffness sufficiently to hold the stirring-stick erect in the ointment; which, when quite cool, is of the consistence of butter in warm weather. Some put the tar previously into the salve-tub, and stir that alone until it loses its blackness, acquiring a mellow yellowish hue; then add the dissolved butter, and continue stirring until the stick stand on-end. If the butter be heated too much, it is thought to injure the tar: it should be barely oiled.

"The time of salving is from Michaelmas or Martinmas.

"The method is this: the feet of the sheep being bound, it is laid upon a bier, provincially a creel (about six feet long, two feet wide in the middle, twenty-one inches toward the ends with four legs about two feet long). The falver sits astride of one end of the creel, the shoulder of the sheep resting against his thigh; its head under his arm. He begins the operation by parting, provincially, shedding the wool from the withers to the tail, leaving a straight open shed or cleft in the wool the whole length of the sheep. This cleft ought to be perfectly straight and clear at the bottom; a form which practice only can give it. It is made by taking the wool on each side in the hands and pulling it asunder, forming the cleft with the thumbs. The failure made and the wool pressed down flat on either side with the hands and wrists, the workman takes a piece of ointment the size of a large hazel-nut (from a kind of dish formed out of a block of wood in the shape of a cheese), upon the side of the end of his fore-finger, and applies it to the skin of the sheep; driving it along the bottom of the shed six or eight inches, with a degree of sleight which experience alone can teach: the perfection of the art lies in distributing the ointment evenly, and in applying it entirely to the skin, without fouling the wool, except immediately at the root. One finger-full being expended, another and another is applied, until the whole length of the first shed be finished; when a second cleft is made, about an inch or an inch and a half from the first. In making the second and every succeeding shed, the fingers of one hand are kept in the last-made cleft, by which means an experienced workman is enabled to make the partings exactly parallel with each other. Towards the back of the sheep the sheds are made closer to each other than they are beneath its barrel; where the wool being thinner, the scab is less liable to make its attack.

"Ten or twelve sheep in the middle size are esteemed the day's work of one man. His wages, and board, fifteen to eighteenpence a day."

Mr. Marshall makes the following observation in his *Rural Economy of Norfolk*, "The shepherd telling me that a cutter in the neighbourhood could extract the concealed testicles of ridgil lambs; and he having last year experienced the inconvenience of three or four of these troublesome and dangerous animals, I let him send for him. This morning he has cut three; the whole number, it seems, this year. They are now from six to eight weeks old.

"Having cut off the end of the bag, and drawn the testicle contained in it, he proceeded to take the other out of the side opposite to that on which the palpable testicle lay.

"It increases the difficulty in cutting ridgils, when the palpable testicle has been priorly extracted; as the operator, then, knows not which side to cut on; and is frequently obliged to cut both sides before he finds the concealed testicle.

"The lamb was laid flat on its side, upon the ground; one man holding it by its neck and fore legs; and another stretching it out, by drawing its hind legs back; both of them at the same time pressing their hands hard to the ground; so that the lamb had no liberty to struggle.

"The cutter then clipped off a patch of wool, about the size and shape of a duck's egg, close below the loin, and about half way between the huckle and the short ribs.

"He then made an incision wide enough to admit, freely, his fore-finger; with which he searched for the stone, and presently brought it out; and, disentangling it very dexterously from the film with his knife, drew out the string.

"He immediately sowed up the orifice, and coated over the wound with cart-grease.

"It is remarkable that the concealed testicles all lay

lay on the same side; namely, the right side; the contrary side to that on which females are cut. This made the operation rather awkward to his hand; he nevertheless performed the business so skilfully, and with so much dexterity, that he extracted the two first in a few minutes. But the last was a remarkably difficult case; the testicle being very small, and braced up close to the vertebræ; and it is observable, he could scarcely draw the palpable testicle of this lamb out of its bag: the punishment to the animal seemed full as much in one operation as the other.

"The price of cutting, a shilling a piece.

"The wind being cold, kept them in the house all night; but the cutter, though the wind continued very pinching, thought it proper for them to go out in the day-time for the sake of exercise: they got very stiff for some days, but are now doing very well.

"One of them, nevertheless, is since dead: owing, I apprehend, entirely to their being too much exposed to an unusually piercing easterly wind."

In the same volume, Mr. Marshall gives the following account of a sheepfold.

"This morning, measured a sheepfold, set out for 600 sheep, consisting of ewes, and wethers, and grown lambs.

"It measures eight by five and a half rods, or forty-four square statute rods; which is somewhat more than seven rods to a hundred, or two yards to a sheep.

"By which it appears that one hundred sheep manured seven square rods daily. But the second folding was thinner; suppose nine rods, this is, on a par of the two foldings, eight rods a day each folding.

"The dung could not be worth less than half a crown a load; and the carriage and spreading ten shillings an acre; together, fifty shillings an acre; which quantity of land the hundred sheep teathed twice over in forty days.

"Supposing them to be folded the year round, they would, at this rate, fold nine acres annually; which, at fifty shillings an acre, is 22l. 10s. a hundred, or four shillings and six pence a head.

"In some parts of the island the same quantity of dung would be worth five pounds an acre, which would raise the value of the teathe to nine shillings a head; which, at two pence a head a week, is more than the whole year's keep of the sheep.

"It does not follow, however, that all lands would have received equal benefit with the piece in consideration; which, perhaps, had not been folded upon for many years; perhaps never before, and sheepfold, like other manures, may become less efficacious the longer it is used on a given piece of land.

"1782, August 29. Last autumn, in order to ascertain the proper time of putting ewes to the ram, I made the following experiment:

"The 20th of September put a score of longwooled ewes of different ages to a Leicestershire ram, and a score of Norfolk ewes to a Norfolk ram. Being in rather low condition, few of them took the ram till the beginning of October.

"The 19th of October put twenty-three long-wooled and forty Norfolk ewes to the same rams, keeping the two breeds separate.

"The 20th of November put the same rams to a score of each sort reserved for the purpose.

"The early lambs were much the stoutest and best for stores; and grafs lamb was out of season before the late ones were fit for the knife.

"But the crones which took the ram early were not able to support their lambs in winter: for grafs was scarce, and they could not break turneps.

"Therefore, this year, all the young ewes have been put to the rams a week ago, and all the old ones are intended for the butcher before this year's grafs be gone: for in a country where turneps are the principal spring food, crones appear to be unprofitable stock."

In his *Rural Economy of the Vale of Gloucester*, Mr. Marshall says, "The sheep is a mountain animal. Even in its present cultivated state, hills are its natural element: Uplands (or very sound dry middlelands) are the lowest stage on which sheep can be kept, with any degree of safety to them; or with any degree of certainty to their owner. Vale lands, in general, are, without great caution, certain ruin to both.

"Formerly, some considerable flocks were kept, or attempted to be kept, in this Vale: even breeding flocks were not uncommon in it. But the wet summer of 1782,

swept the country of them. One farmer, who had, for three or four years back, been recruiting his flock, and got it up to eight or nine score, had not, I was informed, in the autumn of 1783, more than three individuals left.

"The low situation of this Vale, the singular retentiveness of its substrata, and the wateriness of its soils, through a want of surface draining, conspire to render it, what, from experience, it is too well known to be, singularly fatal to sheep.

"How unaccountable, then, is the conduct of those, who attempt to keep store flocks in it? Nothing but the common error, which prevades almost every district, that sheep are essential to farming, can account for it.

"At present, however, the Vale, fully convinced of the folly of attempting to keep store flocks, changes its stock of sheep every year.

"This species of stock, now, consists chiefly of ewes, bought in autumn, and having fattened their lambs in the spring, are themselves finished in the course of the ensuing summer.

"The species of sheep used in this practice are mostly the Ryeland, and the Cotswold; both of which are described in the course of this article.

"Some little folding was formerly done in the fallow fields: but all the folding flocks are dead of the rot. What folly! What cruelty to drive this animal from its native heights; and force it into a situation, where it must inevitably become a prey to disease; and at length, (if not released by the humanity of a butcher), fall a victim to folly, by a loathsome, tedious, lingering death.

"In a district so notorious as this for the rotting of sheep, some accurate ideas of this fatal disorder were of course enquired after. An experienced husbandman, on opening a sheep which he had killed for his own family, and finding a collection of water within it, pronounced the rest of his flock to be tainted. Water he has always found to be the first stage of the disorder: a white scum upon the liver the next: the last, flukes. From these circumstances, and from all the observations I have myself been hitherto able to make on this subject, it appears to me probable, that an unnatural redundancy of water, unavoidably taken in with the food, is the cause of the disorder."

The following is a certain cure for the *Red-Water* in sheep and lambs:

Take one pint of new milk; make it warm; and dissolve in it one ounce of allum, and give it as soon as the disorder is discovered, to the sheep. If a lamb, half the quantity will serve: and let the tail be cut off.

In another part of the Rural Economy of the Vale of Gloucester, Mr. Marshall observes, that "Herefordshire has been celebrated, time immemorial, for a peculiar breed of sheep, called the Ryeland breed; from an indeterminate district, in the southern quarter of the county, which goes by the name of Ryeland; on which this breed of sheep are principally reared.

"The Ryeland sheep are remarkable for the sweetness of their mutton; but still more for the fineness of their wool; which may be said to rival that of the growth of Spain. If the Spaniards improved their wool, by any breed of English sheep, it was most probably by that of the Ryeland of Herefordshire; not by that of the Cotswolds of Gloucestershire.

"The Ryelanders are a small, white-faced, hornless breed. Their form (though little attended to) is often beautiful; and their flesh of the finest quality. The ewes run from nine to twelve or fourteen, the wethers from twelve to sixteen or eighteen pounds a quarter.

"In the management of the store-flocks of this breed a striking peculiarity is practised. Instead of folding them in the open field, agreeably to the practice of other districts, they are generally shut up, during the night, in a building, which is provincially termed a cot, and the practice termed coting.

"The cot is generally, I believe, the ground floor of a large building, which is chambered at five or six feet high. The size is, of course, in proportion to that of the flock. From those which I have measured, a yard square to a sheep may be taken as the medium allowance of room. Racks are fixed up against the walls; and, in the larger cots, some of which will hold two hundred sheep; other racks are sus-

pended across the middle of the room, and hoisted as the dung and litter rise.

"Their food in the cot is sometimes hay, and sometimes barley straw; but most commonly peas halm; a food, which, it seems, is particularly affected by sheep: a fact, which the rest of the kingdom does not seem to be fully possessed of. The halm, however, is not, I find, always thrashed clean; the under-ripe pods being frequently left unbroken for the sheep. The stall is strewed about as litter; and the cot cleaned out once or twice a year; or as often as necessity or convenience requires. The manure is esteemed of the first quality.

"The advantages of coting are not spoken of with sufficient clearness to recommend it, without trial on a small scale, to other districts. The advantage generally held out is, that it fines the wool; but discerning men observe that, in the same proportion as it curbs the growth of the wool, it checks the growth of the sheep; being in this effect worse than folding.

"The dung is, no doubt, of great value: and I have been told, by an intelligent husbandman, that cotted sheep never rot; provided they be kept in the cot in the morning, until the dew be off the grass. This accords with the theory we have before mentioned: the warmth of the cot promotes perspiration: the dry food absorbs the superfluous moisture of the stomach; and keeping them from the grass, until the dews be gone off it, is a still further preventive of superfluous moisture. I have, however, heard it intimated, that if ground be given to rot, coting will not, with certainty, prevent it: nevertheless, I am inclined to believe, that coting, properly, would prevent it.

"Ewes, when full with lamb, are seldom, I understand, cotted; but, after lambing, the cot is found highly beneficial to the young lambs; preserving them equally from cold and from vermin.

"The practice of coting has probably arisen in the tender nature of the Ryeland sheep, which cannot stand the fold. Attempts, it seems, have been made to fold them, but always with great injury to the flock. Housing them was, therefore, the only means of collecting their dung, and rendering them most useful in an arable country: besides preserving them from the vermin of the woodlands, with which this district has formerly abounded, and with which it still abounds.

"This breed of sheep appears to be an object worthy of national attention. Large sums are annually paid to Spain for wool. The wool of the Ryeland sheep is used in the same intention as that of Spain. Though not fine enough as an entire substitute for Spanish wool, it supplies its place, I understand, in some degree. In 1783, Ryeland wool was sold for two shillings a pound, when the ordinary wool of the kingdom was not worth more than fourpence a pound. Spanish wool was then three shillings. Ryeland wool cotted and trended, was this year, 1788, sold for near two shillings. This wool appears to have been formerly considered as a national object. It is under the inspection of sworn trenders; who free it from dirt and oil, and make it up in trendles, or round bundles, for sale. Wool thus made up bears a price of about half-a-crown a stone, (of 12½ lb.) more than the wool of the same quality, in its rough state. And Spanish, I understand, is worth about three shillings.

"It is, I believe, an inevitable consequence, that should the supply of Ryeland wool be discontinued, an increased supply of Spanish wool would be necessary. On the contrary, should the internal supply be augmented, the wants from abroad would be diminished proportionably. Should the long woolled breed of sheep, which is now working its way into all quarters of the kingdom, gain a footing, and acquire fashion, in Herefordshire, the Ryeland breed may, in a few years, be irretrievably lost.

"The farmer's object is the aggregate profit of his flock: no matter, to him, whether it arise from wool or carcase: and, if the carcase of the Ryeland sheep had not been of superior value, it is probable the breed would long ago have been extinct. For although the wool of this breed is sold at a high price, the quantity cut, from a given number of sheep, is in the inverse proportion. Cotted sheep seldom, I believe, afford more than a pound and a half each sheep; while from some breeds of the kingdom, seven or eight pounds of wool are cut; worth at present, 1788, 8d. or 9d. a pound, or twice the value of the Ryeland

land coat. The sheep of those breeds are, however, larger, but not in this proportion.

"What I mean to intimate, in this case, is that the continuation of the supply of Ryeland wool is, at present, in a state of uncertainty; and I leave it to those, whose province it more nearly concerns, to devise the proper means of preserving and encreasing the English breed of fine-wooled sheep."

Mr. Young, in his *Annals of Agriculture*, vol. III. inserts the following receipt to cure the scab in sheep, "Break the scab, and wet it with this liquor when the sheep are dry, it cures at one dressing:

"Two pounds of tobacco, half a pound of verdigris, half a pound of flour of brimstone, five gallons of small lees; boil well, and strain off; then add one pint spirit of turpentine."

In vol. III. he says "if the scab is suspected to proceed from poverty of living, to improve their food. To keep them very clean, and fed as much as possible on high and dry ground. To clip the wool off. To brush and wash them. To anoint them with hog's lard or fresh butter. To dress the parts most attacked with this ointment: take of the mercurial ointment $\frac{1}{2}$ lb. oil of laurels 4 ounces, flowers of sulphur 3 ounces, corrosive sublimate in powder very fine $\frac{1}{2}$ ounce, mix well in a mortar; if too thick add a few drops of oil. Thus made, of mercury and hog's lard equal parts, triturate the former, in a mortar, with a little terebinth, till perfectly divided, then add the melted lard, and mix well till cold. And to wash the parts less affected with the following lotion: human urine three pints, cow's milk 1 pint, leaf tobacco 4 ounces, boil 15 or 20 minutes; this will keep seven or eight days in winter, and four in summer; use it hot. If the scabs should still resist, wash them with extract of Saturn, made by boiling 3 lb. of litharge, in powder, in 3 lb of vinegar. Purgatives are sometimes necessary; the following is proper for a sheep: take of aloes 1 gros, tartarized vinegar $\frac{1}{2}$ oz. honey 1 oz. mix. Thus made, take salt of pot ash 2 oz. common water 4 oz. dissolve and filtre. To this alkaline water add vinegar 1 $\frac{1}{2}$ lb.

"The author, who is at the head of the Veterinarian schools of France, appears to have studied cattle, and their distempers, with great attention. He writes with great knowledge and clearness; I do not permit myself to enter into a particular examination of his work, as his experience in this line must be infinitely superior to my own: I have mentioned it to recommend, not criticize it."

SHEEP'S-DUNG. See the article DUNG.

SHEEP'S-fescue-grass, See the article GRASS.

SHEEP-LEASE, *Sheep-slate*, or *Sheep-walk*, pasture-land, appropriated to the feeding of sheep.

SHEER, pure, clean, unmixed.

SHELLS, a hard, and as it were stony covering, with which certain animals are defended, and thence called shell-fish.

The vast beds of fossil shells found at great depths in the earth, as well as those found lying on the sea-shore, make an excellent manure for cold clayey lands. See the article CLAY.

SHELL-TOOTHED HORSE, is one that from four years, to old age, naturally, and without any artifice, bears a mark in all his fore-teeth, and there still keeps that hollow place with a black mark, which we call the eye of a bean, inasmuch that at twelve or fifteen he appears with the mark of a horse that is not yet six.

For in the nippers of other horses, the hollow place is filled, and the mark disappears towards the sixth year, by reason of the wearing of the tooth.

About the same age it is half worn out in the middling teeth, and towards the eighth year it disappears in the corner teeth; but after a shell-toothed horse has marked, he marks still equally in the nippers, the middle, and the corner teeth; which proceeds from this, that having harder teeth than the other horses, his teeth do not wear, and so he does not lose the black spot.

Amongst the Polish, Hungarian, and Croation horses, we find a great many hollow-toothed horses, and generally the mares are more apt to be such than the horses.

SHEPHERD'S-Needle, the name of a plant, so called from the remarkable shape of the seeds, with their appendage, resembling the crane's bill.

SHIPPEN, a cow-house.

SHOEING of horses, the operation of fastening a piece of iron on the bottom part of a horse's hoof.

The affair of shoeing horses, is so important in its con-

sequences, both for the preservation of the foot, the safety of the legs, and the ease of their motion; that we cannot be too attentive to any innovations that may be recommended to us in this respect; we shall therefore give Mr. La Fosse's sentiments on this subject; with such animadversions as have occurred to us.

In order to understand this new method of shoeing, it is necessary first to premise the following observations; and attend to the anatomical plates referred to.

It is most certain, that all horses, except such as have their feet overgrown; or such as may have a particular occasion of being shod, to preserve the sole, may, at any rate, go without shoes; and there are many examples, without mentioning the customs of Arabia or Tartary, of horses who are at daily work, without the least need of ever being shod: but as we employ all our care, and address, to hollow the foot, by paring it even to the quick; and to form an exact fine frog, it becomes absolutely necessary to set shoes on them.

The original design of shoeing horses, was undoubtedly intended as a preservative of the hoof, and a defence of the sole; but no one sure could think it necessary to pare away, what he wanted to preserve by the use of the shoes; because that would be to act contrary to his first principles, and destroy his own work.

This precaution could never be recommended, but in cases where the horny sole is uneven, inasmuch, that the shoe could not bear equally upon it, which would take off from its necessary firmness; in such a case, it may be reasonable, otherwise it would be very absurd.

Let us now observe the going, as well as the external and internal structure of a horse's foot.

The horse then who draws, presses first on the toe, then successively on the sides, to ease the toe; then the horse's heel yields upon the heel of the shoe, from which it immediately rises again.

The saddle, or pack horse, places the toe but lightly, so that the point of support is fixed neither upon the heel or toe, but between both; which is easy to demonstrate anatomically.

Thus the cannon-bone presses on the pastern, this on the coronary, the coronary upon the coffin, or foot-bone, and upon the nut-bone.

By this description of the bones, we may observe two essential things, which lay open the faults in the present method of shoeing, and points out the means of being able to remedy them for the future; one is, that the effort of the weight of a horse, does not bear either upon the toe or heel, but on the middle between both; the other shews, the greater the distance of the sole from the ground, or from whatsoever point of support, the more the pushing the coronary-bone upon the nut-bone will fatigue the nerve, or tendon upon which it rests, by the inordinate distension it undergoes at every step the horse takes.

Thus we see, that by hollowing away the sole in paring, the horse is sustained only upon the walls of the hoof, which having no assistance of support from the horny sole, is immediately worn, and battered by the weight of the horse's body; and the sooner he treads upon any hard substance, the sooner he grows quite lame.

For by the connection, thickness, and flexibility, as well as contexture of the horny sole, it seems to be wholly destined by nature to serve as a cushion to the fleshy sole, and tendon, which rests upon it, in order to break the violent shocks of a pavement, stone, or any kind of stump, or external violence; but by paring it away in the customary manner, the horse loses his defence of nature, against stumps, nails, glass, &c. and thus the fleshy sole becomes easily bruised or wounded.

It is observable, that a horse seldom goes easy, or escapes being soon jaded, if the frog does not bear upon the ground, and it is the only point of support to the tendon; so that if you keep it at any distance from the ground, by paring it away, an inordinate distension will happen to the tendon: which being repeated at every step he goes, fatigues it, and causes an inflammation; whence also relaxations, de-fluxions, and tendinous swellings, especially after long journeys, or hard riding, which are occasioned more by the paring of the sole, than the length of the journey; experience has shewn, that the frog neither suffers, or has shewn the least sign of fatigue, or sensibility, by being thus exposed; and indeed from the structure of it, it is scarce possible; for being of a soft-spongy flexible substance, by its natural elasticity, yields to the weight of the body, the

the instant the horse presses his foot to the ground, and immediately recovers it again; however, there is one case, whereby the frog may occasion lameness, which is when it grows hard or dry; but by taking off the little end of the frog, this disorder is soon remedied.

As the bad consequences of paring away the sole and frog, have been pointed out, and, I think, evidently proved, let us observe now, the ill effects of modern shoeing; for it is upon the form of the shoes, and the manner of setting them on, that not only the preservation of the foot, but also the safety of their legs, and the ease of their motion depends.

In effect, the more easy our shoes set upon us, the more active we are; so a large, long, thick shoe ought to have the same effect upon horses, that wooden shoes have upon us; that is, make them heavy, unwieldy, and hobbling.

A long shoe is not only perfectly useless, but it is even prejudicial; for the horse's heels coming to sink upon those of the shoes, the longer the lever, the greater will be the drag upon the clinches of the nails of the toe; and thus horses will be more apt to strike them off on many occasions; especially when they are apt to over-reach.

The longer the shoe is, and the more it covers the sole, the more liable the horse will be to fall, trip, and hobble in his walk; particularly if he goes on a pavement; because the surface being formed of round parts, and the shoe having a large uniform hard face, he can scarce have above two or three points of support.

It is thought by some, that strong shoe-heels are an ease to the weak heels, and fetlocks of horses; as if the body of the shoe was flexible enough to yield to the horse's heel; and under this notion, they raise the shoe-heel, and leave a vacant space between that and the horse's heel; but the direct contrary happens, for it is the hoof, that, by its flexibility yields to the shoe-heel, which is quite inflexible: the thicker the shoe-heel is, the more subject that of the horse is to meet it, and instead of being eased, the horse's heel becomes more compressed, as if in a constant vice, because it has always the same point of support.

By this means, they deprive them of the liberty of going with ease upon a pavement: because the shoe does not bear upon a level, and produces an effect, like that of a pivot, upon the middle of the shoe-heels, and the vault, or hollow.

To obviate these inconveniencies, M. La Fosse proposes the following method of shoeing; that neither the sole or frog should be pared at all; for neither will ever become too large by its growth; but in proportion as it grows, it will dry, scale, and fall off in flakes; that the edge of the hoof, if thought too long, should be taken down as usual; and then a shoe, in form of a half moon, set on, reaching the middle of the hoof, the heels may be thinned, and the shoes made a little longer for such horses as have weak hoofs.

Eight small nails, made in the old way, that is, having very small heads, are incrustated in the holes, which are made, as the head is, in an oblong form; the figures both of the shoe and nail are to be seen in the plate. This is the whole mystery.

By this method, the sole is preserved, and consequently the foot defended against hard, or sharp bodies, which the horse may chance to tread on; thus inflammations, and dangerous compressions are avoided, and the many inconveniencies already mentioned, from the lodgment of sand, gravel, or stones.

Another advantage arising from this method of shoeing, and preserving the sole, that natural defence against external injuries, is, that in not paring away the sole, nor setting on any more shoe than is necessary to preserve the horny sole; the horse will not be subject to slip, either on the winter's icy pavement, or the dry smooth one of the summer.

For by making a horse walk upon the frog, and partly upon the heel, and the former being strongly rubbed, and pushed against the ground, or pavement, impresses itself, as it were, by the weight of the horse's body, into the inequalities and interstices it happens to meet in its way; by this means, the foot resting on a great many more parts, which mutually ease it, by multiplying the points of support, gives the animal a stronger adherence, and more security upon the place he goes.

By paring away the sole, the air, when it is in this thin

state, penetrates, and dries it to such a degree, that by its contraction, it compresses the fleshy sole, so as to lame the horse.

By this means, also sand, and gravel get in, and are ground between the sole, and shoe; and again between the horse's heel, and those of the shoe; which not readily coming out again, cause compressions, inflammations, &c. which last accidents are very often the effects of a stone's being wedged in between the shoe-heels.

To recapitulate the whole;

The weight of the saddle-horse does not press upon the toe, or heel, but on the middle between both; so that the greater the distance of the sole from the ground, or from whatever point of support, the more the great tendon will be fatigued, by the inordinate distension it undergoes at every step.

The more the sole is covered by the shoe, the more the horse will slip, slide, or fall; because the surface being formed of round parts, and the shoe having a large uniform hard face, he can scarce have above two or three points of support; so that the greater contact the horse's foot has with the ground, the more points are multiplied, and the safer of consequence he goes.

By shoeing, no other intention could be expected, but preserving the hoof, after paring away its luxuriance.

That long shoes, and raising the shoe heel, is a very pernicious custom.

By paring away the horny sole, it hardens in proportion to its being thinned, and by compressing the fleshy sole, makes a horse lame; he loses also the defence of nature against external bodies, by which means, the fleshy sole becomes often wounded, bruised, &c.

By paring the frog so much way, that it is not in contact with the ground, the tendon will be inordinately distended: by which means, it becomes subject to inflammation, relaxation, defluxion and rupture.

Lastly, it appears from the anatomy of the foot, that horses are chiefly lame in those bones and its tendon; that the present method of shoeing contributes greatly thereto, by paring away the horny sole, and hollowing the foot; by which means, the fleshy sole becomes more exposed to accidents, and the tendon fatigued, strained, and ruptured; its support being taken away by paring the frog.

We may learn also from hence, that no more of the toe should be pared away, than to keep the foot uniform with the shoe; that the shoe should be made flat, in order to adapt itself the better to the foot; not made too thick, or hollow, nor projecting beyond the horse's heel.

This is the substance of M. La Fosse's new method of shoeing; which from its simplicity, and the great ease of performing it, seems to demand our regard and attention; but though it appears well calculated for the flat pavements, and roads of France, yet we doubt its general success with us; especially in some of our rough stony countries, where the heel, and frog, being left so entirely defenceless, might be liable to frequent injuries from such irregular loose bodies, as flints, loose stones, &c. We should suspect also its success, on moist, greasy, and slippery soils, or chalks; where the shoe heel, or cramps, seems of great use, to support a horse, by the impression it makes in the surface; how inconvenient soever it may be in other respects: though it must be confessed, from our method of shoeing race-horses, where the whole foot comes into immediate contact with the ground, notwithstanding the course they run over is often very slippery, yet they seldom fall.

But though this method may not be so generally adopted by us, in its utmost extent, for the reasons above given, as well as from the different texture of the horse's feet, which in some will always demand a particular method of shoeing; yet it undoubtedly may suit many horses, and many different parts of the kingdom; and this particular advantage every one may reap from it, viz. to pare away as little of the sole and frog as possible, even in the old method of shoeing: the many inconveniences of which, we apprehend, have been sufficiently pointed out, and amply explained; and would, by this means, be in a great measure obviated.

EXPLANATION of fig. 1, 2, 3, 4, Plate XXIV.

Fig. 1. represents the bottom of a horse's foot.

a, a, a, is the horny sole.

b, the frog.

2. The

2. The hoof towards its lower edge, called by the author the wall of the foot.

Fig. 2. shews the horny sole *a*, raised from the fleshy sole *c, c, c*, round which is the enchanelled flesh, 6. placed in the fulcus of the inner surface of the hoof: 5. the horny part of which is soft and white.

Fig. 3. represents the under part of the fleshy sole *a*, raised from the foot-bone, or what Gibson calls the coffin-bone *d, d, d*. *g*, the covering or sheath of the tendo Achillis. 2. The cartilage. 6. The edge of the fleshy sole confined in the furrow of the channelled horny substance. *Bartlett's Farriery, p. 352.*

SHOODS, oat hulls.

SHOVEL, a well known instrument, consisting of a long handle, and a broad blade, with raised edges.

SHOULDER OF A HORSE, is the joint in the fore quarters that joins the end of the shoulder-blade with the extremity of the fore thigh; also that part of his fore-hand that lies between the withers, the fore-thigh, the counter and the ribs.

SHOULDER-PEGGED HORSES, are so called when they are gourdy, stiff, and almost without motion.

A horse charged with shoulders, is a horse that has thick, fleshy, and heavy shoulders.

SHOULDER-SPLAIT, a horse is said to be such when he has given his shoulders such a violent shock, as to dis-joint the shoulder-bone from the body.

SHOULDERS OF A HORSE, should be sharp and narrow at the withers, of a middle size, flat, and but little flesh upon them; for if he be charged with shoulders, he will not only be heavy on the hand, and soon weary, but trip and stumble every minute, especially if with such shoulders his neck be thick and large.

Some saddle-horses, on the contrary, are too small in the shoulders; that is, when their breasts are so narrow that their fore-thighs do almost touch: such horses are of little value, because they have a weak fore-hand, and are apt to cut by crossing their legs, and carry them so confusedly in galloping that they are subject to fall.

The shoulders of a well shaped horse are compared to those of a hare, and the distance between them should be little more than half the breadth of his hind-quarters.

SHOULDER-PIGHT IN A HORSE, is a malady, being the displacing of the point of the shoulder by some great fall, rack, or pain, which may be known by one shoulder-point's sticking out farther than its fellow, and also he will halt downright.

As for the cure, swim the horse up and down in deep water a dozen times, which will cause the joint to go back into its right place again.

Then take two pins of assiwood, about the bigness of a finger, about five inches long, and sharp-pointed; slit the skin an inch above and beneath the point of the shoulder, and from above thrust one of these pins downwards, so that both the ends may equally stick within the skin: but if the wooden pin will not pass through easily, you may first make way for it with an iron pin.

When you have done this, make two other holes cross to the first, so that the other pin may cross the first right in the midst, with a right cross, and the first pin should be somewhat flat in the midst, to the end that the other being round, may press the better without stop, and close more exactly together.

Then take a piece of a line, a little bigger than a whip-cord, and make a loop at one end, which being put over one of the ends of one of the pins, so that it may lie between the pin's end and the skin; fasten this last end with your packthread to the rest of the cord, so that it may not slip; both the pins and the cord should be first anointed with hog's grease.

Then bring the horse into the stable, and let him rest for nine to ten days, but let him lie down as little as may be: put a pattern shoe on the fore-leg, and after nine or ten days, anoint the fore place with a little dialthæa, or hog's grease, so turn him out to grass, and let him run there till the pins are rotted off; if he be worked in a cart after the end of a month, it will settle his shoulder the better, and make him the fitter for riding. *See STRAITS.*

SHOULDER PINCING, a misfortune that befalls a horse by labouring or straining when too young, or by being over-loaded.

This malady may be known by the narrowness of his breast, and by the consumption of the flesh of the shoulders, inasmuch that the fore-part of the shoulder-bone will

stick out and be higher than the flesh; and if it be of a very long standing, the horse will be very hollow upon the brisket, towards the arm-holes, and go wider beneath the feet than above the knee.

For the cure: give him a slit with a sharp knife an inch long, upon both sides, an inch under the shoulder-bone; when it is done, with a large quill into the slit, blow up first one shoulder, put then another, as big as possibly you can, and even up to the withers, and with your hands strike the wind equally into every part of the shoulders, and when they are both full, beat all the wind places with an hazle wand, over all the shoulder; after that, with a flat iron slice, loosen the skin within from the flesh.

Then rowel the two slits or cuts with two round rowels made of the upper leather of an old shoe, with an hole in the midst, that the corruption may run out; let the rowels be three inches broad, and put in flat and plain within the cut; this may be as large as you think fit to lay the same open.

SHOULDER-SPLAITING, or SHOULDER-TORN, a malady that may befall a horse by some dangerous sliding, either at home or abroad, by which the shoulder is parted from the breast, and so leaves an open rift, not in the skin but in the flesh, and the film next under the skin, which renders the horse so lame that he is not able to go; and it may be known by his trailing his legs after him in going.

For the cure: put a pair of strait pasterns on his feet, and keep him in the stable without disturbing him. Then take a pint of salad oil, one pound of dialthæa, half a pound of oil of bays, and as much fresh butter, which melt all together in a pipkin; and with this anoint the part, and also round about the sides of the shoulder; this will cause both the said places and all the shoulder to swell in two or three days time; then prick all the swollen parts with a hamet, or fleam, or a sharp hot iron, and anoint the parts with the before-mentioned ointment.

But if it still continues to swell and gather to a head, you must lance it where the swelling gathers most, and feel the softest under your finger, and tent it with green ointment.

SHOULDER-WRENCH, a misfortune that befalls horses several ways, sometimes by turning and stopping too suddenly upon some uneven ground, sometimes by running too hastily out at some door: at other times by slipping or sliding either in the stable or abroad, and by several others.

The best receipt for the cure of it, is to take up the horse's sound leg before, to double it backwards in the joint, and so tie it with a list, or some soft thing, so fast that it will not untie; and then to force him to go upon his three other legs till he sweats at the roots of his ears, flanks, and between his legs; then untie his leg and let it down, and this will cause the blood to descend into the plate-vein, that it will be more visibly seen when it is tied up; but if it does not appear so plain as you would have it, wet it with warm water with your hands, and stroke it downwards towards the place where you are to let him bleed, and this will cause it to appear more visibly.

Then tie up his leg again, and bleed him in the common bleeding place, between his chest and lame leg, taking away two quarts or more, according as the strain is great or small: save a quart of the blood, and put a handful of salt in it, stirring it while it is running, that it may not clod; and when he has done bleeding, and you have pinned up the mouth of the plate-vein with a leaden pin or needle, to prevent it from bleeding, and bound some hairs of the main or tail about the pin, to keep it fast and steady, till a day or two after that you take it out, smear him with the blood; but before you pin him up, anoint him all over the shoulder and breast, between his legs, and down to his knee, with oil of turpentine and strong beer or ale; in equal parts, shaken and mingled together very well in a glass vial, clapping and dabbing it well with your hand; then smear all the said places anointed, with the blood and salt, chasing and dabbing this also very well with your hand; then set him up to his meat, and with a list, or garter, tie both legs together as close as you can; then the next day untie him and walk him out, and if you find that he goes pretty well, ride him gently about a mile; and then set him up again, tying his fore-feet together as before.

But if he does not go well the first day, do not ride him, but only walk him the second; and the third day, after his dressing, do not only tie his legs, but put a flat stick on both sides, like a wedge, about the bigness of a six-pence; drive this between the toe of the shoe and the toe of his foot, fast, so that it may not come out; and always while he stands still in the stable, tie his legs close, and peg him

with the wedge ; and when you take him out to walk or ride, untie his legs and take out the wedge.

Do this every night and morning until he is cured, which will be in a few days, if the hurt has been newly received.

The Sieur de Soleysel, and others, prescribe the following medicine for these maladies :

Take half a pound of new wax, the same quantity of rosin, pitch, and common turpentine ; a pound of oil of olives, two pounds and a half of capon's grease, the same quantity of badger's, horse's, and mule's, and of the marrow of a stag : oil of turpentine, two ounces ; castor, worms, camomile, St. John's wort, linseed, and of foxes fat, two ounces : set the olive oil in a basin over a clear fire, with the wax, rosin, and pitch pounded together, stirring them over the flame till they are dissolved ; then add the fats and stag's marrow, and then the turpentine, and let the whole incorporate over a gentle fire.

Then pour in the oils, and keep stirring them for half a quarter of an hour ; then take it off the fire, continuing to stir it till it is cold.

When you apply this ointment, rub the affected part with a wisp of straw, and having warmed your hand, chafe in the ointment as hot as the horse and your hand is able to bear it, holding a hot fire-shovel near the part to cause it to penetrate : repeat this once in two days.

SHOWEL, a blind for a cow's eyes.

SHROUD, a shelter or harbour.

SHUCK, a hulk or shell.

SICKLE, a toothed hook, with which corn is reaped.

SIEVE, hair, lawn, or basket work, strained on a hoop, for separating the flour from the bran, the dust from corn, &c.

SIG, urine, chamber-lie.

SIGNS OF SICKNESS IN HORSES. The first sign of a horse's indisposition, is, his loathing his food ; then it must be observed, whether he hath a wild and haggard look, for the eye of an horse is, as it were, a glass, through which you may discern the inward disposition of his body ; observe likewise, whether his ears be cold, his mouth hot and foaming, or clammy, the hair of his flanks rough and staring, and paler than usual about the ends ; his dung hard or black, or greenish, and his urine clear and undigested like water.

In this case his eyes are subject to weep, his head heavy and hanging down ; he is apt to stumble as he walks ; he is slow and dull, though he was vigorous before ; he never minds other horses ; contrary to his former custom, he rises and lies down often in the stable, looking towards his flanks, which are doubled and folded in ; his heart beats, which may be perceived, by laying your open hands between the shoulder and sangle, on the left side ; and he is also indifferent and unconcerned at what is done to him.

The Sieur de Soleysel observes, when a horse has been long sick, stales without striding, and even without thrusting forth his yard, letting the water drop from the skin or sheath, it almost always portends death, unless in such horses as have that custom when they are in health ; in which case, you must draw no conjectures from this sign, though they continue to stale after the same manner during their sickness.

Another no less fatal sign is, when the hair of his tail, and on his skull, can be easily plucked off.

It is a dangerous sign, when a horse either never lies down, or starts up immediately, not being able to breathe freely in a lying posture ; whereas, if in the declension of this disease he lie down, and continue long in this posture, it is a very good sign.

When a sick horse turns up the whites of his eyes, you may conclude that he is in pain, and that his disease is of long continuance.

From these signs, you may conjecture in general, that your horse is sick, and afterwards you must endeavour to discover his particular distemper, that you may be able to apply suitable remedies ; for a disease that is known is half cured.

But to be more particular : heaviness of the countenance, extreme looseness, or costiveness, shortness of breath, loathing of meat, a rotten cough, slowness of pace, hollowiness of flanks, hanging down of ears, &c. but

especially if an horse, who before was of a chearful countenance, hangs down his head, it is a sign of a fever, head-ach, the staggers, or sore eyes.

If he turns his head backward on the right side to the part aggrieved, it indicates an obstruction in the liver ; but if down to the belly, of the cholic, bots, or worms.

If water run out of his mouth, it is a sign of the staggers, or wet cough.

The hollowiness of a horse's temples, is a sign either of the strangles, or old age.

A swelling about the ears indicates the poll-evil ; if it be under them, it is a sign of the vives ; and in the mouth, of the canker, flaps, or lampers.

If he has a stinking breath, or foul matter issues from his nostrils, it is an indication that he has an ulcer in his nose or head ; if the matter be black, it is a sign of the mourning of the chine, or the like ; and if white, of the glanders ; if yellow, it shews a consumption of the liver, and rottenness of the lungs.

If his breath or body be hot, they indicate a fever and heat of the stomach ; when a horse's tongue hangs out and is swelled, it indicates the stronger that his liver is inflamed ; if besides he forsakes his meat, that he has either the dry or moist yellows.

Shortness of breath, and beating of the flanks, indicate a fever, or the strangles ; but if the passage of his throat be stopped, it is a sign that the film of the lungs is broken and the spleen is troubled, or else that he is broken winded.

If a horse eats and drinks little, it is a sign of a cold liver ; but if he covets to drink much, and eats a little, it is either a sign of a fever, rotten lungs, heat in the stomach, heat in the liver, or the dry yellows.

If there be a swelling under his throat, an indication of the glanders ; if about the roots of the tongue, of the strangles ; but if there be nothing but little knobs, like wax kernels, they indicate no more than that he has a cold.

Coughing, or an offering to cough, is a sign of the glanders, or a wet or dry cough, or a consumption, or foundering of the body.

If a horse be scabby, and ulcerous all over his body, and about the neck, it is a plain indication that he has the mange ; an ulcer full of knots, creeping about the veins, shews the farcy : if it spread abroad only in one place, it is a canker ; when hollow and crooked, a fistula ; but if it be a spongy wart, full of blood, it is an anbury.

A swelling on the left side, is an indication of a sick spleen ; in the flank, of a cholic ; but if in the belly and legs, of the dropsy.

The hollowiness of the back is an indication of the dry malady of the dropsy.

Staring of the hair indicates a bad stomach, or a foundering in the body ; but generally a cold, or want of cloathing.

Leanness and gauntness indicate him to be hide-bound, in a consumption, that he is troubled with a dry malady, inflammation of the liver, foundering in the body, worms, cholic, or the yellows.

Staling with pain shews foundering in the body, the stone or wind cholic ; and if his urine be blackish and thick, a pain in the kidneys ; but if yellow, the glanders.

Trembling is an indication of a fever, or of foundering in the body ; and if a horse trembles after drinking, it shows he has an ague fit upon him, and he will afterwards glow, and sometimes he will sweat afterwards.

Laxativeness, or looseness of body, is an indication of the heat of the liver ; and on the contrary, costiveness indicates the dry yellows, or diseases of the gall.

If a horse strikes at his belly with his foot, it is a sign of the cholic ; but if in striking he fikes his tail also, then either bots or worms are indicated.

If a horse lie much on his left side, it is a sign of the spleen ; and if on the right side, of the heat of the liver ; and if he be restless, it is probable it may be caused by bots and worms, cholic or griping in the belly ; but if he spreads himself abroad, it indicates the dropsy ; and if he groans when he is down, it betokens a sick spleen, moist yellows, bots, or film broken ; but if he is not able to rise when he is down, it is a sign either of a mortal weakness, or foundering in the body and legs.

Signs may also be taken from the urine of a horse ; these, according to some authors, are accounted not so material and certain as those from the dung are, yet others again say they are more certain. And,

That

"That if a horse in his sickness stales clear, and it being saved and set by, there be no sediment in it, it is an indication of a growing distemper: but if the urine turn of a reddish or yellowish colour, and has either a cloud swimming in it, that is not black or earthy, and a sediment falling to the bottom, and begins to have a rank smell, it shews that the disease is beginning to break; but if the cloud be of an earthy or black colour, cohering in a body without parting, it is a sign that the disease will prove mortal.

"Again, if a horse's urine be different at different times, sometimes giving indications of soundness, and at other times of sickness, it then intimates there is a malignity of the disease, proceeding from an inequality of the composition of the blood, which also causes an inequality in its motion.

"Urine of a yellowish colour, rather thick than thin, of a strong smell, and piercing quality, is reckoned healthful, sound, and good; but, on the contrary, if it be of a deep red tincture, either like or inclining to blood, then the horse has either had too great heats, by being over-ridden, or ridden too early after winter grass.

"If a horse's urine be of a high colour, clear and transparent, like old March beer, it is a sign there is an inflammation in his body, and he has taken a surfeit; if it bear a little cream at the top, it indicates a weakness in the back, or consumption of the feed; but a green one is a kind of a consumption in the body; with bloody strokes, is a sign of an ulcer in the kidneys; and one that is black, thick and cloudy, indicates approaching death.

"The dung of a horse is the best discoverer of his inward parts; the colour or complexion of which ought to be well observed, when he is in best health, and at best feeding; and as he is found to alter, so a judgment is to be made, either of his health or sickness. But to be more particular:

"If his dung be clear, crisp, and of a pale yellowish cast, hanging together, and not separating, more than as it is broke by its own weight in falling, and is neither so thick nor so thin, but that it will flat a little on the ground, and indeed both in scent and substance, resemble the ordure of a sound man, then he is clean, well fed, and without imperfection.

"If again his first and second dung be well coloured, yet fall from him in round knots or pellets, and the rest be good, it is not much matter; for it is only an indication that he has eaten hay lately, and that will always come away first; but if all his dung be alike, then it is a sign of foul feeding, and that he has eaten either too much hay, or too much litter, and too little corn.

"When his dung is in round pellets, and blackish or brown, it is a sign of inward heat in the body; if it be greasy, of foulness, and that the grease is melted, but cannot come away.

"If he voids grease in gross substance with his dung, and it is white and clear, and comes away kindly, he is in no danger; but, on the contrary, if it be yellow or putrified, then it is a sign that the grease has lain long in his body, and, if not prevented, that sickness will ensue.

"Again, if the dung be strong and hard, it indicates that he has had too strong heats, and that he will afterwards be colicive, if it be not prevented; if it be pale and loose, it indicates either inward coldness of body, or too much moist and corrupt feeding; but if the dung is stinking, it shews the heat of the liver: but on the contrary, if it have no smell, the coldness of the liver; but if it be indigested, then it is an indication either of a consumption, or of a dry malady.

"Signs may also be taken from the pulse of a horse, which may be very plainly felt upon his temples, and fore-legs; but as that method has not yet obtained, among the experienced in that way, I shall pass it over.

"But notwithstanding what has been said, in a more particular manner, as to the signs of sickness in horses, it ought to be observed in general, that it is a very difficult task to arrive at any certain knowledge of the diseases of brute beasts, and therefore it ought not to be wondered at, that even farriers themselves are often mistaken, as to the signs, because they can only judge by outward appearances; and especially because there are many diseases that have the same common symptoms; and although a person may by them be assured that a horse has a fever, or a stranguery, yet he can scarcely at the same time be certain,

without a very nice examination, whether he may not have an inflammation in the pleura, or in his kidneys; for the signs that these animals usually give in the affections of particular parts, is their turning their heads towards that part, and indeed that is not always to be depended on; for a horse may turn his head to the right side of his belly, and thereby a person may be mistaken in supposing that distemper to be a diseased liver, as the horse often gives the same sign in the colic."

SIKE, a litterill, a water-furrow, a gutter.

SILVER-WEED, or *Wild Tansey*, a species of cinquefoil, which grows naturally upon cold stiff land in most parts of England, and is a sure mark of the sterility of the soil. Its stalks spread upon the ground, and send out roots from their joints; by which means, and by the frequent sheddings of its seeds, for it flowers during the whole summer, it soon over-runs, and fills the land to a great distance. The leaves of this plant are composed of several lobes or wings, which are generally placed along the mid-rib, and terminated by an odd one: they are jagged at their edges, and are of a silvery colour, especially on their under side. The way to destroy this kind of weed has been already pointed out. Mr. Rays says, that the root of wild tansey, which is somewhat of the parsnip kind, is good to eat, and that hogs are very fond of it.

SIMPSON, groundsel.

SINEW-*Sprung*, is a violent attaint, or over-reach, in which a horse strikes his toe, or hinder-feet, against the sinews of the fore-leg.

For cramps or convulsions in the sinews: these are violent contractions, or drawings together of the limbs, either throughout the whole body, particularly in one limb or member; and proceed from causes either natural or accidental; if from natural causes, they proceed either from too great fulness or emptiness.

When they proceed from fulness, they are caused by a surfeit, either in eating or drinking, or the want of proper evacuation.

When from emptiness, they proceed from too frequent, and too plentiful blood-lettings, or too much and violent purgings, or too hard labour; all which fill the hollowness of the sinews with cold, windy vapour, which are the only great causes of convulsions.

If they proceed from accidental causes, then it is either from some wound received, where a sinew has been half asunder, or only pricked, which presently causes a convulsion all over the body.

The signs of the distemper are, the horse will carry his neck stiff, and will not be able to stir it; his back will rise up like the back of a camel, or like a bended bow; his crupper will shrink inward, his fore-legs will stand close together, and his belly will be clung up to his back-bone; when he lies down he will not be able to rise, especially from the weakness of his hinder limbs.

The cure. First sweat him, either by burying in a horse dunghill, or else by applying hot blankets doubled, about each side of his heart, and body; then after his sweat, anoint his body all over with oil of petroleum, for that is much better than oil of bay, or oil of cypress.

Then give him to drink the following liquor:

Take one dram of assa foetida, with aniseeds, seeds of fenugreek, and cummin seeds, of each half an ounce; put these into a quart of strong white wine, and add to them three or four large spoonfuls of olive oil, taking care to keep him warm after the drink, and to feed him with good bean bread, and warm mashes, made of malt, ground, and warm water; and this will, in a little time, reduce his sinews to their former ability.

But if the convulsion came accidentally, as by the prick, or half cut of a sinew, then search for the wounded sinew, and, with a pair of sheers, clip it asunder, and the convulsion will cease.

But if it be only a cramp, and but in one limb, then rub or chase the grieved part with a hard wisp, or hay-rope, and the pain will cease.

SIT-FAST, a part of a horse's hide turned horny, and which if it cannot be dissolved and softened by rubbing with mercurial ointment, must be cut out, and afterwards healed as a fresh wound. It generally proceeds from a warble. See the article WARBLE.

SIZZING, yeast, or barn.

SKID,

SKID, the chain by which the wheel of a waggon is fastened, so as to prevent its turning round, upon descending a steep hill.

SKILLING, an isle, or hay of a barn.

SLAB, the out-side plank of a piece of timber when sawn into boards.

SLECK, small pit coal.

SLEDGE, common and moulding. See **PLOUGH**.

SMUT, a distemper incident to corn, and which, according to M. Duhamel, may be distinguished by the following marks.

" 1. This distemper destroys entirely the germ and substance of the grain.

" 2. It affects not only the ear, but also, in some degree, the whole plant, when it has made a great progress.

" 3. It very seldom happens but that when one stalk is smutty, all the ears of the other stalks from the same root are so too.

" 4. So early as in March or April, upon opening carefully the hood or blades which cover the ear, and examining the young ear, then not above the sixth part of an inch in length, and almost close to the roots, I found this embryo already black, and attacked with this distemper. Perhaps it may not always seize the plants so early.

" 5. When the distempered ear comes out of its coverings formed by the blades, it looks lank and meagre: the common and immediate coverings of the grains are in this case so very slight and thin, that the black powder is seen through them; and from this time nothing is found, in lieu of grain, but a black powder, which has a fetid smell, and no consistency. As this powder, of which the constituent particles have but very little cohesion, and of which the coverings are destroyed, is easily blown off by wind, or washed away by rain, the husbandman, in housing these plants, houses only skeletons of the ears. If any impression of this powder remains, it is easily taken off by sifting: but I have not experienced it to be contagious, like that of burnt grain.

" M. Tillet, who gained the prize proposed by the Academy at Bourdeaux for the best account of what renders black the mealy substance of grain, has observed that these corrupted ears are often found to be vitiated even in the hood, though this last, looks as green and perfect as if nothing ailed the corn within. The upper part of the stalk of a smutty plant is, not, commonly, quite straight, from within about half an inch below the ear. If such a stalk is squeezed there, it scarcely yields at all to the pressure. If it be cut asunder at about a sixth part, or a quarter of an inch, below the ear, it will be found to be almost entirely filled with pith, in such manner that only a very small opening can be perceived in the heart of this stalk, instead of the large pipe that is in healthy stems. M. Tillet concludes from hence, that the circulation of the juices is obstructed in the upper part of the stalk of smutty plants.

" Bearded wheat is apt to be smutty, as well as that which is not bearded; but neither M. Tillet nor I have ever met with a smutty ear of rye.

" Causes of smut.—The smuttiness of corn cannot be owing to a want of fecundation, as many have hitherto mistakenly imagined; since it affects and destroys the organs of both sexes long before the time of that fecundation.

" It cannot be imputed to the settling of wet upon the ears, or to fogs, or to a violent impression of the sun; since we have seen the ears smutty long before they ceased to be covered with the blades, which continue green till the distemper has made great progress.

" The same observations refute absolutely the opinion of those who suppose the cause of the smut to be in the grains after they are formed, and before they are past their milky state.

" The smut of corn has been also ascribed to the moisture of the earth: but we do not see more smutty plants in the lowest, and consequently wettest parts of a field, than in the highest and most dry. Besides, why should there be a single smutty plant in the midst of numbers of sound ones? However, as it appears that corn is more frequently attacked with this distemper in wet years, than when the seasons are dry, too much moisture may perhaps, without being the immediate cause of the smut, favour its progress more than drought would do.

" Some naturalists have ascribed this distemper to insects. If I am not authorised absolutely to deny this, I can at least assert that, after having been of this opinion for some time,

all my endeavours to establish it by facts have proved ineffectual. Some observers have indeed shewn me different insects in smutty grains; but as I found the very same kinds likewise in sound ears, I believe, with M. Tillet, that they are not in any manner the cause of this distemper. We know that the corn-caterpillar devours the mealy substance of the grain: but it does not occasion smut. Numbers of flies lay their eggs upon these seeds; and the worms and maggots which proceed from them, eat the seeds: but this does not occasion any thing like smut. The Reverend Dr. Hales, to satisfy himself whether the smut of corn might not proceed from the seeds being bruised by the flail, took a number of grains of different sizes, and bruised them with a hammer. They grew well, and bore ears which were not smutty. Thus his own experience convinced this skilful philosopher, that he had conceived a wrong idea of the cause of this distemper.

" Several cultivators have thought that pigeons dung and that of sheep render corn smutty: but this is a groundless notion. We have large pigeon-houses, the dung of which is strewed upon our wheat lands: the same is done with the dung of our sheep, and we even fold our flocks upon those lands: yet we do not find that these fields are more infected with smut than others. This allegation is therefore absolutely destitute of proof.

" Wolfius was of opinion that the smut of corn proceeds from a monstrosity of the embryo: but M. Aimen has refuted that supposition, by shewing that the male flowers of certain kinds of plants are attacked with this distemper: now the flowers have not any embryo.

" M. Aimen, M. D. has very judiciously observed, that the smut of corn cannot derive its origin from a defect in the sap; as all the parts of the plant, except the ear, look healthy, and there are plants whose roots are perennial, which appear vigorous, though their seeds are smutty every year. He is of opinion, that whatever weakens the plant is apt to bring on the smut, and instances, as a proof of this, that it is a frequent custom in his country to cut rye as soon as it spindles, for food for their cattle; and that this rye generally produces other ears, which seldom contain any but distempered grain: to which he adds, that seed-corn which had been pricked or run through with a needle; or which is not thoroughly ripe, and that which produces lateral or second ears, is subject to the smut.

" The same observer, who has made several careful researches into what is properly called the smut of corn, holds that this distemper proceeds from an ulcer which attacks first the parts that sustain the seeds, and afterwards spreads to the rest of the flower. But, some will say, what is the primary cause of that ulcer? In order to discover it, M. Aimen examined several grains of barley with a microscope: some of them were bigger than others; some were very hard; and others yielded to the pressure of his nail: some were of a deeper, and others of a lighter colour; some longer, and others rounder, than they ought to have been: their rind was somewhat wrinkled in several places, whereas in its natural state it is smooth; and lastly, he perceived upon some of them black spots, which, when examined with a magnifying glass, appeared to be covered with mould. These grains were separated carefully, according to their several conditions, and sown apart, though in the same ground. All the mouldy grains produced smutty ears, the shrivelled, the parched, and those that were attacked by insects, either did not grow at all, or did not produce any smut.

" He then singled out a parcel of sound grains, sowed them, and some time after took them up in order to examine them again with a magnifying glass. He found some of them mouldy, replanted them all, and observed that the mouldy grains produced smutty ears.

" M. Aimen, without pretending that this is the only cause of the smut of corn, concludes from these experiments, that mouldiness is a cause of this distemper.

" It is very hard to conceive how mouldiness can produce this distemper; for as soon as the seed has sprouted and produced its plant, the whole substance of the grain is consumed. Whether the hulls or coverings grow mouldy or not, seems to be a circumstance quite immaterial to the plant, which ceases from that time to subsist on what the seed had supplied it with till then. We readily conceive that if this mouldiness attacks the plant, it might either kill it or render it poor and weak: but we cannot imagine how this mouldiness should affect only the organ of

fructification, and entirely destroy them, without doing any visible injury to the other parts of the same plant, even though it be a perennial. However, M. Aimen relates facts; to account for which one might conjecture, supposing the increase of plants to be only an extension of the embryo, that the organs of fructification which exist in imperceptible miniature in the seed, were already affected by the mouldiness before the grains were deposited in the earth. But let us abide by well observed facts: it being of more importance to collect them, than to be in a hurry to explain them by conjectures hitherto attended with little probability.

"Means of preventing this distemper: M. Aimen is of opinion, that to prevent this distemper, the finest and ripest corn should be chosen for seed, that it should be threshed as soon as possible, and that it should be limed immediately after, as well, says he, to keep it from growing mouldy, as to destroy the mould already formed, if any such there be; adding, that every method he has tried to make corn so prepared grow mouldy, has been ineffectual, and that he has never known it produce smutty ears."

According to this principle, the preparations which have been experienced to be serviceable in the case of burnt-grain, and particularly M. Tillet's lye, may be equally beneficial to guard against smut. But we shall not attempt, continues M. Duhamel, to make any addition to M. Aimen's advice, because we have not studied the distemper properly called smut, so much as we have that far more dangerous one which we distinguish by the name of burnt-grain. According to some experiments made by M. Tillet, the black powder of smutty corn does not appear to be contagious. However, we should speak more affirmatively on this point if we had been able to collect a sufficient quantity of that powder: but, as was said before, the wind and rain carry it away, and but very little of it is found in granaries. We exhort those who wish to contribute to the progress of agriculture, to make farther trials, in order to ascertain whether the smut of corn be really contagious or not: but at the same time we caution them to be careful not to confound this distemper with the ustilago, or burnt-ear; for want of which distinction several philosophers have hitherto been misled.

As weak plants are most subject to smut, M. Aimen recommends good tillage, as a sure means of giving them strength and vigour. It is probably for this reason that corn is very smutty when managed according to the New Husbandry.

He observes, that all the lyes generally made use of, preserve the plants from mouldiness; and of all of them, lime seems to him the most effectual.

"M. de Lignerolle says, that the surest means of avoiding smut, and that which he has practised with success ever since the year 1739, on upwards of three hundred acres of land, is to change the seed every year, to be very careful that the seed corn be well dried and thoroughly ripe, and that it be not smutty, nor have any smutty powder sticking to it. He then pours boiling water on quick lime, in a large tub; and after the ebullition is over, as much cold water as there was hot, and stirs it all strongly together, in order to dissolve and thoroughly mix the lime. The quantity of wheat intended to be sowed is sprinkled with this lye, and then well stirred with a shovel, and laid in as high a heap as possible. It is best to keep the grain for a week after this preparation, turning it every day; for otherwise it would heat so as to destroy the germ. By these means he has not had any smut, when the fields around him have been infected with that distemper.

"M. Donat, near Rochelle, thinking the ingredients commonly employed in steeping too dear for the use of farmers, studied for some years to find out something cheaper, easy to be had every where, and therefore better calculated to be of general use. "I have had, says he, in a letter to M. Duhamel, the good fortune to accomplish what I wished, for now I only use pigeons-dung, quick-lime, ashes, and sea-salt; where this last can be conveniently had. I have sometimes made with these ingredients, steeped in water, so strong a liquor, that it has even destroyed the germ of the grain. But there will be no danger of that, if care is taken to observe the following directions, which are the result of seven years successful experience, even at times when farmers who have neglected to follow my example, have had such wretched crops as have not paid the charge of reaping.

"Take quick-lime and pigeons dung, of each twenty-five pounds, forty pounds of wood-ashes, and twenty-five pounds of sea-salt, or salt-petre. Put all these into a tub large enough to hold half a hoghead of common water added to them. Stir them all well with a stick, till the lime is quite dissolved. This lye will keep some time without spoiling. It must be stirred again just before the corn is steeped in it. The grain is then put into a basket, and plunged in the lye, where it remains till it has thoroughly imbibed it; after which it is taken out, and laid in a heap, till it is quite drained of all its moisture: or, which is a still better way, take a mashing-tub, fill it with grain to within four inches of the brim, and then pour in the lye well stirred beforehand. When the tub is full, let the lye run out at the bottom into some other vessel, in order to use it again for more corn. Let the grain be then taken out and laid in a heap to drain; and continue in this manner to steep all your seed-corn. The wheat thus prepared may be sowed the next day, and must not be kept above five or six days, for fear of its heating. This I say from experience. The quantity of lye above prescribed, will serve to prepare more than twenty bushels of wheat.

"Mr. Tull observes, that brining and changing the seed are the general remedies for smut. The former of these, he had heard, was discovered about seventy years before he wrote, by the sowing of some wheat which had been sunk in the sea, and which produced clean corn, when it was a remarkable year for smut all over England: but he afterwards doubts whether this might not happen by its being foreign seed, and therefore a proper change for our soil. He tells us that two farmers, whose lands lay intermixed, used seed of the same growth, from a good change of land, and that the one, who brined his seed, had not any smut, whilst the other, who neglected that precaution, had a very smutty crop. But again he doubts whether this seed might not have been changed the year before, and so might not be greatly infected; or at least not more than the brine and lime might cure. He adds, that smutty seed wheat, though brined, will produce a smutty crop, unless the year prove very favourable; for that favourable years will cure the smut, as unkind ones will cause it: but, above all, he assures us, that the drill-husbandry is the most effectual cure."

"Count Ginanni, a patrician of Ravenna, who has favoured the world with a very accurate and ingenious treatise on the distempers of corn in the blade, deems the rust incurable, after it has once taken place. He has prevented it by sprinkling the plants, before their ears were formed in their hoods, with a solution of sal ammoniac or salt-petre in water mixed with salt of tartar, and with other alkaline substances; but observes that such preparations are too dear for the use of farmers. He thinks, that sowing thin, and keeping the corn quite free from weeds, will generally be a good preservative, as he himself has frequently experienced."

"The smut in wheat, says a writer in the Museum Rusticum, is an evil which has long been complained of, and many methods tried to prevent it, all of which have proved ineffectual, or, at best, but a mitigation of the disease; which methods I need not here enumerate, as they are generally known, or are to be met with in various authors who have wrote on agriculture; some of them being calculated to forward vegetation, and strengthen the plant, such it will be advisable to continue in the practice of.

"But amongst all the authors who have wrote on this subject, I do not remember to have seen one who has pointed out a probable conjecture with respect to the cause of this malady so as to be supported by any tolerable degree of reason. And inasmuch as natural history has been and is my favourite study, (of which I take agriculture and a knowledge of cattle to be no small part), I have frequently employed some leisure hours, to endeavour to assign causes for various diseases, to which the productions of the earth are subject; among which this of smut in wheat is one. And being desirous to improve my knowledge, I am willing to communicate, that if any thing worth notice might come from me, I may have the pleasure of doing something for the public good, and thereby induce others to make their discoveries known, from which myself, as well as many more, may reap some advantage.

"I remember to have read a little treatise, wrote some years since, by James Logan, (chief justice, and president of the council of the province of Pennsylvania) on the generation of plants, containing observations made on the

maize, by which he discovered the plant to be (what Linnæus calls monoecia, or) a plant bearing male and female flowers, and, as such, capable of being impregnated with a fructifying dust from another plant of the like kind.

"I own, the reading this pamphlet first gave me the hint of the generation of vegetables, from which I continued my observations respecting other plants, and among the rest to wheat, and the like; though this is not of the same class with maize, but of the class triandria of Linnæus, and is hermaphrodite, yet, nevertheless, equally subject to be impregnated by dust from another plant, as well as with dust from itself.

"Having frequently observed amongst wheat, while green, (though shot up into spindle) several black, blighted ears, I examined them, and found these were ears in which, by some accident, the intention of nature was prevented; I suppose, by being detained too long in the sheath, and by the natural humidity of the plant, a fermentation was promoted in its ear, destroying the small vessels through which the corns were to receive nourishment; by which means their contents became black, dry, and dusty: these ears, growing up with the others, imbibe moisture sufficient to cause the dusty particles in the grains in them to expand, and burst the fine skin which contained them: being thus set at liberty, the air, if it happens to be a dry season, dries them again; by which means they become light enough to float therein, when separated from the skin which held them. If this happens when the wheat is in blossom, which it often does, part of the dust enters the stigma of healthy corns, and thereby infects them: the pulp in those becoming black, a fermentation is raised therein which destroys the life of the grain thus impregnated; hence the disagreeable smell is acquired peculiar to this disease (the smell in a grain of smut being the same as in a black blighted ear.)

"From hence it is easily accounted for, why, often, a few grains in an ear are smutty, and the others good.

"Some may perhaps object, if this be the case, why are not barley and oats subject to the like disease, since both these are subject to the black blight as well as wheat? Such objectors would do well to observe, that these have a more tough skin than wheat, which does not burst till after the blowing of these sorts of corn is over; therefore, when it does burst, the dust can do no harm.

"Having thus pointed out the cause, I now proceed to prescribe the remedy, which is, when the corn is shot into spindle, and the ears begin to appear, let some persons go along each furrow in the field, and carefully break off all ears of the black kind, (not pull them up, because often from the same root grow several others, which are good and sound ears), and when broke off put them into a bag, and carry them away; for should they be thrown on the ground, there may still be danger of infection from them; as it is possible, there may be some of these diseased ears, which are not bursten, and therefore may escape being gathered, these may be known by the stalks at the neck being crooked, and bent in the length of three or four inches backward, and forward five or six bends, and the sheath nearer to the head of such than the ears which are good.

"The seasons in which wheat is most liable to be smutty are, it is well known, such in which it happens to be dry weather and windy at the time of blowing; but if it happens to be wet during that time, it is very rare to see a smutty ear in a field." *Museum Rusticum*, vol. II. p. 19.

"As the smut in wheat, says another writer in the same work, is an evil greatly complained of, and not without reason, among farmers, I have no doubt but your readers will be well pleased to be informed of a means of preventing the damage which is annually experienced in this respect.

"As I write from experience, what I communicate may be depended on; and I have great foundation for thinking it will be found of particular service to such of your readers as are practical farmers, and who yet are unacquainted with the method I intend to recommend.

"I have for many years past, escaped having smutty crops, by a proper care of the seed-wheat before it is put into the ground; and the method I pursue, though efficacious, is in itself simple and cheap.

"I take four bushels of pigeons dung, which I put into a large tub; on this I pour a sufficient quantity of boiling water; and, mixing them well together, let them stand six hours, till a kind of a strong lye is made, which, at the end

of that time, the grosser matter being subsided, I cause to be carefully drained off, and put into a large keeve, or tub, for use.

"This quantity is sufficient for eighty bushels of seed-wheat.

"My next care is to shoot into this steep a manageable quantity of my seed, which is immediately to be violently agitated, with either birchen brooms, or the rudders that are made use of in stirring the malt in the mash-tub in a brewing office. As the light grains rise, they must be diligently skimmed off; and after the seed has been agitated in this manner for the space of perhaps half an hour, it may be taken out of the steep, and sown out of hand, with great safety: and I can venture to say, that if the land is in good heart and has been properly tilled, it will not, when sown with these precautions, produce a smutty crop." *Museum Rusticum*, vol. III. p. 81.

"Another gentleman, who signs himself a Norfolk farmer, declares he always observed, that if the seed was well washed it never failed: that he took the hint, and washed some seed which he knew to be smutty, in a large tub filled with plain simple water, stirring it violently with birchen brooms, taking care from time to time to skim off the light. This answered very well, and he has ever since continued the practice.

"I read, says another gentleman, the above account with some degree of satisfaction, but am sorry that your correspondent should be so much a lover of brevity, as to say no more upon a subject of such infinite importance.

"The truth is, we English farmers have hitherto known very little of the nature of this disease in wheat, imagining that whenever the corn was black, it was infected with the same disorder; but this is far from being the case, as any of your readers may see, by referring to a piece written by Mons. de Gonfreville of Normandy, published in the second number of the Foreign Essays on Agriculture, &c. (which I cannot but esteem a very useful work), and containing a detail of a number of experiments made by the above gentleman to ascertain the cause of the smut.

"I was not a little pleased to find that the method prescribed in this invaluable essay, for guarding against this distemper, does not materially differ from that above recommended.

"Both these gentlemen depend on the clean washing of the seed, and the trials of both met with the wished-for success."

We shall conclude this article with the following method of preventing this destructive distemper, sent us by the ingenious Mr. Bromwell Powell, of Green's Forge, near Stourbridge in Worcester, dated September 1766.

"I have here, says he, sent you an infallible remedy against the smut in wheat, a thing so prejudicial to the community in general, and which I myself have made use of for several years past, and have sown smutted wheat, prepared as under directed, and have not had one smutted ear from the produce; and am well assured, if the farmers will observe the under direction, they never will have any. Now, as the coating of wheat with brine and lime is so well known to the farmers in general, I need say no more on that subject, as you have directions from many authors concerning it: but when wheat is so prepared with brine and lime, as is usual, then to every strike of wheat so prepared, add one pound and a half of red lead, by putting it into a cullender, and shaking it gently over the prepared corn, and sometimes stirring the corn with a shovel, that every corn may have a spot or two of the lead adhere to it, which, when so done, is an effectual preservative against the above malady, nor will any fowls lie upon it after so prepared.

"By the above method several of the penurious farmers will look upon it to be a great expence, as the lead will cost, bought in small quantities, three-pence per pound; but admit every strike was to cost six-pence per strike, it would greatly answer the farmers purpose; I therefore have ordered as small a quantity as can be complied with; but if more was added it would still be a greater preservative. As the time of sowing is now near at hand, I hope the gentleman will apply to some farmer, whom they can depend upon to try the experiment of one strike so prepared; and if they can readily procure it, let half a strike of it be smutted corn when sown, and to that half a strike would advise one pound of the lead to be applied, which will be a convincing proof of the utility in the above."

SNAIL-COD, or *Snag-greets*, a name given by Mr. Worlidge to a species of manure found at the bottom of deep rivers.

rivers. It is a kind of mud or sludge, very soft, full of wrinkles, and intermixed with many little shells and snails, to which it is thought to owe a great part of its fatness.

SNAKES, and ADDERS. To drive them from the garden, plant wormwood in various parts of it, and they will not come near it.

Or, smother the place with hartshorn, or lily roots, burnt in a fire-pan, and they will fly from the place.

Or, old shoes burnt, or other stinking stuff, will drive them away; or ash-tree boughs, while green leaves are on them, laid about your ground, will have the same effect.

Or, take a handful of onions, and ten river crab fish, beat them well together, and lay them where the reptiles come.

SNATHE, the handle of a scythe.

SOAP-ASHES. See **ASHES**.

SOIL, a general name for all sorts of land. See the article **EARTH and GROUND**.

Soils are divided by our farmers into clay, clayey loam, loam, sandy loam, sand, gravelly loam, gravel, pebbly loam, stony loam, chalky loam, chalk, flinty loam, flint, ragstone loam, limestone loam; as well as other general divisions, stiff or light, wet or dry, good or bad, &c. and the following remarks are relative to soils:

A clayey loam is difficult to be ploughed; a retentive soil ought to be raised in hillocks, or acclivated; clayey loams are fitter for the scythe than the sickle; patched soils are teasing to the plough; light soils are ploughable at a small expence; stiff soils are expensive: a dry loam, culturable by whip-reins, is perhaps the most pleasant and profitable. But a clayey loam, with a retentive subsoil, is the most untoward of arable soils.

The following hint, of importance to the owners and occupiers of lands, is given by Mr. Leyburn, jun. of Hunmanby. This gentleman says, that in order to prevent manure sinking too deep in low or springy meadow or pasture land, a sufficient quantity of the strongest lime that can be procured, should be laid on it; that he has used Knottingley lime with great success; the quantity not less than six chaldrons to a statute acre, to be laid on the land in the winter season. In twelve or thirteen months after, by putting a spade into the ground, it will be found that the lime will be formed into a compact body, which will prevent manure sinking any lower than the lime, and consequently the lands will receive benefit so long as the manure will last. The lime should be laid in heaps till it be wet, before it be put on the land. See the article **SAND, GRAVEL, CHALK, &c.**

SOOT, a fuliginous substance formed in chimnies.

Soot, either of vegetables or of coal, is good both for corn and grass, especially on cold moist grounds, or lands apt to over-run with moss. Many have found their account in strewing it early over their green wheat and barley: but Mr. Ellis says neither of them ought to be sooted after the 25th of April, because the wheat, and generally the barley, have then done gathering and branching, and are upon the spindle. He likewise thinks it proper to be sown over young turneps, just after they have appeared. But care should always be taken not to strew it too thick, lest its hot nature should hurt the plants. Mr. Worlidge seems to think wood-soot the best; but Mr. Mortimer prefers that which is made from sea-coal, of which about forty bushels are commonly allowed to an acre; though some grounds will require more: to which he adds, that it produces a very fine sweet grass, and destroys worms and weeds; and that it ought not to be sown upon wheat till Candlemas, because the long cold rains and snows are apt to wash it in too soon: nor is it safe to lay it on later, lest a drought succeed and burn it up. See the articles **COAL-SOOT and MANURE**.

Mr. Marshall recommends its being sown by a man and horse before rain, which a shower washes in, and will be of obvious service; but if it lies on the surface till near harvest, without rain, there will be no benefit derived from it. A rich soil wants no soot, but a soil much out of heart wants 40 or 50 bushels. In his Rural Economy of Norfolk, he says that, "Near towns, soot is used as a top-dressing for wheat, in February or March.

"The time of sowing is considered as very material. If it be sown early, and the frost catch it, its strength is thereby lowered: if late, and no rain falls to wash it in, it is thought to be rather injurious than beneficial to the crop

of wheat. And it is not, in any case, found of much, if any, service to the succeeding crop of barley.

"The method of sowing it is extremely simple; and, in the only instance I saw the sowing of soot practised, here, was very complete.

"A favourable opportunity being embraced, when the wind blew gently and in the direction, or nearly in the same direction, as the lands or ridges lie, the same waggon which brought it from Norwich, and which, until the opportunity offered, had stood safe under cover, was drawn, in a furrow, against the wind: while a man, standing on the outside of the waggon, spread the soot, with a shovel, several yards wide, on either side of him; the height of his situation at once enabling him to spread it wide and even. As he reached the windward end of the lands, the team wheeled round under the hedges, and took a fresh width.

"The quantity set on was forty bushels an acre."

SORRANCES, maladies incident to horses, and are accounted two-fold, as either an evil state or composition of a horse's body, which is to be discerned either by the shape, number, quantity, or sight of the member diseased; or it is the loosening and division of an unity, which as it may change diversely, so it has divers names accordingly; for if such a loosening and division be in the bone, then it is called a fracture; if in any fleshy part, a wound or ulcer; if in the veins, a rupture; if in the sinews, a convulsion or cramp; if in the skin, an excoriation.

SORREL, is a reddish colour, with which the mane ought to be red or white; it is distinguished according to the degrees of its deepness, into a burnt sorrel; and a bright or light sorrel; but, generally speaking, it is the sign of a good horse.

SOUND, a horse is such, that does not halt.

When a jockey sells a horse, he warrants him sound, hot or cold; that is, that he does not halt, neither when you mount him, nor when he is heated, nor yet after alighting, when he stands and cools.

SOUR LAND, a cold clayey soil. See the article **CLAY**.

SOW, the female of the swine. See **HOG**.

SOWING, the action of scattering the seeds of plants in the ground.

Writers of different countries mention the usual seasons for sowing their several kinds of grain, but do not take notice of any sign by which the husbandman may be directed when to sow his corn with the greater chance of success. For a rule of this kind we are indebted to the justly celebrated Linnæus, a man truly great, not only for his unequalled knowledge in natural history, and his indefatigable industry in the pursuit of that science; but even still more so for his disinterested zeal to turn the result of his studies to the advantage of his country. Far superior to that mean jealousy which little minds are apt to entertain on their discoveries, he nobly calls forth every assistant, and invites each of them to become his rival in promoting the general welfare of mankind, as we are particularly informed by one of his disciples.

"It is now the fourth year, says the ingenious Mr. Harald Barack, a member of the Swedish academy, since our illustrious president exhorted his countrymen to observe with all care and diligence, at what time every tree expands its buds, and unfolds its leaves; imagining, and not without good reason, that our country would, some time or other, reap some new, and perhaps unexpected benefit, from observations of this kind made in different places."

As one of the apparent advantages, he advises "the prudent husbandman to watch with the greatest care the proper time for sowing; because this, with the divine assistance, produces plenty of provisions, and lays the foundation of the public welfare of the state, and of the private happiness of the people. The ignorant farmer, tenacious of the ways and customs of his ancestors, fixes his sowing season generally to a month, and sometimes even to a particular day, without considering whether the earth be prepared to receive the seed: from whence it frequently happens, that the fields do not return what might be expected, and that what the sower sowed with sweat, the reaper reaps with sorrow. The wise economist should therefore fix certain signs whereby to judge of the proper time for sowing. We look up to the stars, and without reason suppose that the changes on earth will answer to the heavenly bodies; entirely neglecting the things which grow around us. We see trees open their buds and expand leaves, from whence

we

we conclude that spring approaches, and experience supports us in this conclusion: but no body has hitherto been able to shew what trees Providence intended to be our calendar, so that we might know on what day the countryman ought to sow his grain. No one can deny but that the same power which brings forth the leaves of trees, will also make the grain vegetate; nor can any one justly assert that a premature sowing will always, and every where, accelerate a ripe harvest. Perhaps therefore we cannot promise ourselves a happy success by any means so likely, as by taking our rule for sowing from the leafing of trees. We must, for this end observe in what order every tree puts forth its leaves, according to its species, the heat of the atmosphere, and the quality of the soil. Afterwards, by comparing together the observations of several years, it will not be difficult to define, from the foliation of trees, if not certainly, at least probably, the time when annual plants ought to be sown. It will be necessary likewise to remark what sowings made in different parts of the spring produce the best crops, that by comparing these with the leafing of trees, it may appear which is the most proper time for sowing; nor will it be amiss in like manner, to note at what times certain plants, especially the most remarkable in every province, blow; that it may appear whether the year makes a quicker or slower progress. In upland, the sowing of barley nearly coincides with the foliation of the birch.

Mr. Stillingfleet, who has given us a judicious translation of some select pieces published by several ingenious members of that great, and hitherto unrivalled school of natural history, the university of Upsal in Sweden, under the presidency of the excellent Linnæus, was told by a common husbandman in Norfolk, that when the oak catkins begin to shed their seed, it is a proper time to sow barley: "and why," adds he, very properly, "may not some other trees serve to direct the farmers as to other seeds." The prudent gardener never ventures to put his house plants out, till the mulberry leaf is of a certain growth." Hesiod, continues this gentleman in his ingenious note on M. Barck's foliation of trees, began to fix the proper seasons for ploughing, sowing, &c. by the appearance of birds of passage, or of insects, or by the flowering of plants; but I do not find that this method was ever after attended to till Linnæus wrote. Hesiod says, that when the voice of the crane is heard over-head, then is the time for ploughing: that if it should happen to rain three days together when the cuckow sings, late sowing will then be as good as early sowing: that when snails begin to creep out of their holes, and climb up the plants, it is time to leave off digging about vines, and take to pruning. There is a wonderful coincidence, which probably takes place in all countries, between vegetation and the arrival of certain birds of passage. Linnæus says, that the wood-anemone (in Sweden) blows from the arrival of the swallow: and Mr. Stillingfleet finds by a diary which he kept in Norfolk for the year 1755, that the swallow appeared there on the 6th of April, and the wood-anemone was in bloom on the 10th of the same month. Linnæus observes, that the marsh-marygold blows when the cuckow sings; and Mr. Stillingfleet finds by his diary, that the marsh-marygold was in blossom on the 7th of April, and the cuckow sung the same day.

A due temperature of the season, with respect to heat or cold, drought or wet, for all these greatly influence the state of the earth, is essentially necessary, and should be carefully attended to by the husbandman when he sows: but the precise time most proper for this work, cannot, by any means, be invariably fixed, because it will always depend on the concurrence of a variety of circumstances. The seasons are more or less forward, and the ground is more or less dry in some years than in others. A proper series of well made observations would furnish the best of rules in this respect, but certainly would not fix the time of sowing to any particular day, or week, for years to come. Linnæus's method, of carefully observing the foliation of trees, &c. would determine the proper time for spring sowing; and Pliny, after mentioning the several constellations by which farmers were guided in his time, instructs the husbandman with regard to autumnal sowing, upon a principle similar to that of our great modern naturalist. "Why," says he, "does the husbandman look up to the stars, of which he is ignorant, whilst every hedge and tree point out the season by the fall of their leaves? This circumstance will indicate the temperature of the air in every climate, and shew whether the season be early or late.

This constitutes an universal rule for the whole world; because trees shed their leaves in every country according to the difference of the seasons. This gives a general signal for sowing; Nature declaring, that she has then covered the earth against the clemency of the winter, and enriched it with this manure."

I therefore can only say, in general, that it is better to sow early in autumn, than too late, provided the season will admit of it; because the plants are better able to resist the severity of the winter, after they have acquired a certain degree of strength; and their roots being then longer, and consequently better fixed in the earth, they will be less liable to be thrown out by frost. For this reason, in particular, perhaps the colder the climate is, the earlier the wheat should be sowed. Some lands are of such a nature, that they swell greatly in hard frosts, and subsiding again upon a thaw, leave the roots of plants quite bare upon their surface. There have, indeed, been years in which fields sowed very late, for instance, in December, have done extremely well: but that ought not, on any account, to be made a rule, experience shewing that such late sowings very seldom answer. On the other hand, the corn is likewise exposed to many dangers when sowed too early: for the stalks which shoot up before winter cannot well bear hard frost, though wheat would not be hurt by them when only in the blade.

M. de Chateauxeux, than whom we cannot have a better guide, is clearly of opinion, that though the proper time of the year for sowing be come, the corn should not be put into the ground if the temperature of the season be not favourable, and that on the contrary, the sowing of it ought to be deferred, in hopes of a change. "If," says he, the weather is very hot, and the earth extremely dry, it will be absolutely necessary to wait till some rain has fallen; for otherwise the seed will rise but very imperfectly. This I am sure of, by which I contradict the common saying of some farmers, that the earth is the best granary to keep the corn in. Full of this notion, whenever the stated times come round, they sow without distinction, in wet land or in dry: even heat does not hinder them: they think their seed will certainly sprout well after the first rain; but I have always experienced that the plants have come up thin.

"To satisfy myself still farther in this point, I tried an experiment purposely to know whether corn can be sowed with any reasonable expectation of success, when the weather is very hot, and the earth very dry. Upon reading M. Duhamel, du Monceau's excellent Treatise on the Preservation of Corn, I observed, that he had found by his experiments, that wheat dried in a stove heated to sixty degrees of M. de Reaumur's thermometer, had lost its faculty of growing. From thence I conjectured, that wheat which should undergo a heat, for example, of thirty degrees during a longer time, would be equally parched up, and rendered incapable of vegetating. I considered the earth, when hot and dry, as a kind of stove, in which the seed, if it remain too long without receiving any moisture, may become so dry, that the greatest part of it will never be able to sprout. This reasoning is just, and I therefore determined to have recourse to that trusty guide, experience.

"On the 18th of July, 1754, at four o'clock in the afternoon, I placed M. de Reaumur's thermometer two inches deep in the earth, and screened it from the immediate impression of the rays of the sun. The liquor rose to the thirty-first degree, which shewed me the heat of the earth.

"The thermometer being afterwards exposed to the sun, the liquor rose to thirty-six degrees.

"The same day, I sowed eighty grains of wheat in this ground. The heat continued near the same during the rest of that month, and almost all August. On the 21st of July, only ten grains had shot up, and on the 16th of August there were in all sixteen; after which not one more rose; consequently sixty-four grains out of the eighty never sprouted at all.

"On the 28th of July I sowed fifty grains. Only four of them rose by the sixteenth of August, and not one after. Here were again forty-six grains which did not grow at all.

"The same day, I sowed sixty grains in another place. On the sixteenth of August only six grains had sprouted, and not one plant more ever appeared after; consequently here too were fifty-four grains which never grew. All

these grains were sowed in my garden, in exceeding good mould.

"I was sure that the wheat which I sowed was perfectly sound, and in every respect capable of growing. It was therefore quite clear, that so great a numbers of grains out of the whole, which did not sprout at all, had lost the faculty of growing, by their being parched up by the heat, and dryness of the earth. To be still more certain of this three weeks after I had sowed these grains, I watered half of them several times: but to no purpose: not one of them rose, and I found several of them quite whole in the earth where I had sowed them.

"After this experiment, on the 11th of August I suspended the sowings I had begun on the 8th, and did not resume them till the 26th, after some rain which fell on the 22d and 23d. These last sowings rose much better than the first."

Upon the whole, M. de Chateauxvieux concludes, from his own repeated practice, that the best time for sowing in such a climate as Geneva, (which differs very little from ours) is from the 20th of August to the end of September: and thinks that even the first fortnight in October may be taken in, if the land cannot possibly be sowed sooner. But he allows of this only in a case of necessity, and judges that, rather than sow later, it is best to stay till spring.

"Thus, says he, it is, that experience and observation teach us to leave off bad customs, or such as are not founded on principles with which a man of sense may rest satisfied."

It is of the greatest consequence to the farmers that every seed be placed in the earth at a proper depth, and in the best manner: but experience is yet wanting to determine with due exactness, what is the depth which best suits each kind of grain, in different soils.

The method which Mr. Tull proposes, is a very good and easy way to ascertain this point for each particular sowing." Saw off twelve sticks, of about three inches diameter; bore a hole in the end of each stick, and drive into it a taper peg; let the first peg be half an inch long, the next an inch, and so on; every peg to be half an inch longer than the former, till the last peg be six inches long; then in that sort of ground, where you intend to plant, make a row of twenty holes with the half-inch gauge; put therein twenty good seeds; cover them up, and then stick the gauge in the end of that row; then do the like with all the other eleven gauges: this will determine the depth at which the most seeds will come up."

Upon the same principle, M. Duhamel dug a trench twelve feet long, sloping it gradually from the surface at one end, to the depth of two feet at the other. He then sowed different seeds in this trench, and having put the earth into its former place, observed, 1. That hardly any seeds rise when buried deeper than nine inches: 2. That some seeds rise extremely well at the depth of six inches; and, 3. That other seeds do not rise at all when they are above one or two inches deep. Experience shews, that the same seeds may be sowed deeper in a light, than in a heavy soil; that grains which lie too deep in the earth to spring up in a dry year, may rise in a warm and moist season; and that others which are buried still deeper in the ground, will sometimes remain there sound and unaltered for ten or twenty years; at the end of which they will grow extremely well, and produce their proper plants, if they chance to be brought to the surface, by moving the earth, as was mentioned before.

The usual way of sowing in broad-cast cannot answer all the intentions of placing the seed properly in the earth, and must be attended with several inconveniencies; such as the seeds becoming the prey of various birds and animals; its being laid so superficially, that the sun often parches it up, or a long continued rain; instead of promoting a kindly vegetation, soaks into the grains, and bursts them; the seed is very unequally sowed, because of the inequality of the handfuls which different sowers grasp: and great part of it necessarily falls together into hollows, where the surface of the ground is any way unequal, &c.

Sensible of these disadvantages, farmers have, especially for their winter grain, adopted the method of sowing under furrow, that is, sowing one half of the seed in broad-cast, and then ploughing it in, and afterwards sowing the other half, which is covered by harrowing. But this method is also liable to almost as many objections as the other: for

the quantity sown in each particular spot, and the equal distribution which ought to take place throughout the whole, cannot but be even more uncertain than in the broad-cast, where the whole is sowed at once; nor dares the farmer, in this sowing under furrow, to omit sowing the second quantity, lest great part of what as been plowed down be buried so deep that it cannot rise, especially if the soil is at all strong.

Another general fault in the common ways of sowing, is, that too much seed is employed; partly, because custom has established a kind of rule in that respect, and partly on account of the allowance which it is necessary to make for what the birds eat, and for what lies too deep ever to rise; the circumstances by which a very great quantity of corn is absolutely lost.

These inconveniencies are prevented by the drill, which, 1. drops the seed at whatever depth and distance experience has shewn to be fittest for the particular kind which is sowed: 2. fills all the furrows with earth, so that none of the grain remains uncovered: and 3. lets fall into each furrow the exact quantity of seed which has been found to be most proper. By this means every seed is so rightly placed in the earth, that we may be confident they will all do well, if they are not hurt by insects. But as this instrument sows only the absolutely necessary quantity of seed, the husbandman ought to be certain of the growth of every grain; because it often happens, that part of the seed is imperfect and does not sprout at all. As the eye cannot distinguish its quality, he should assure himself of it, by previously sowing fifty or an hundred grains taken by chance, but exactly counted: when these spring up, the number of plants will shew what proportion is deficient, and the quantity of the seed should be increased accordingly. To know what space should be left between each seed thus planted in the furrow, for that space ought to be different, according to the nature of the plant, it will be necessary to observe how much ground a strong and vigorous plant of the same kind takes up when arrived at its greatest perfection, which it will most probably attain when cultivated according to the New Husbandry; and the drill may then be set so as to drop each grain at a due distance.

Besides leaving stated distances between each of the seeds which the drill deposits in the furrow, a farther essential object in the New Husbandry, is to leave proper spaces between the rows of corn, which, in this method, are sowed with the greatest regularity, nearer together, or farther asunder, according to the nature of the plants intended to be cultivated. Some do best in single rows, others in double, others again in treble rows, and others in quadruple; as will hereafter be more fully shewn by several experiments. See the article DRILL-PLOUGH.

"Mr. Marshall says, finding a great waste and inconvenience attending the broad-cast sowing, he ordered his seedsmen to walk on the left-hand inner furrow, with his face towards the land to be sown, and to make his cast diagonally, not across the land. This gave him a great scope; and after a few minutes practice he made very good work: before night he walked at the rate of three or four miles an hour, and though a young seedsmen, made as good work as could be wished. A man walking in the smooth, open inner-furrow, may sow three acres in less time, with more ease, than on walking among the rough clods and loose mould could sow two acres. This method proved superior to the usual way, being cropped as well, and with less seed. The extra expence of sowing is about two-pence an acre, but the saving of the seed was at least two shillings per acre.

The method observed was, the seedsmen walks up one side of the bed, and down the other side; always keeping his face, and the hand with which he sows, towards the bed he is sowing. He also keeps his eye on the edge of the opposite inter-furrow, and delivers his seed, principally, on the side of the bed next to it: as he returns, the sides of course are reversed, and the beds become evenly seeded. An old seedsmen, who has been used to throw large handfuls with all his might, in wide casts straight across his walk, will find it awkward at first to make the single diagonal cast which is necessary in sowing five about-beds singly.

SOWING-MACHINE. See HORNE'S *universal sowing Machine*.

SOW-THISTLE, a species of thistle common in corn-fields and pastures.

SPADE, a well known instrument used in digging.

SPANCEL, a rope to tie a cow's hinder legs.

SPARSED-LEAVES are those which are placed irregularly about the several parts of a plant.

SPARROWS are the most mischievous birds to a farmer; and were all the farmers of a neighbourhood to agree to their destruction, by offering rewards for their heads, their numbers might be lessened. Were the practice general, surely the whole race might be extirpated. Suppose six-pence a dozen the first year, nine-pence the second, and a shilling for the third year would nearly reach their extirpation. To enforce this, consider how soon twelve sparrows destroy twelve-penny-worth of wheat. The island of Bermuda was so much pestered with red-birds, (originally brought there merely as curiosities from America) that an act of assembly was thought necessary to decrease their number, and it had the desired effect.

SPATLING-POPPY. See **CHICKWEED**.

SPAVIN, a disease in horses, being a swelling in or near some of the joints, and causes a lameness.

There are two kinds of spavins, called a blood-spavin, and a bog-spavin.

A blood-spavin is a swelling and dilatation of the vein that runs along the inside of the hock, forming a little soft swelling in the hollow part, and is often attended with a weakness and lameness of the hock.

The cure should be first attempted with restraints and bandage, which will contribute greatly to strengthen all weaknesses of the joints, and frequently will remove this disorder, if early applied: but if, by these means the vein is not reduced to its usual dimensions, the skin should be opened, and the vein tied with a crooked needle and wax thread passed underneath it, both above and below the swelling, and the turgid part suffered to digest away with the ligatures: for this purpose, the wound may be daily dressed with turpentine, honey, and spirit of wine, incorporated together.

A bog-spavin is an encysted tumor on the inside the hough, or according to Dr. Bracken, a collection of brownish gelatinous matter, contained in a bag, or cyst, which he thinks to be the lubricating matter of the joint altered, the common membrane that incloses it forming the cyst: this case he has taken the pains to illustrate in a young colt of his own, where he says, When the spavin was pressed hard on the inside the hough, there was a small tumor on the outside, which convinced him the fluid was within the joint; he accordingly cut into it, discharged a large quantity of this gelatinous matter, dressed the fore with dossils dipped in oil of turpentine, putting into it, once in three or four days, a powder made of calcined vitriol, alum, and bole: by this method of dressing, the bag sloughed off, and came away, and the cure was successfully completed without any visible scar.

This disorder, according to the above description, will scarcely submit to any other method, except firing, when the cyst ought to be penetrated to make it effectual; but in all obstinate cases that have resisted the above methods, both the cure of this, and the swellings called wind-galls, should, I think, be attempted in this manner. If, through the pain attending the operation or dressings, the joint should swell and inflame, foment it twice a day, and apply a poultice over the dressings till it is reduced.

SPAYING, the operation of castrating the females of several kinds of animals, as sows, bitches, &c. to prevent any farther conception, and promote their fattening.

It is performed by cutting them in the mid flank, on the left side, with a sharp knife or lancet, taking out the uterus, and cutting it off, and so stitching up the wound, anointing the part with tar, and keeping the animal warm for two or three days. The usual way is to make the incision aslope two inches and a half long, that the fore finger may be put in towards the back to feel for the ovaries, which are two kernels as big as acorns, on both sides of the uterus, one of which is drawn to the wound, the string thereof cut, and thus both taken out.

SPELT, the name of a species of grain, which though commonly reckoned a summer corn, is sowed either in autumn, or in the spring, at the same time as wheat and rye. This grain, of which there are two sorts, one with a single, and the other with a double chaff, though both have always two seeds in each husk, was formerly much esteemed in Italy and Egypt, and is now very common in Germany, where they make bread of it, which is very nourishing, and well tasted, but hard to digest. They likewise brew beer from it in some places. It was of this

grain that the ancients made their frumenty, of which they were very fond. Though commonly ranked as a species of wheat, which it is not unlike when growing, its grain is smaller and of a blackish hue, its stalk thinner and less firm, and its ear flat and bearded, with seeds only on each side. Some writers distinguish a third sort by the name of white-rye, which they take to be the olyra of the Greeks and Latins; and seems to be what Mr. Mortimer calls tritico speltum, a sort of naked barley, or wheat barley, cultivated in Staffordshire, shaped like barley, but with a grain like wheat. It is much sown at Rowley, Hamstall, and Redmore, where they call it French barley. It makes good bread, and good malt, and yields a great increase; and therefore would do well to be tried in other places. It ripens early, does best in a dry soil, and is not apt to be much hurt by birds, from which its beard and double husk preserve it.

SPIKY-ROLLER, a very useful instrument in husbandry, lately introduced by the ingenious Mr. Randall, of York, who has also obliged the world with the following account of it:

"I think, says Mr. Randall, it was in the spring of 1752, when I had fifty acres of ground, designed to be sowed with barley, at one particular farm; but the weather had been so unfavourable, and the spring so extremely dry, that there was no such thing as preparing the ground for the reception of the seed: and this was the case with the whole country, in these parts of England. On looking, one morning, at a barley-roller, which laid just before me, I recollected, that Mr. Ellis, in one of his eight volumes in Husbandry, made mention of a spiky roller, and referred the reader to another volume for its plate and description, which were no-where to be found. I immediately sent for some workmen, and produced this useful instrument against the next morning, as the season was far spent, and much ground was to be sowed, in several farms, with this grain.

"On this morning, a neighbouring, substantial farmer, passed by us, with half the country for clotters, as we were going to put the horses to the roller, as he had no longer patience to wait for rains, to reduce the rough state of his ground, designed for barley seed; he gazed at the roller, smiled, and went his way with his troop. They, after clotting two acres, all returned the same way at night; their master rolled his eyes all over a field of about twenty acres, saw it perfectly fine (as the roller came back upon the same ground it went down), and, after a pause, said, that was a good hedgehog, for doing ten times more in one day than all his troop together, and ten times finer, than a thousand clotters could do in the same time. This was the first time this farmer ever could be brought to say a civil thing of any useful instrument, though common sense would pronounce the utility of this on his first seeing it; but the truth is, nothing but such glaring effects can ever convince these people, as they have the great art of despising what they do not understand, or have not had in practice for ten centuries.

"While the same man was going over the other ground that stood in equal need of the roller, the ploughs were set on to turn up the ground he had rolled; and when all was thus ploughed, the roller went again over the whole, to crush the clots, thus turned up, and made all as fine as before, by going twice in a place: then they ploughed for a seed furrow, sowed the seed in the usual way, and harrowed it in; then the roller with a thorn bush fastened behind, went over again, once in a place, and left all exceeding fine, which even would not have disgraced a gardener in his manner of preparing the ground for the garden culture in general.

"The consequence of this lucky hit was, that, before the country could get their seed into the ground, my barley was fairly up, went forwards, and did extremely well; while, in general, my neighbour's barley made but a sorry appearance, arising from the rough state of the ground which they could not bring into that fine order this grain requires, notwithstanding all their toil and expence. This achievement of the spiky roller established its reputation among the neighbouring farmers; but still they could not prevail on themselves to be at the expence, which indeed was not small, in having one made for their own use. The result of all was, that I had other rollers made for the ground in other parts belonging to me, only they were made heavier, and both longer and larger, the better to suit the soils that were much stiffer.

"From

" From this time we never sowed any seed in the common form, but the spiky roller and thorn-bush at its tail, followed the harrows; as it effectually buried the seed, and left the ground in a fine state. It may easily be conceived, that this operation is of consequence to vegetation; for the fine mould, being thus swept into the holes made by the irons, and where the seed was buried, must needs greatly promote their growing soon, and nourish them well above-ground; as it is well known, the finer the mould is, where the seed is deposited, there vegetables are pushed on to their destined maturity, if all other requisites concur. And upon this principle it is, that if the corn in the spring is rolled once in a place in like manner, the owner will be far from having any cause to complain of the practice, provided the weather and state of the ground, will or ought to bear the tread of the horses, and weight of the spiky roller.

" I am very sensible this will appear strange to many persons, as it looks like sending a herd of rapacious wolves to nourish a flock of tender lambs, or tearing, bruising, and throwing all the corn up from their very roots, and bringing on a general desolation over all the ground. This is like Sisyphus in Homer: we crop the ground with much sweating and tugging, and then suffer all to be destroyed again, by this ponderous, grinning creature. But it may not, perhaps, be ill expressed, when we say, that, in order to come at the truth of things in farming, we must, according to the Greek epigram, ascend downwards, and descend upward: the most triumphant success, in the true bias of nature, in establishing agriculture, rises safely and surely on the foundation laid by bold experiments, that seem to contradict superficial reason.

" Let us now consider the effect of this terrible desolator, as it goes over the young corn. If we consider the system of irons on the roller, they must leave some of the corn untouched by them, and then this is only rolling the corn in the common way, as it is only squeezed by the roller, and not bruised by the irons: so far there is no harm done. There must be corn, you will say, that is crushed and bruised, if not quite destroyed, by the violence of the irons: but supposing the corn lost, wherever the irons pitch, which is very far from being the case, yet the untouched corn will be so improved, by this shattering and loosening of the soil about their roots, and scraping of the mould by the thorn-bush, and shaking and tearing the tender blade, that the owner will judge for himself, whether the Greek epigram ought to have a place among the paradoxes in agriculture. However, it can do no gentleman much harm to let the roller go down in one place, and up again in another, and give over; and this single trial is all that the author pleads for, and that the weather and state of the ground be such as will safely admit of the experiment.

" The use of the roller, in making the fallows, and preparing the ground to a requisite degree of fineness, in the old, new, and what this Treatise calls the Semi-Virgilian Husbandry, is by this time pretty evident to the reader, and needs no more instances, where such perfection is desired. We now come to speak of its use on grass land, where the sward is worn out by age, spoiled by mofs, or a bad sort of grass; or defective in any shape, from some cause or other, and yet it is very dangerous to plough it up, and lay it down better, on account of its situation, or it is not convenient perhaps, for other reasons, to disturb it with the plough: whatever the case is, the owner, undoubtedly, would be exceeding glad to have a better burden of grass on the ground, for the maintenance of his live stock, or for the pleasure of seeing his ground, about his house, put in a better appearance.

" Here then there must be some compost prepared; that is, a mixture of the dunghill, sods, ashes, lime, mould, soap-ashes, and such like ingredients, or as many of them as can be conveniently procured, laid up in a heap, in this manner: a stratum of mould about half a foot deep, then dung, then sods, then soap-ashes, then common ashes, then lime, then dung; and to cover all with mould, about half a foot deep. When these have laid some time, that the dung may communicate its juice to the strata beneath, the heap may be thrown down with spades, so as, in the operation, these ingredients, being mixed together, the first stratum of half a foot, of the new heap, may be composed of all the ingredients; and so, in like manner, all the rest of the strata, till the new heap is completed; and

after these have laid some time, they will be very mellow, and fit for use the Michaelmas after the winter when the first heap was formed.

" We must now suppose the clove, whose sward is to be improved, to have been laid down even, and not in ridges; and that between Michaelmas and Martinmas, the sooner after the former the better, the ground is to be so moist, as to admit the irons of the spiky roller, but not the horses feet; that is, the irons will penetrate three inches, or thereabouts, and the horses feet make little or no impression. Here then the roller must go up and down, till the sward and ground are pretty well broken up: this being done, the seeds of clover, trefoil, and ryegrass, or any other mixed with them, must be sown in the usual way and quantity: then the compost must be spread over the seed, so as to cover them, and a common barley roller, with a thorn-bush fastened to it, must follow, and the ground shut up, lest cattle should do harm, by treading the ground. A gentleman making this experiment, will have great cause to be pleased with what he has done; and will also see the necessity of laying down his ground as even as possible for the future, that he may increase the burden of his grass, whenever it falls short of a proper quantity or quality." *Randall's Semi-Virgilian Husbandry, Append. page 1.*

We have added the figure given of this useful instrument by the above ingenious gentleman, on Plate XXIV. fig. 5.

A correspondent of the editors of the Museum Rusticum, who calls himself a clay farmer, has made the following observations on the structure and utility of the spiky roller:

" Give me leave, says he, to communicate to my brother farmers, a most useful implement in husbandry, which has but of late been introduced amongst us. It is so very efficacious, and its power so much superior to all other instruments yet contrived for the reduction of strong land, that, I think, there is not any possessor of such ground (who has no objection to a fine seed furrow) that will be without this instrument. This last autumn it has been of the greatest utility. For whilst the neighbouring farmers were waiting for rain, so that they might with their own rolls and harrows bring their land to that degree of fineness they could wish to have their seed sown in, those who were possessed of the spiky roller, (for that is the name of the implement I am going to give some faint idea of, as it is impossible by letter to make any body more fully acquainted with it) had their fallows in such a degree of fineness, as I never before saw that kind of land in; and had finished the whole of their sowing, before the others ever thought of taking their ploughs, &c. into the field.

" To begin then with the best description I can give of the most complete I have yet seen. The roller is of oak, six feet three inches long, seventeen inches diameter, hooped with iron at each end; the circumference divided into eighteen equal parts, where rows of iron spikes are set (in the quincunx order) at six inches distance one from the other, in the rows: so that there are thirteen spikes in one row, and twelve in every other throughout the circumference. The number of the spikes is two hundred and twenty-five. They are to project four inches and a half from the roller, and to be one inch by three quarters of an inch square at that part of the spike next the roll, tapering off to three quarters of an inch by half an inch at the top part. The whole length of the spike, with what is driven into the wood, will be about nine inches long. And I would advise the falling side at the end of each spike to have a stroke or two with the hammer, that they may be a little more pointed to give them greater facility in penetrating the very hard clots they are designed to break. Every spike will weigh about one pound and a quarter, which will be of sufficient strength.

" The frame should be made for horses to draw a-breast, or with a pole for oxen. For by the horses, &c. drawing double, the roll is more easily turned; and, besides, it is likely to prevent the end of the roller from going over the driver, if by chance he should fall. That it may with greater ease and convenience be conveyed from field to field, or to any distance, an axis is fixed upon the frame immediately above the roll with wheels; so that by turning the frame, the wheels take up the roll, and away you may drive; and when you have brought it to the field, in

in order to make use of it, by turning the frame back again, you let down the roll, and then the wheels are carried by the roller.

"Since making of the above description, I have talked with the wheelwright, who tells me, he could greatly improve the manner of fixing the wheels, by making them run within the frame; for as they now run without, it sets the wheels at such a distance, as makes it difficult to pass through gates made only the common width. And likewise says, that great care must be taken in fixing that part of the frame which the gudgeons of the rolls run in: for by that means the roll will be let down with greater ease; which will not be the case, if regard is not paid to that particular. The roller, frame, wheels, &c. are, together, about eleven hundred weight.

"If your land, by once passing over it with the roller, is not so fine as you could wish to have it, let a large harrow be fastened to the frame of the roller, which will pull up the remaining clods, and thereby give the roller a better chance for breaking of them the second time going over. Four able horses are equal to this work." *Museum Rusticum*, vol. V. page 372.

These observations induced the inventor, Mr. Randall, to send the following letter to the editors of the *Museum Rusticum*:

"In your *Museum* for the last December, says he, I observe my name mentioned concerning the spiky roller. Without making any comment on the clay farmer's dimensions, for constructing this implement of husbandry, I beg leave to tell him, and the rest of your readers, that the length of mine, which was the first I ever saw or heard of, except what the late Mr. Ellis mentioned to so little purpose, was seven feet, the diameters of the ends eighteen inches, and the whole cylinder made of the heart of oak: and when the irons were burnt in, and the man seated on the box designed for that purpose, the weight of the whole was about a ton. But you will think it strange, that the blunt end of the irons were opposed to the clods, and run more taper, till they came to the surface of the cylinder, into which the irons were burnt, and inserted about three inches, which was their length above the surface of the roller, and which, I always found very sufficient to crush the hardest clod that ever came in their way. Had I, indeed, attempted to go on the ground when the soil was not perfectly dry, this position of the irons would have carried the clods round with the roller: for it is not its province to squeeze but crush. Nor indeed can a man do more harm to his ground, than going upon it, when it is not quite dry, with a roller, constructed according to the clay farmer's form and size of the irons; or by that which I have recommended. I am sensible those who construct the roller, according to the clay farmer's directions, imagine, that by inverting the shape, there is less danger of carrying the moist clods round with the roller; but I must say again, there is no occasion for this precaution: for, if the other form be at all necessary, it must be in the moist state of the ground, which is the only reason why we should keep the roller off the soil. I had the irons fixed in four inches asunder, in the first row, from end to end. The second row began just between the first and second irons of the first row. The third row was like the first, and the fourth like the second. Then alternately for the whole surface of the cylinder, as near as could be, the irons were four inches asunder in each individual row, and four inches from row to row, as nearly as the superficies of the cylinder would permit. I do not know how to convey a juster idea to your readers of the shape of the irons, than to call them ox-harrow teeth, for when I sent for the workman, I desired him to make so many of this denomination, six inches in length; and burn the small end three inches into the wood: he went from me, as perfectly understanding what I meant; brought his number of irons, and inserted them a proper depth into the cylinder. If some of your south-country readers should be at a loss to know what is meant by ox-harrow-teeth, they will be pleased to remember, that they are irons fastened into two harrows, which are drawn by either four oxen and two horses, or six oxen alone, in very stiff soils. Now, it will appear to you, that the roller itself, and one harrow, will require at least four able horses, according to the clay farmer's stating the case: but my roller, without harrows, always stood in need of three stout horses, which the man from his box always drove a-breast, for the greater convenience of turning on

the land's ends. But were I to have two ox-harrows, (which would only extend the length of the roller) following the roller, for the purpose of tearing up clods, in order to be crushed, on going a second time over the same, seven feet in length, I should be obliged to have a much stronger team than four stout horses; and therefore, I must beg leave to observe, for this, an unanswerable reason, that harrows are better omitted; as they always were, by my people, who set in with their ploughs, and turned up the soil from all requisite depths, in order to have it crushed by the roller going twice in a place.

"If the clay farmers will not take it amiss, I would tell him, that wheels to the roller only create expence and trouble. For I do not remember we ever had any disadvantage from the weight of them in my four rollers, made for near a thousand acres of land, of all denominations of soils, stiff and light: for, when the fellows had occasion to convey the roller from one inclosure to another, and sometimes over the hard high road, I never heard, or observed, there was the least difficulty of doing it: as the irons were so stout, as not to receive any injury in the passage, otherwise than by friction; by which they would be indeed in time somewhat impaired. As to the width of the gates, I think there was never any stoppage; since the men, when they found the passage rather too strait, could, by turning the horses heads, easily incline the roller on one side, and by that means wriggle it in, where it was too long for entrance. Let who will be the father or grandfather of this valuable instrument of husbandry, I had reason to be extremely well pleased with my lucky hit, in constructing it from Mr. Ellis's barely mentioning a spiky roller: though from his usual giddiness, he gave his readers no more than the name. As it is of consequence to the world, to keep the expence of this instrument as low as possible, I shall be very sorry to hear any more of wheels, for it may deter farmers from using it; and without their hearty concurrence, all will be only playing at farming. Gentlemen may please themselves in every variation of the implements and modes of culture: but without the assistance of those, who bless the nation with their endless toil, a thousand years hence will be as to-morrow.

"Besides the purposes already mentioned, this roller must undoubtedly be of use in laying, originally, down lawns, or large pieces of grass required to be level. Mr. Randal only mentions the restoring such when depraved: but certainly this instrument must be extremely effectual in the case of all stiff lands, for the producing a good face in the first forming of fine pieces of grass. The manner of doing this, in such cases, is too obvious to persons qualified for executing such work, to require any explanation: as the instrument may be used concurrently with any of the common methods of manuring and sowing grass seeds, as well as with Mr. Randal's compost, &c. they being no ways particularly necessary to the effects of the roller, though it may greatly aid them.

"This roller may likewise be very useful in preparing clay for the making canals or pieces of water. For where, as sometimes happens, the clay grows dry, and will not admit of being duly tempered for use without great pains in breaking it, a very large quantity may very soon be reduced to the requisite fineness, by spreading it on hard ground in a due thickness, and passing this roller a few times over it. In very great works, much trouble and labour may be sometimes saved by this means, where such a roller is at hand; and the clay prepared in a manner that will answer the purpose much more effectually.

"It is certainly an instrument which no farm, where the land is stiff, or in the least liable to clot, should want. For besides the constant advantage of saving labour, and bringing land to a better condition for any kind of sowing than the plough and harrow with any assistance of the work of hands can make it, in favourable seasons, and under such circumstances as Mr. Randal has mentioned in the above quotation, the loss of the whole crop by an otherwise unavoidable delay beyond the seed time, may be with certainty prevented."

We shall conclude this article with the following ingenious account of the uses of this instrument, which we have been favoured with from Mr. John Berington, of Winsley, near Hereford.

"As I live, says he, in a clay country, and had been often put to a great deal of difficulty in a dry unkind season, in reducing the land to a proper tilth, I resolved to make

make a trial of Mr. Randal's spiky roller; but apprehending great stress must lie upon the horse and frame, in turning such, as well as tearing up the ground, it occurred to me, that I had seen recommended a double roller, that is, one divided in two parts. It is very probable that you have it already in design; if not, the following directions, I imagine, may suffice.

"Let the ends of each part be bound with narrow but strong bands of iron, and let the spikes at the ends be placed close to them; let each part have a separate frame, but let the cheeks in which the inward gudgeons turn, be made of iron plates, about two inches wide above, and four where the gudgeons enter; the thickness, a common flat bar of iron; and these fixed in any firm manner, to two cheeks of wood reaching down just to the bands, and of such a thickness at bottom as not to interrupt the spikes. Let the inward gudgeons be made with quite flat heads, to prevent their slipping out in working; and this brings the two ends of the roller near together, which is of some little consequence, as the fewer clots will be missed in working."

"Let the frames be joined together by four eyes, like those of a small gate, two at one end, about five or six inches apart; the two at the end of the other, to take place just within them; an iron pin through all four, and keyed. Let the trills be placed just on the middle of each frame, and a bar of wood just behind the horse to strengthen them; the bar sawed through in the middle, and joined by a strong flat hinge: one side made to hasp upon a staple, kept down with a wooden clet. This gives the whole proper play in working; and I may venture to affirm, it will be found, next to the plough, the most useful instrument in tillage, not only in reducing a stiff soil, but with a bush at its tail, as Mr. Randal, expresses it, will cover the seed when sown much more effectually, and in a better manner, than a harrow, as it turns up the earth light and fine behind it; and though seemingly unweildy, will turn with ease, and may be worked with one, two, or three horses at most, upon any land that is of a proper dryness to work upon, of which I cannot well forbear giving you an instance: the carter that was to drive it exclaimed, when he first saw it, that it would kill all his horses; some time after, as he was using it upon a piece of fallow, a fellow-servant wanted a horse for some use, and was going to catch one; the carter called to him, and told him, he might take one of his, having three, as he could do very well with two. Now I believe you will allow, that if it could so easily overcome the obstinacy of a clown, there are very few clods that will be too hard for it."

"The spikes are about four inches without, and three within the wood; the thickness of the roller, and number of spikes, I think, may be determined, in some measure, by the nature of the soil it is to work upon."

The spiky roller is, undoubtedly, one of the most useful instruments in husbandry of modern invention, and will be found applicable to several other purposes, besides those above-mentioned: one in particular is, to assist in reducing the half burnt turf of burn-baked land, which requires much labour, as commonly done by hand; but by going over the land several times with the spiky roller, and harrowing it with heavy harrows alternately, to pull up the turfs, or ploughing them up, they may be reduced fine, in a much shorter time, and at a much less expence, than by beating, to break them by hand.

"In Devonshire and Cornwall, says Mr. Harte, p. 84. of his *Essays on Husbandry*, they Denshire their old pastures, which when very coarse and grassy, and choaked with weeds, they pare off the surface about three inches thick, with the old English beating axe, (which is nearly the same as the Marquis, de Fourbilly's cob, or paring axe) into turfs about two feet three inches long, and ten or eleven inches broad; and the workman or parer sets up these turfs very dexterously, into a sort of spiral pyramid or cone, with his axe, something in the form of an high-crowned hat, but more obtuse, with the grassy side outmost; in which position they dry conveniently and speedily. They commonly make about two hundred such small heaps upon an acre; but in burning these small heaps, a great part of the outmost turfs will remain uncalcined; and therefore Mr. Harte proposes to make but forty heaps upon an acre, with half a furze faggot placed near the bottom of each, and an air-hole

fronting the wind. That he has known above five hundred bushels of ashes procured from a single acre, and the common expence there, of paring, burning, and spreading the ashes, is about twenty-seven shillings per acre.

But where a paring-plough can be used, much of the expence of paring may be saved. And here we see, that a great part of the outmost turfs remain uncalcined, which must be broken by hand, but much more speedily with the assistance of the spiky roller.

The Marquis of Fourbilly directs the turf, of land over-run with heath, fern, &c. to be pared four inches deep, and the turfs to be cut eighteen inches long and nine broad, to be laid flat with the bare or earthy side downwards; the end of each turf to rest upon the preceding one. Or, if to be dried sooner, in wet weather, to set them up on edge in little round heaps, or else in pairs leaning one against another, with the heathy side outward; and when dry, to be set up in large heaps, rounding towards the top, with the heathy or grassy sides all laid downwards, and a small hearth or chimney near the bottom of each heap, facing the wind: ten heaps to be ten feet diameter, and ten feet high; to be immediately set fire to, as soon as made, with a little straw, &c. at the end of a fork; but he directs no furze to be laid on the hearth, nor is it necessary, if the turfs are dry when set up; for then they will readily take fire by carrying some hot coals from one heap to another, in shovels. The Marquis computes the expences, as it cost him, at about thirty livres per arpent, amounting to about twenty shillings per English acre.

"I have, says the Marquis, often remarked, that in those places where the upper turfs of the clumps, which had burned slow, remained almost whole, and were but merely calcined, insomuch that it was necessary to break them before the ground could be sown, the corn always flourished most, and much better than in those places where the furnaces, after burning every thing, were totally converted into heaps of ashes alone. In general, these heaps where the ashes after burning are white, are the least valuable, as well as least in bulk. This denotes vitrification more than calcination. In proportion as the ashes are yellowish, brown, or black, which is the degree of their perfection, they are the best, and the heaps generally the largest. In proportion to these colours, the calcination exceeds the vitrification." For this reason, those who burn-beat their land, choose to perform it with a smothering fire, as that is a means of preventing the vitrification, and makes the greater improvement; but this leaves a greater proportion of turfs imperfectly burnt, and renders the spiky roller of more use to break and pulverise those imperfect burnt turfs, with less manual labour, especially, as the Marquis observes, the turfs cannot be all broken sufficiently by hand work the first year, but some will remain unbroken to the second year after burning, notwithstanding his giving the land five ploughings, and as many harrowings, before it was sown with wheat or rye; and yet the first crop was but indifferent.

"As to the little freeholders, continues this gentleman, and farmers, who have but a few acres, and after having grubbed, cleared, and burned them, in the manner before mentioned, labour them by the strength of their arms, with the pick-axe, shovel, spade, or other instrument, and wish to sow in one of the above-mentioned methods; they must take care to mix the ashes well with the soil, and to carry off all the stones and roots. These are they who will, in proportion, reap the most corn the first year, as digging stirs the ground much better than ploughing. Were it possible to cultivate all one's ground thus, with a spade, it would produce a great deal more."

Hence appears the advantage of giving such land good and deep culture the first year, and immediately after the ashes are spread upon the land: which may be done by the assistance of the spiky roller, which will break and reduce the imperfect burnt turfs before the land is ploughed up, and will afterwards quickly reduce also the land after it is ploughed and dry, at a much less expence than can be done by the plough and harrows, as appears by the above examples, of the powerful effects of it, upon strong and cloddy land.

Instead of sowing this land, when thus reduced, with corn, for a first crop, it will be better to sow turneps, if the land is ready in proper time; and if they are drilled upon four feet ridges, and horse-hoed, the occupier may obtain, not only a great crop of turneps, which land thus prepared is found to produce, but the land will be admirably

bly prepared (by repeated deep horse-hoeings, and thoroughly mixing the ashes with the land for any succeeding crop; or to lay it down in fine order with saintfoin or grals feeds; in doing which (or for any other crop) great care should be taken, to procure perfectly clean seed, and to lay no farm-yard or stable dung upon the land, or any other kinds of manure, which are suspected to have any feed of weeds in them; for the fire having wholly destroyed the grals, and all the feeds and roots of weeds that were in the land, (together with the worms and noxious insects), it may now be kept perfectly clean, and continued so with proper care, for many years: "for a considerable time, says the Marquis, not so much as a blade of grals grows in the corn: there is scarcely any as yet appears in the lands that I pared and burned at first:" which was more than twenty years before he wrote this.

SPINDLING, running to seed.

SPLINT, a hard excrescence growing on the flank bone of a horse.

Some horses are more subject to splints than others; but young horses are most liable to these infirmities, which often wear off, and disappear of themselves. Few horses put out splints after they are seven or eight years old, unless they meet with blows or accidents.

A splint that arises in the middle of the flank bone is no ways dangerous; but those that arise on the back part of this bone, when they grow large and press against the back sinew, always cause lameness or stiffness by rubbing against it; the others, except they are situated near the joints, seldom occasion lameness.

As to the cure of splints, the best way is, not to meddle with them unless they are so large as to disfigure a horse, or so situated as to endanger his going lame.

Splints in their infancy, and on their first appearance, should be well bathed with vinegar, or old verjuice; which, by strengthening the fibres, often puts a stop to their growth; for the membrane, covering the bone, and not the bone itself, is here thickened; and in some constitutions, purging, and afterwards diuretic drinks, will be a great means to remove the humidity and moisture about the limbs, which is what often gives rise to such excrescences.

Various are the remedies prescribed for this disorder: the usual way is to rub the splint with a round stick, or the handle of a hammer, till it is almost raw, and then touch it with oil of origanum. Others lay on a pitch plaister, with a little sublimate, or arsenic, to destroy the substance: some use oil of vitriol; some tincture of cantharides; all which methods have at times succeeded; only they are apt to leave a scar with the loss of hair. Those applications that are of a more caustic nature often do more hurt than good, especially when the splint is grown very hard, as they produce a rottenness which keeps running several months before the ulcer can be healed, and then leaves an ugly scar.

Mild blisters often repeated, as recommended in the article spavin, should be first tried as the most eligible method, and will generally succeed, even beyond expectation: but if they fail, and the splint be near the knee or joints, you must fire and blister in the same manner as for the bone spavin.

Splints on the back part of the flank-bone are difficult to cure, by reason of the back sinews covering them; the best way is to bore the splint in several places with an iron not very hot; and then to fire in the common way, not making the lines too deep, but very close together.

To SPRAIN feeds, signifies, to throw them with a single motion of the hand at a certain distance from one another.

SPRIG, a small branch, a spray.

SPRING, the season in which plants vegetate.

Spring also signifies a fountain, or issue of water from the earth. See the articles **DRAINING**, and **WATER**.

SPRING-WHEAT, a species of wheat sown in the spring. See the article **WHEAT**.

The following experiment and observations on the comparative ripening of spring and common wheat, made by the ingenious Mr. John Wynn Baker, and reported by that gentleman to the Dublin Society, must not be omitted here.

"Some little time after receiving the instructions I was honoured with from the society, I was desired by the committee, then sitting, to settle the premiums for the succeed-

ing year, to make a comparative experiment between spring and common wheat.

"The purpose of this experiment was to discover, whether common wheat would not ripen when sown late in the spring, as well as spring wheat.

"Accordingly, on the twenty-eighth day of March, I sowed two perches of each sort of wheat in my garden, in drills three feet asunder, at the rate of five stone to an acre. I had but two pounds of spring wheat, otherwise I should have extended the experiment.

"The common wheat came up well, but the spring wheat came up very thin in the drills, which for some time, I apprehended, was owing to some fault in the seed: but the case was otherwise, as appeared afterwards from a second sowing in another place: add to this, that in a few days I discovered mice had eaten great part of the seed; however, some little of it escaped, and planted greatly, as did the common wheat.

"As a substitute for the horse-hoe, which could not be introduced in these small experiments, I used the spade, and the plants grew to admiration.

"The fatality which attends all small experiments in the corn tribe followed these: for I was obliged to cut the spring wheat before it was ripe, the birds, in defiance of all protection, having devoured most of it; however, it would have ripened completely, and, as a proof of this assertion, I had a few ears, which I selected from the rest, which are very fine.

"It may be proper to observe, that the spring wheat was more exposed to the ravages of birds than the other, as the common wheat I sowed was bearded, which is always a great, though not a perfect, protection to it from birds.

"The common wheat met with a distemper which was quite as fatal to it as the mice and birds were to the other: this was the rust, or mildew. Before this disease came upon it, it was as fine corn as ever I saw, but it never ripened; though in appearance the ears were very fine.

"This disease attacking this corn, and sparing the other, I am inclined to attribute to this circumstance, viz. that this was very thick and strong; whereas the other was very thin, from the accident before mentioned: perhaps, had it been as thick, it might have shared the same fate. So that I think these experiments are not by any means conclusive, as to the ripening of either of the species of wheat, when sown late in the spring.

"I sowed another plot of ground, as was before mentioned, on the fourth of May, with spring wheat, which came up well, grew up very strong, and formed very fine ears in appearance, but never ripened.

"On the twenty-ninth of April, I sowed an acre of very good ground with common wheat, which I steeped beforehand in putrid water; it came up in eight days, but made no figure till June; it formed small ears, but produced no grain at all.

"So far we have two conclusive experiments, that spring wheat will not ripen when sown in the beginning of May; and that common wheat will not ripen when sown the latter end of April.

"Notwithstanding that our question is not answered by the two first experiments, yet the disease attending the common wheat has furnished some observations with respect to the mildew, or rust, upon corn and other plants, which tend principally to confirm those made by the ingenious Mr. Tillet, director of the mint at Troyes, and seem to contradict most of our English writers on this disease: many of whom seem to have implicitly followed others, who, I am afraid, have undertaken to account for, and furnish remedies against, a disease which perhaps they had never seen.

"Various are the opinions, and many of them contradictory in themselves; but upon the whole, candour obliges me to own myself as much at a loss to determine with certainty the cause of this disease, as I find, the many writers are, who have thought themselves perfect masters of it. Even by reading six pompous pages, which I have gone over many times, I should scarcely know the disease, so faint is the description; but it will ever be known by the greatest strangers to country affairs under the French name, which indeed is as truly descriptive as it is laconic; by them it is called *rouille*, or rust. By the Romans it seems to have been called *rubigo*.

"I shall omit to give my observations upon this disease at present, as it would oblige me to quote many tedious passages

pages from the books; and where there is a contrariety of opinions, although without evidence: yet a little man, with a few facts only to support a new theory, would stand a chance of making but a poor figure.

"At present I join in opinion with Mr. Tillet and Mr. Reneaume; who seem to think that the extravasated juices of the plants, operated upon and condensed by the acrimony of the air, I should rather say incruited, are the occasion of it. To this I shall only add, that I am at present of opinion, that the lacerated parts of the plant giving passage to, or rather changing the course of, the juices before-mentioned (which are the nutriment and life of the plants), to the diminution and loss of the vegetable food to the nobler parts, is the true cause of the plants failing in their produce: but, I repeat it, I attempt not here to account how, and from what cause, those lacerations, which I believe to be the basis of the disease, happen.

"The comparative experiment between spring and common wheat, I think, should be repeated, as the discovery thereby sought for tends to a public benefit; but it should be in a larger way, and in an open exposure.

"A circumstance has recurred to my memory, which had escaped my attention from the time it happened, till since I entered upon this subject.

"Last spring, a poor neighbour of mine told me he had lost the season for sowing his wheat, for want of money to buy seed, but that, if he could get a barrel of Poland wheat, (as he called it) which was the white cone, he would then sow his ground: accordingly he obtained the seed and did sow it; but I understand, upon enquiry, that it produced not a good crop. He sowed it some time about the beginning of February.

"And yet I am informed there is a gentleman in Scotland, who makes it his constant practice to sow his wheat in the spring by choice; and that he intends to publish a recommendation of that practice.

"The latest I ever sowed any with success was the thirtieth of December; but that was only a small experiment.

SPROUT-HILL. See the article **ANT-HILL**.

SPRIT, a shoot, or sprout.

SPUR, a distemper which frequently attacks rye, and sometimes does damage likewise to wheat. The following remarks will give an idea of it.

"1. The grains which have the spur are thicker and longer than the sound ones, and generally project beyond their husks, appearing sometimes straight, and sometimes more or less crooked.

"2. Their outsides are brown or black; their surface is rough, and one may frequently perceive in them three furrows, which run from end to end. Their outward end is always thicker than that which sticks to the chaff, and the most swollen end is sometimes split into two or three parts. It is not unusual to find on their surface cavities which seem to have been made by insects.

"3. When a spurred grain is broken, one perceives in the middle or centre of it a pretty white flour, covered with another flour, which is reddish or brown. Though this vitiated flour has some consistency, it may nevertheless be crumbled between one's fingers. M. Aimen has indeed sometimes found this powder almost as black as that of finutty wheat.

"4. These grains, when put into water, swim at first, and afterward sink to the bottom. If chewed, they leave a bitter relish on the tongue.

"5. The chaff appears sound, though what is outmost is somewhat browner than when the ears are sound.

"6. All the grains of the same ear are not ever attacked with the spur.

"7. The grains which have this distemper stick less to the stalks than sound grains do.

"8. M. Aimen imputes this distemper to the grains not being impregnated; and assures us that he has not ever found a germ in grains which had the spur. The same observer has collected, in a memoir which he has sent me, several reflections and microscopical observations; but I pass over in silence such researches as are more curious than useful.

"9. I shall not stop to refute the opinion of those who have pretended that fogs, dews, rain, the moisture of the earth, may give this distemper to rye. But I cannot help saying, that Mr. Tillet thinks, as does also M. Aimen, that other plants besides rye, are subject to the spur. M. Tillet has seen, and M. Delu has shewn me grains of wheat

which had the spur. The spur ought therefore not to be confounded with the ustilago on burnt-grain: they are two different distempers: and what seems still more to establish this difference, is, that M. Tillet's experiments prove that the powder of the spurred grains is not contagious like that of the carious or burnt.

"M. Tillet is strongly inclined to think that the spur is occasioned by the sting or bite of an insect, which turns the rye into a kind of gall; and he suspects a small caterpillar of being the cause of this mischief. But neither he nor I dare to speak affirmatively on this point.

"Dodard, Langius, Fagon, Delahire, Noel, and lately, M. Salerne, gave particular accounts of the diseases with which numbers of people have been seized in some years, owing to their having lived upon bread in which there was much rye affected with this distemper.

"As most of the distempered grains are much bigger than the sound ones, it is easy to separate the greatest part of them by sifting. It is what the peasants of Sologne do, when corn is not dear; but in times of great scarcity or dearth, they are loth to lose so much grain; and then it is that they are attacked with a dry gangrene, which mortifies the extreme parts of the body, so that they fall off, almost without causing any pain, and without any hæmorrhage. The Hotel-Dieu at Orleans had had many of these miserable objects, who had not any thing more remaining than the bare trunk of the body, and yet lived in that condition several days.

"As it is not every year that the spur in rye produces these dreadful accidents, Langius is of opinion that there may be two kinds of this distemper; one, which is not hurtful, and the other which occasions the gangrene we have been speaking of. It is however probable that there is but one kind of spur, and that it does not hurt; first, when sufficient care is taken in sifting the grain; and, secondly, when only a small part of the corn is distempered. It is also said, that the spur loses its bad quality after the grain has been kept a certain time: in which case, the reason why some peasants are attacked with the gangrene in years of dearth, may be, that they consume their crop as soon as the harvest is over." *Duhamel's Culture des Terres.*

SPURRE-WAY, a horse-way through inclosed lands, and free to any one to ride in by right of custom.

SPURREY, the name of a weed common in many parts of England. It seldom rises above six inches in height, flowers in the beginning of July, ripens its seed in August, and is an annual plant.

The best method of exterminating this weed is by summer fallows, and cutting it down before it can scatter its seeds, which are very small.

They cultivate two species of this plant in Holland and Flanders for the winter food of cattle, when there is a scarcity of grass. It is said to enrich the milk of cows so as to make it afford excellent butter; and the mutton fed on it is preferable to that fed on turneps. Hens also eat this plant greedily, and it is commonly thought to make them lay an extraordinary number of eggs.

Though this plant cannot, from the lowness of its growth, afford a very great quantity of fodder, yet as it will grow on the poorest land, where no other grass will thrive so well, it may be cultivated to considerable advantage in many places; and by feeding it off the ground, the dung of the cattle will improve the land.

The farmers in the low countries commonly sow it twice a year; the first time in April and May, to be in flower in June or July; and the second time after their rye-harvest, to serve their cattle in November and December. The usual allowance with them is about twelve pound of seed to an acre.

STABBING of cattle. See the article **HOVEN**.

STABLE, a place or house for horses, &c. furnished with stalls and proper apartments to contain their food, &c.

Nothing conduces more to the health of a horse than the having a good and wholesome stable. The situation of a stable should always be in a good air, and on a firm, dry, and hard ground, that in winter the horse may go out and come in clean. It should always be built somewhat on an ascent, that the urine and other foulnesses may be easily conveyed away by means of trenches or sinks for that purpose. As there is no animal that delights more in cleanliness than the horse, or that more abominates bad smells, care should be taken that there be no hen-roost, hog-

hog-stie, or necessary house, near the place where the stable is to be built, for the swallowing of feathers, which is very apt to happen, when hen-roosts are near, often proves mortal to horses; and the steams of a bog house or hog's dung will breed many distempers. The walls of a stable, which ought to be of brick rather than stone, should be made of a moderate thickness, two bricks, or a brick and a half at least, for the sake of warmth in the winter, and to keep out the heat in the summer. The windows should be made on the east or north side of the building, that the north wind may be let in to cool the stables in the summer; and the rising sun all the year round, especially in winter. The windows should either be sashed, or have large casements, for the sake of letting in air enough; and there should always be close wooden shutters, that the light may be shut out at pleasure, by which means the horse may be made to sleep in the day as well as in the night, when it is judged proper he should do so. Many pave the whole stable with stone, but that part which the horse is to lie on should be boarded with oak planks, which should be laid as even as possible, and cross-wise rather than length-wise; and there should be several holes bored through them to receive the urine, and carry it off underneath the floor into one common receptacle; the ground behind should be raised to a level with the planks, and it should be paved with small pebbles. There are two rings to be placed on each side of the stall, for the horse's halter to run through, and a logger is to be fixed to the end of this sufficient to poise it perpendicularly, but not so heavy as to tire the horse, or to hinder him from eating; the best place for him to eat his corn in, is a drawer or locker made in the wainscot partition, which need not be large, so that it may be taken out at pleasure to clean it, by which means the common dirtiness of a fixed manger may be avoided. Many people are against having a rack in their stables; they give the horse his hay sprinkled upon his litter, and if they think he treads it too much, they only nail up three or four boards, by way of a trough, to give it to him in: the reason of this is, that the continual lifting up of the head to feed out of the rack, is an unnatural posture for a horse, who was intended to take his food up from the ground, and makes him, as they express it, withy-cragged. When there is stable-room enough, partitions are to be made for several horses to stand in: these should always allow room sufficient for the horse to turn about and lie down conveniently, and they should be boarded up so high towards the head, that the horses placed in separate stalls may not be able to smell at one another, nor molest each other any way. One of these stalls ought to be covered in, and made convenient for the groom to lie in, in case of a match, or the sickness of a horse. Behind the horses there should be a row of pegs, to hang up saddles, bridles, and other utensils; and some shelves for the brushes, pots of ointment, &c. The other requisites for a stable are a dung-yard, a pump, and a conduit.

Mr. Young, in his *Annals of Agriculture*, vol. VII. gives the following account of littering stables with sand, instead of straw. "Yarmouth is in a manner surrounded by marshes and the sea; straw of course becomes there a dear article. This, and the vicinity of the sea-shore, has established a practice, which I believe has been in use time immemorial, of littering stables with sea-sand instead of straw. As the bed becomes soiled or wet, fresh sand is scattered on, until the whole is in a degree saturated with dung in urine; the stall is then cleared, and a fresh bed of sand laid in. By this means, much of a quality singularly excellent is produced; it is fetched by the farmers of the Fleg hundreds to a very great distance.

To the want of general cleanliness, pure air and regular exercise may be justly attributed all the ills which attend those horses kept at inns and livery-stables. Upon entering the major part of their stables (particularly if the door has been a few minutes closed and is opened for your admission) you are instantly assailed with a disagreeable smell of dung and urine. Here you find from ten or twelve to twenty horses, standing as hot, and every crevice of the stable as closely stopped, as if the very external was infectious, and its admission must inevitably propagate a contagion. You observe each horse standing upon an enormous load of litter, that by occasional additions (without a regular and daily removal from the bottom) has acquired both the substance and property of a moderate hot-bed. Thus stand these poor animals a kind of patient sacrifice to ignorance and indifferetion, and what is an additional contribu-

tion of folly, each horse is loaded with a profusion of body cloaths. In this state such horses are found to be in an almost perpetual languid perspiration; so depressed and inactive, for want of pure air and regular exercise, that they appear dull, heavy, and inattentive, as if conscious of their imprisonment and bodily persecutions. The effect of this mode of treatment soon becomes perceptible to the judicious eye of observation. The carcase seems full and overloaded for want of gentle and gradual motion; the legs become swelled, stiff, and tumefied, and terminates in either crack, scratches, grease, or some other disorder. The hoofs by being constantly fixed in heat of dung, acquire a degree of contraction indicating hoof-bound lameness. The eyes frequently give proof of habitual weakness, in a watery discharge, the heat of the body, &c. all tending to constitute a frame directly opposite in health, vigour, and appearance, to those whose condition is regulated by a very different system of stabularian management.

STACK, a large quantity of corn, hay, straw, &c. regularly piled up; and generally thatched to defend the contents from the weather.

It is very common, in order to preserve corn in the straw, to make it up into stacks, by which means they often meet with very great losses by the dampness of the ground, which commonly rots and spoils it, sometimes near a yard thick; and by rats and mice, and other vermin that breed in the stack, which eat and devour a great part thereof. To prevent both these inconveniencies, where timber is plentiful, they set four, or six, or more posts into the ground, according to the bigness that they design the stack, granary, or barn that the corn is to be laid in: on these posts they lay what is the ground plats of other buildings, upon which they make a floor, or lay pieces across to support the stack: and if they make a barn or granary of it, they erect sides and a roof upon it; but if only a stack, they cover it with thatch, and the post that support it is, by some persons, covered round with tin near the top, for about a foot or so in breadth, in order to prevent the mice and rats getting up. But as tin is apt to rust, and so to lose its smoothness, it will not answer the design long; therefore the better to prevent their getting up, is to cover them with Dutch tiles, which will always keep smooth. But in Hampshire and other counties, where they have plenty of stone, they make their supporters of two stones, which is the best way.

The lower stone is about three feet high, two feet wide at the bottom, and one at the top; over this they lay another stone, of about a yard square: some make it of a round form, which is the best. This prevents not only the mice and rats from climbing up, but also the dampness of the ground: and this way you may keep corn as long as you will, without much inconvenience or loss, except what it loseth in the first year's shrinking, and loss of weight, which is very inconsiderable. Only you must observe, that what corn you stack must be bound up in sheaves, that so the ears of the corn may be turned inward, and the straw ends out, which will save the corn from pigeons, crows, and other fowls, and likewise from the rain that beats on the sides. If your stack be of wheat, you may lay oats or other coarse grain on the top of it, under the thatch, the greatest danger of wet being from the top, if any of the thatch should blow off. And if you suspect any rats or mice have got into the stack, grease a stick and thrust it into it; and if there be any, they will gnaw the stick. The chief inconvenience that attends this way of keeping of corn, is its bulkiness, and the farmer's wanting of his straw to make dung with, and the chaff to give to his cattle, &c. *Also timer's Husbandry*, vol. II. p. 141.

Mr. Marshall, in his *Minutes of Agriculture*, recommends, to hinder the rats from harbouring in truss-bound straw, and gnawing the bands; and to save the trouble and expence of stacking it out of doors, stacking it in the barn, leaving a passage round it for dogs, cats, and rat-killers; and vacancies between the trusses of the first and second layer, wide enough for a tarrier, cat, or ferret, to creep under every part of the pile.

This judicious gentleman-farmer recommends the form of the stacks to be rather smaller than in general has been the method; but he remarks, though at first they appear awkwardly tall and top-heavy while it shall be making; but when the roof is on, and the stack settled, it considerably improves in appearance, and has the advantage of not taking

ing-up so much roots, or requiring so much thatch as they generally do that are made on the old plan. He lays down the following as general rules worth remembering.

A square, not round nor a parallelogram, is the best form of a stack-frame at bottom; this figure is more pleasing to the eye, takes less thatch, and stands firmer, taken jointly, than any other.

The stem should be carried up as plumb as possible, (except the last course, which should project five or six inches, to form the eaves); for the weight of the roof will press out the upper part of the stem sufficiently. If it over-hang in making, its own weight and the weight of the roof will squeeze it too flat, will spoil its appearance, and waste both thatch and thatching.

The stem should contain about two thirds, and the roof one third of the whole stack. If it be built on a frame, the stem should contain less, and the roof more; if on a bottom, the reverse. The corners of the stem should not be built too sharp; should be carried up snug; by which the sides will look fuller, and the swell given by the pressure, will be more perceptible.

The ends of the roof should have a gentle projecture, answerable to the stem; and the sides should be carried up rather convex, than flat or concave. Perhaps a roof gently convex shoots off the rains preferable to any other.

A corn-stack should not contain above 21 loads, as the risk of making and getting-in is much less on a small than on a large-stack; besides, a large stack does not settle so true as a small one, and of course will not stand the weather so well. It is true, a large stack does not in proportion take so much thatch and thatching, which is its only advantage.

STACK of Wood, a pile of wood three feet long, as many broad, and twelve feet high.

STADLE, the bottom of a corn mow, or hay-stack. It also signifies a tree suffered to grow for coarse or common uses, as posts or rails.

STAG-EVIL. See the article **STAGGERS**.

STAGGERS, a disease incident to horses: a kind of apoplexy.

Farriers generally include all distempers of the head, under two generally denominations, viz. staggers, and convulsions, wherein they always suppose the head primarily affected. But in treating these disorders, we shall distinguish between those that are peculiar to the head, as having their source originally thence, and those that are only concomitants of some other disease, where the head is affected secondarily by consent of nerves, the source of this disorder being in the stomach, bowels, &c. By this method we shall avoid many blunders which would otherwise arise in practice, for want of knowing the true seat of the disorder.

In an apoplexy a horse drops down suddenly, without other sense or motion than a working at his flanks.

The previous symptoms are drowsiness, watery eyes, somewhat full and inflamed; a disposition to reel, feebleness, a bad appetite; the head almost constantly hanging, or resting on the manger; sometimes with little or no fever, and scarce any alteration in the dung or urine: the horse is sometimes disposed to rear up, and apt to fall back when handled about the head, which is often the case with young horses, to which it does not prove suddenly mortal, but with proper help they may sometimes recover. If the apoplexy proceeds from wounds, or blows on the head, or matter on the brain, besides the above symptoms, the horse will be frantick by fits, especially after his feeds, so as to start and fly at every thing. These cases seldom admit of a perfect recovery; and when horses fall down suddenly, and work violently at their flanks, without any ability to rise after a plentiful bleeding, they seldom recover.

All that can be done is to empty the vessels as speedily as possible, by striking the veins in several parts at once, bleeding to four or five quarts, and to raise up the horse's head and shoulders, supporting them with plenty of straw. If he survives the fit, cut several rowels; give him night and morning, glysters prepared with a strong decoction of fenna and salt, or the purging glyster; blow once a day up his nostrils a dram of powder of asarabacca, which will promote a great discharge, afterwards two or three aloetic purges should be given; and to secure him from a relapse, by attenuating and thinning his blood, give him an ounce of equal parts of antimony and crocus metallorum for a month; or which is

preferable, the same quantity of cinnabar of antimony and gum guaiacum.

If the fit proceeds only from fulness of blood, high feeding, and want of sufficient exercise, or a fizy blood (which is often the case with young horses, who though they reel, stagger, and sometimes suddenly fall-down, yet are easily cured by the above method), an opening diet with scalded bran and barley will be necessary for some time; and the bleeding may be repeated in small quantities.

As to the other disorders of the head, such as a lethargy, or sleeping evil, epilepsy, or falling sickness, vertigo, frenzy, and madness, convulsions, and paralytical disorders, as they are most of them to be treated as the apoplexy and epilepsy, by bleedings and evacuations, with the alteratives they are directed, we shall wave treating on them separately but mention some particular rules to distinguish them, according to the plan we laid down, and then offer some general remedies for the several purposes.

Thus, in order to distinguish epileptic disorders and convulsions (which are often occasioned by worms, bots, and ulceration of the stomach, bowels, and midriff) from those which arise from original causes in the head only, we shall describe the symptoms which distinguish them from each other; by which means we shall be able to avoid any mistake in the application of the remedy: and as epileptic disorders have by ignorant farriers been mistaken for the gripes, we shall also distinguish these disorders by the symptoms.

In an epilepsy, or falling sickness, the horse reels and staggers, his eyes are fixed in his head, he has no sense of what he is doing, he stales and dungs insensibly, he runs round and falls suddenly; sometimes he is immovable, with his legs stretched out, as if he was dead, except only a quick motion of his head and lungs, which causes a violent working of his flanks: sometimes he has involuntary motions and shaking of his limbs, so strong, that he has not only beat and spurned his litter, but the pavement with it; and with these alternate symptoms a horse has continued more than three hours, and then has as surprisingly recovered; at the going off of the fit, he generally foams at the mouth, the foam being white and dry, like what comes from a healthful horse when he champs on the bit.

But in all kinds of gripes, whether they proceed from disorders in the guts, or retention of urine, a horse is often up and down, rolls and tumbles about, and when he goes to lie down generally makes several motions with great seeming carefulness, which shews he has a sense of his pain, and if he lays stretched out for any time, it is generally but for a short space.

Epilepsies and convulsions may arise from blows on the head, too violent exercise, and hard straining; and from a fullness of blood, or impoverished blood, and surfeits; which are some of the causes that denote the original disorder.

But the head may also be affected by sympathy of nerves; for excessive pain in any part of the body will excite convulsions, especially if the nerves and tendinous parts are affected, as by wounds, punctures, and bruises externally; and by ulcers, gatherings of matter, and by bots and worms, wounding and vellicating the nervous parts internally; long costiveness has sometimes also occasioned these disorders. In all such cases, the original cause must principally be attended to.

In lethargic disorders the horse generally rests his head with his mouth in the manger, and his pole reclined to one side; he will shew an inclination to eat, but generally falls asleep with his food in his mouth, and he frequently swallows it whole, without chewing: emollient glysters are extremely necessary in this case, without the nervous balls recommended for the staggers and convulsions: strong purges are not requisite, nor must you bleed in too large quantities, unless the horse be young and lusty. In old horses rowels and large evacuations are improper, but volatiles of all kinds are of use, when they can be afforded; an alterative purge may be given and repeated on his amendment.

This distemper is to be cured by these means, if the horse is not old and past his vigour. It is a good sign if he has a tolerable appetite, and drinks freely without flabbering, and if he lies down, and rises up carefully, though it be but seldom.

But if a lethargic horse does not lie down, if he is altogether stupid and careless, and takes no notice of anything that comes

near him ; if he dungs and stales seldom, and even while he sleeps and dozes, it is a bad sign if he runs at the nose thick white matter, it may relieve him, but if a viscid gleet that sticks to his nostrils like glue, which increasing, turns to a profuse running of ropy, reddish, and greenish matter, it is an infallible sign of great decay of nature ; and that it will prove mortal.

Young horses from four to six years, are very subject to convulsions, from bots in the spring ; and the large coach-breed more than the saddle : they are seized without any previous notice, and if bots and worms are discovered in their dung, the cause seems to be out of doubt, more especially if they have lately come out of a dealer's hands.

When this convulsion proceeds from a distemperature of the midriff, or any of the principal bowels, it is to be distinguished from bots and vermin, by previous symptoms : the horse falls off his stomach ; and grows gradually weak, feeble, and dispirited in his work ; and turns short-breathed with the least exercise.

The lively description of that universal cramp, or convulsion, called by some the stag evil, which seizes all the muscles of the body at once, and locks up the jaws, so that it is impossible almost to force them open, we shall give in Mr. Gibson's own words ; who says, As soon as the horse is seized, his head is raised with his nose towards the rack, his ears pricked up, and his tail cocked, looking with eagerness as an hungry horse when hay is put down to him, or like a high spirited horse when he is put upon his mettle ; inasmuch that those who are strangers to such things, when they see a horse stand in this manner, will scarce believe any thing of consequence ails him ; but they are soon convinced, when they see other symptoms come on apace, and that his neck grows stiff, cramped, and almost immovable ; and if a horse in this condition lives a few days, several knots will arise on the tendinous parts thereof, and all the muscles both before and behind, will be so much pulled and cramped, and so stretched, that he looks as if he was nailed to the pavement, with his legs stiff, wide, and straddling, his skin is drawn so tight on all parts of the body that it is almost impossible to move it ; and if trial be made to make him walk, he is ready to fall at every step, unless he be carefully supported ; his eyes are so fixed with the inaction of the muscles, as gives him a deadness in his looks ; he snorts and sneezes often, pants continually with shortness of breath : and this symptom increases continually till he drops down dead ; which generally happens in a few days, unless some sudden and very effectual turn can be given to the distemper.

In all these cases the horse should first be bled plentifully, unless he is low in flesh, old, or lately come off any hard continued duty, then you must be more sparing of his blood ; afterwards give the following ball :

Take assa foetida half an ounce ; Russia castor powdered, two drams ; valerian root powdered, one ounce ; make into a ball with honey and oil of amber.

This ball may be given twice a day at first ; and then once, washed down with a decoction of mistletoe, or valerian, sweetened with liquorice or honey : an ounce of assa foetida may be tied up in a piece of strong coarse linen rag, and put behind his grindlers to champ on.

The laxative purges and emollient glysters should be given intermediately to keep the body open ; but when the former balls have been taken a week or ten days, the following may be given once a day with the valerian decoction.

Take cinnabar of antimony six drams ; assa foetida half an ounce ; aristolochia, myrrh and bayberries, of each two drams : make into a ball with treacle and oil of amber.

This is the most effectual method of treating these disorders ; but when they are suspected to arise from bots, and worms, which is generally the case, mercurial medicines must lead the way. Thus,

Take mercurius dulcis, and philonium, of each half an ounce : make into a ball with conserve of roses, and give the horse immediately ; half the quantity may be repeated in four or five days.

The following infusion should then be given, to the quantity of three or four horns, three or four times a day, till the symptoms abate ; when the above nervous balls may be continued till the bots are removed.

Take penny-royal and rue, of each two large handfuls ; chamomile flowers one handful ; assa foetida and castor, of each half an ounce ; saffron and liquorice root sliced, of each two drams : infuse in two quarts of boiling water ; pour off from the ingredients as wanted.

If the castor is omitted, add an ounce of assa foetida.

The following ointment may be rubbed into the cheeks, temples, neck, shoulders, spines of the back, and loins, and wherever there is the greatest contractions and stiffness.

Take nerve and marshmallow ointment, of each four ounces ; oil of amber two ounces ; with a sufficient quantity of camphorate spirit of wine : make a liniment.

To horses of small value give the following :

Take rue, penny-royal, and tobacco, of each a handful ; assa foetida an ounce ; boil in a quart of forge-water : let the decoction stand on the ingredients, and give as the former.

When the jaws are so locked up that medicines cannot be given by the mouth, it is more eligible then, to give them by way of glyster : for forcing open the jaws by violence, often puts a horse into such agonies, that the symptoms are thereby increased. The infusion above may be given for this purpose, or the following :

Take rue, penny-royal, and chamomile flowers, of each a handful, valerian root two ounces, boil in five pints of water to two quarts ; in the strained liquor dissolve castor and assa foetida, of each half an ounce, or of assa foetida alone one ounce, common oil four ounces. Give this glyster once a day.

In this case also he must be supported by nourishing glysters, made of milk pottage, broths, &c. which must be given to the quantity of three or four quarts a day ; glysters of this kind will be retained, and absorbed into the blood ; and there have been instances of horses thus supported for three weeks together, who must otherwise have perished.

Mr. Gibson mentions some extraordinary instances of success in cases of this sort by these methods, and repeated frictions, which are extremely serviceable in all convulsive disorders, and often prevent their being jaw-set ; they should be applied with unwearied diligence every two or three hours, wherever any stiffness or contractions on the muscles appear, for a horse in this condition never lies down till they are in some measure removed.

He takes particular notice of a horse, whose jaws were so locked up for three weeks, that both food and medicine were forced to be given by glyster ; that not having recovered the use of his jaws for a fortnight, though he now moved them with less stiffness, he was determined, from the known relaxing power of opium, to give him half an ounce of it, dissolved in one of his glysters, the good effects of which were so evident, by a general amendment, that he was encouraged to continue it in the following manner :

Take Matthew's pill, and assa foetida, of each an ounce : make into a ball.

This ball he gave for one dose, and repeated once : and by this, and the use of the nervous medicines given twice a week, and gentle purging, the horse was perfectly recovered.

The use of rowels in these cases is generally unsuccessful, the skin being so tense and tight, that they seldom digest kindly, and sometimes mortify ; so that if they are applied, they should be put under the jaws, and in the breast.

The red hot iron so frequently run through the fore-top and mane, near the occipital bone, for this purpose, has often been found to have destroyed the cervical ligament. See the article ROWEL. Bartlett's Farriery, p. 78.

A stable-keeper asserts, that he had lost several horses in the staggers, when he was persuaded to keep a he-goat in the stable. This he at first looked on as a vulgar superstition, and neglected paying any attention to it ; but on losing more horses in the same way, he procured a he-goat, which lived about nine years, and during that time the stable-keeper declared his stables were totally free of the staggers, and although they contained a great number of horses. A few months after the death of the goat, he lost several horses in that disease, which induced him to procure another he-goat, to ascertain, by experience, whether the goat was a pre-

a prevention of the like misfortune ; which he asserts with great confidence is such, as from the time he procured a second goat, he has never lost a single horse by that complaint, and the goat still remains in the stables.

Sheep are also subject to the staggers, and the best remedy they find for it is, to drive them to change of grounds, often, to keep the grounds from tainting.

" I observe, says Mr. Lisle, that those lambs which die of the staggers, do not die till they begin to eat grafs, and of those the finest and lustiest ; whence I conclude, that it is not the cold weather alone that brings the staggers, but from their feeding on cold watery grafs in the months of March and April, which makes them abound in watery humours in the bodies, which the cold winds seize on and chill, and bring those cramps and aches into their limbs. It is observed this disease is much prevented by the early folding of lambs, and with good reason, for thereby, in the cold nights, the lambs are kept warm, and also prevented from eating so much grafs as they otherwise would, whereby such watery humours are fed. *Lisle's Husbandry*, vol. II. p. 210.

STAGGERWORT. See the article **RAGWORT**.

STAKE, a piece of wood, or strong stick fixed in the ground.

STALE, urine.

STALK, the stem, or stock of a plant.

STALL, a crib at which a horse is fed, or where any horse is kept in a stable.

STALL-FED, fed with dry food, not with grafs.

STALL-FEEDING. See **FATTENING**.

STALLION, a stone-horse, designed for the covering of mares, in order to propagate the species. See the article **HORSE**.

STAMWOOD, the root of trees grubbed up.

STANCHING BLOOD ; in case a horse, &c. happens to be cut or hurt, fill the cut full of the wool of a hare or rabbit, and hold it in some time with your hand, or else bind it on the part ; then burn the upper leather of an old shoe, and strew the ashes among the wool, and let it lie on for twenty-four hours, and it will stanch the bleeding. Or,

Boil together honey, wax, turpentine, swine's grease, and wheaten flour, stirring and mixing them well together, till they are become an ointment, then take it off the fire, and put it up in a gallipot for use ; but if the cut be of any considerable depth, put in a tent of flax, or linen cloth dipped in the ointment, and lay a plaister of the same over it, letting it lie on twenty-four hours.

If a horse happens to bleed violently at the nose, stamp betony in a mortar with salt, and put it into his nose, applying it to the wound and it will stop it : but if he be taken suddenly in the highway, &c. and you cannot get the herb, scrape a felt hat or piece of woollen cloth with a knife, and apply it to the part, and it will stanch it.

STANDARDS, or *Standrels*, signify the young trees reserved at the felling of woods, for the growth of timber.

STANDARDS, also imply fruit trees, intended to grow in an open exposure, and not to be hacked and mangled with the knife, as the dwarf trees, and those planted against walls are.

STANK, a dam, or bank to stop water.

STANNER-WORT. See the article **RAG-WORT**.

STAVERS. See the article **STAGGERS**.

STEE, a ladder.

STEEPS, certain preparations for steeping of corn intended to be sown. See the article **SEED**.

STEELE, a stalk, a handle.

STEER, a young bullock.

STEM, that part of a plant arising from the root, and which sustains the leaves, flowers, fruits, &c.

STEG, a gander.

STERCORARY, a collection of dung properly secured from any injuries of the weather.

In collecting manures from time to time, as they come to hand, farmers generally keep them together in what they call dung-hills, where they remain exposed to the heat of the sun, the washing of rain, and drying winds : by which means all their virtue is drawn forth, and carried away. M. Evelyn justly censures this wrong practice, and at the same time gives the following directions for making a stercorary, to contain the compost collected by husbandmen.

Dig a square or oblong pit, of the size suited to the quantity of compost wanted, or proportioned to the ex-

tent of the ground intended to be manured. Let the side next the fields be made sloping, so as to receive a cart to load or unload easily. Let the bottom be well paved, and both the sides lined, unless it be made in a bed of clay or chalk, that it may be capable of retaining water like a cistern ; for it is of great importance, as Columella observes, that the dung be well soaked in liquor, in order to destroy the vegetative faculty of the seeds of weeds which may chance to be mixed with it, or the litter. If channels or gutters can be directed to this pit, from the stables and offices about the house, they will be of great service. Mr. Evelyn is of opinion that this stercorary should be under cover, so as at least to hinder downright rains from falling upon it :—but if care be taken to make the pit in a place where no running water, or springs can come to it, and if the farmer covers the dung, as it is collected, with a coat of mould, to prevent the sun's exhaling, or the rain's washing away its richness, I cannot help thinking that the quantity of water which falls in rain, would not be more than requisite to moisten the mixture, and bring on that putrid fermentation which is necessary for the due incorporating and perfecting of the compost. It will, however, be right to have a shed to put over it occasionally, in case the season should prove extremely wet.—Columella informs us, that the Romans covered their stercoraries with hurdles ; but does not speak of covering them with mould, as here directed.

The pit being thus prepared, the farmer's next study should be to fill it with a compost suited to the nature of his land. Thus, if his soil is a strong clay, a layer of dung should be covered with a layer of sand, rubbish of old houses, or other substances already mentioned for the improvement of clay. Litter of all kinds becomes of good addition, because it is slow in decaying, and if mixed with the clay, keeps its parts asunder. The compost for meliorating clay may be carried out, and mixed with the earth, fresher than for any other soil ; because in this state, it will more effectually keep the particles of the clay separated ; and if some degree of its putrefaction is carried on in the soil, it will much more powerfully open it. If, on the contrary, the soil is sand, the dung should be mixed with clay, scouring of ponds, or other fat slimy substances, which may give consistence to the sand. And if the farmer is happy in a soil in which neither of the extremes prevail, he may then mix his manure with the richest mould he can find, and incorporate them well together, by frequent turning, before the compost is carried to the field. Columella thinks they are slothful husbandmen, who, in thirty days, have not a load of dung of twenty bushels, from each of the lesser cattle, and ten loads from each of the larger sort, by means of judicious mixtures with their dung. He thinks this mixture, or compost, most beneficial to corn, after it is a year old ; because it still retains all its strength, and does not then breed weeds.

" Many good effects, says Dr. Home, particularly that of hindering the oils from being volatilized, and of fixing them, will arise from a mixture of lime with these composts, after they are thoroughly rotted. But as many experiments have proved that quick-lime powerfully resists putrefaction, it does not seem judicious to mix it with dunghills which are not sufficiently putrefied, as it must stop that process.

" There is a very great attraction betwixt quick-lime and all oily bodies. It unites intimately with expressed oils. With this intention it is used in the manufacture of soap, to help the junction of the alkaline salts and oils. It must, therefore, attract the oils powerfully from the air and earth, dissolve them, and render them miscible with water : it must, from this reason, soon exhaust the soil of all its oleaginous particles, if the farmer does not take care to supply them by dung or animal substances. Farmers have, by experience, discovered it to be a great impoverisher of lands ; but they did not know how it acted. Its operation is, to exhaust the earth of its oils. The proper cure for this is, to mix dung with the lime, so that it may have something to act on.

" Lime is a great dissolver of all bodies, both vegetables and animal ; but particularly the latter. We know how soon it reduces hair and woollen rags into a pulpy substance. This effect is so strong, that in the common method of speaking, it is said to burn them. In this way it certainly operates in the earth, by dissolving all animal and dry vegetable substances, and converting them to the nourishment of vegetables, at least sooner than otherwise they

they would be. Like other calcarious bodies, it is not dissolvable but by acids. With these, a great effervescence happens, a solution of the calcarious body is made, and a neutral salt is formed from that conjunction. This neutral salt is always soluble in water, unless where the acid of vitriol is used." *Home's Principles of Vegetation*, p. 69, 70.

The Society of Improvers in the Knowledge of Agriculture in Scotland, have paid great attention to the subject of composts, and are very particular in their instructions on this head, to several of their correspondents. I gladly take this opportunity of paying the tribute of praise justly due to their public spirit, and congratulate them on the great success which has attended their labours in many parts of their country. At the same time I cannot help regretting, that, though all our neighbours have set us so many examples of periodical instruction in this most useful art, there are yet many institutions of that kind in England. It is to be hoped, that the Society for the Encouragement of Arts, Manufactures and Commerce, will soon take off this reproach, and not suffer it to be longer said that agriculture lies neglected in this kingdom, where the people enjoy every advantage requisite to promote it, in a far higher degree than the inhabitants of any other country in the world. The wealth of our farmers is incomparably greater; their property, and the tenure of their lands are infinitely better secured; and the happiest of soils and climates combine to reward their labour.

The Society in Scotland gave to a gentleman who had written to them, and who had clay and lime at command, the following judicious directions for collecting a compost, or making a stercorary, for the improvement of a sandy soil. "Take, say they, in the field intended to be manured, a head ridge, the most conveniently situated for a stercorary. Plough it two or three times, as deep as can be in the cleaving way, if the ridge be high gathered, and harrow it well: then lay thereon your slimy clay, about a foot thick, leaving a part of the ground uncovered: next lay a thin layer of dung, another of clay, and after that a layer of unslaked lime, at least a foot thick: then throw up the earth left uncovered on each side. After this, repeat another layer of clay, and lime-stone, as before, and finish it with a layer of clay and sea-wreck, covered with earth. The more of the slimy clay the better: for though it may be cold, yet it will not be the worse for a sandy hot ground. If you examine the clay, we doubt not but you will find it a very fat substance; being, as we conjecture, mostly muscle and other shells mixed with earth, brought by the tide and river Southesk. On the coast of Lothian we found that slimy substance to be nothing else; and if it be so with you, it is certainly one of the best manures.

"After this stercorary has stood six weeks or two months, incorporating and fermenting, turn and mix it; and that this work may be performed to the better purpose and with as small an expence as possible, yoke your plough, enter upon your stercorary with a cleaving furrow, and continue repeating the ploughings the same way, until the very bottom of the stercorary be ripped up; then harrow it: it is impossible to over-do it. If it be very cloddy, it should be harrowed between the ploughings. Begin then in the middle, and plough again and again in the gathering way, until it be brought into as narrow bounds, and be raised as high as possible. Let all that the plough has left be gathered up, and thrown with shovels on the top. Every such turning and heaping occasions a new ferment, and improves the manure. If the seeds of barley, or of any other quick growing vegetable, were sprinkled thin on the stercorary, and the plants buried in it, when fullest of sap, before they come to seed, by turning or more heaping, the manure would be improved." This might be repeated several times in the course of the season; for the practice has been found successful. *Maxwell's Collection*, p. 26.

In another place, they observe, that such a stercorary may be turned in the same manner as ground is trenched. The higher it is raised the better. Each turning will make it heat like a garden hot-bed, and this fermentation will reduce it to a fine fat mould. If the first heat should go off (which may easily be known by thrusting a pole into it) before it has produced this effect, it may be turned over again, and will take a new heat, which is of great advantage to it, besides the better mixing of the several manures. About fifty or sixty cart loads of this compost

are used upon an acre of ground. I have been the more particular in extracting this account, because any farmer, by attending to the rules here given, may suit his compost to the nature of his soil. Where the soil varies, he will do well to have another stercorary, properly composed, in a convenient part of the field he intends to manure.

The same society, in their directions for the management of sheep's dung, where the sheep are housed, or fed under cover, during the inclemency of the winter, advise laying under them substances suited to the nature of the soil intended to be improved. A layer of sand, for instance, for stiff land, will be greatly benefited by being covered with a couch of litter in the sheep-house. When their dung becomes troublesome or offensive to them, or begins to make them dirty, the whole should be removed to the stercorary. But if the dung of the sheep is to be laid on a sandy soil, clay, or any such substance, though covered with litter, it would soon become wet, and too cold for the sheep to lie on; it would therefore be better, in this case, to spread a thick couch of litter under the sheep, and mix this in the stercorary with the lime, &c. by which means the same advantage may be obtained, without injury to the cattle. If loam, or a rich mould, be laid under sheep, the judicious farmer will be careful to collect a sufficient quantity of it, when it may be got dry, in the summer. Whatever is used for this purpose, should be renewed as often as it is sufficiently impregnated by the urine and dung of the sheep.

The well preparing of mixed dung, is, as Mr. Worlidge rightly insists, a piece of husbandry by no means to be neglected; for the more and better the dung is, the greater will be the crop; and an increase of the crop will augment the quantity of dung. On the contrary, a decay in the dung makes a decay in the crop, &c. The rise or fall of the value of many farms in this kingdom must therefore necessarily depend upon the good or bad management of this essential part of husbandry. See the article DUNG-HILL.

The carriage being a principal article of the expence of manuring land, the farmer should endeavour as much as possible, to save this expence; for which purpose he should contrive to dress the lands of his farm, that lie at the greatest distance from the home stead, with such manures as are of the lightest carriage; such as soot, coal, or peat ashes, pigeon dung, lime, &c. and with the sheep fold.

Next to these in cheapness, is making composts upon the head lands, as recommended above by the Edinburgh Society. In arable fields, the earth of the head lands is continually accumulating by the plough turning upon them, inasmuch that in no long course of time, the head lands are thereby raised so high above the adjoining parts of the field, that they obstruct the current of the water that should be discharged there from the furrows, and keep the land wet; for which reason it is advisable to carry the earth frequently off the head-lands, so that they may lie lower than the contiguous ridges; and to turn this earth to the best account, it may be mixed and made into a compost, with dung or other manure, and afterwards carried and spread upon the field. If the head-lands at the two opposite ends of the field are thus prepared, and the compost carried from each end, and spread till it meets in the middle, half the carriage will be saved, which will render this a cheap method of manuring.

Instead of carrying the compost upon the land as soon as it is mixed with the earth of the head-land, if the head lands are planted with potatoes in the spring, a good crop of them may be obtained, and the tillage bestowed upon them will thoroughly mix the compost, and prepare it to be laid on the field.

But for such lands as are situated near the farm-yard, it is best to collect the manure there: and if the farm-yard is laid regular, having a hard dry bottom, and the sides rising gradually all round, so as to form a kind of basin, a great deal of excellent manure may be collected there, without losing any of the dung or urine of the cattle: for this purpose some good mould should be spread all over the yard, and fern, straw, litter, or stubble upon the mould; and when that is trod and mixed by the cattle, add more mould and straw. The cattle should be foddered, and the dung from the stables regularly spread all over the yard, till the whole is sufficiently raised, to be collected in heaps, and then covered with earth: this will prevent the dung being wasted by the sun

sun and drought; and the drainings from these heaps, being thrown up from time to time upon them, a moderate fermentation will be kept up, and great quantities of excellent manure will be thus obtained.

Those who give directions in what manner to prepare composts, commonly advise to lay strata of different materials, clay, lime, dung, &c. each six or eight inches, or even a foot thick; but when clay or strong earth is laid so thick, the fermentation of the intermediate layers, not being strong enough to penetrate those thick strata; when the compost is turned, they rise in great lumps, and must be several times turned and broken before the whole can be thoroughly mixed and incorporated. It is therefore a much better way to lay the several ingredients in thin layers at first, and still better to lay them in heaps, round the foundation of the compost dunghill: and if men are employed, one or more at each heap to throw up and spread them equally over the compost heap, still, as it rises, the materials will thus be well mixed at first, the fermentation will go on regularly, and the compost will be prepared, and ready to lay on the land sooner, and in much better order, than if made of thick layers of strong earth.

STERILE, barren, unfruitful.

STEW, is a kind of fish-pond, contrived for serving the daily use of a family, so that with little trouble the house may be furnished with fish at any time.

This should be so situated as to be near the chief mansion-house, and inclosed, the better to be defended from robbers.

If you have two great waters of three or four acres a-piece, it will be proper to have four stews, of two rods wide and three rods long each.

In making of these the sides should be cut down sloping, carrying the bottom in a continual decline from end to end, so as you may have a convenient mouth, as horse-ponds have, for the taking out your nets when you have drawn for fish; and if you have room enough you may make a mouth at both ends, and the deepest part should be in the middle, by which means your net may be drawn backwards or forwards, and the fish should not have such shelter as a depth under a head will be.

Add to this, that fish will delight in coming upon the shoals, and in all probability thrive the better.

These may chiefly be reserved for carp, but not absolutely; and if you perceive your tench and perch to increase and prosper, you may make lesser stews to serve them a-part, and so you may have them when you please, without disturbing the other fish.

STIFF-LEGS, a disease in horses, under which are also comprehended dry, decayed, or bruised legs.

For the cure, take of spirits of wine a quart, oil of nuts, half a pint; butter half a pound; put them into a glazed earthen pipkin and melt them, covering the vessel with another that is less, exactly fitted to it, lute the junctures well with clay, mixed with horse-dung, or hair; and after the cement is dry, set the pot on a very gentle fire, and keep the ingredients boiling up, very softly for the space of eight or ten hours; then take off the pot and set it to cool: when used, rub the largest sinews with your hand till it grows hot, then anoint it with this composition, chafing it in, and repeat the same every day.

STIFFLE in a horse, a large muscle, or that part of the hind-leg which advances towards his belly, and is a most dangerous part to receive a blow upon.

STIFFLING, is a malady that accidentally befalls a horse either by some strain, by leaping, or by a slip in the stable, or on travelling, or else by some blow or stroke, which puts out the trifle-bone, or much hurts and strains the joint.

The sign of this is by the dislocated bone bearing itself out, which will make him go lame, and unwilling to touch the ground but only with his toes, till it be put in again.

The common method of cure is to swim the horse in some deep water or pond, till he sweats about his ears, which will put the bone into its right place again, and when he is thought to have swam enough, to take him out of the water and to throw an old blanket over him, to prevent him from taking cold, and lead him gently home.

Then being in the stable; they put a wooden wedge of the breadth of a sixpence between the toe and the shoe, on the contrary foot behind, and when they find him thoroughly dry anoint the part aggrieved with hen's grease, or oil of turpentine, and strong beer, of equal parts alike, well shaken and mixed together in a vial.

It is to be well chafed in with the hand, one holding at the same time a hot bar of iron or fire-shovel, to make it sink in the better: or you may apply to it brandy and common soap, and strong beer, mixed together:

Or, tie down the horse's head to the manger, and fasten a cord to the pastern of the stiffed leg, and draw his leg forwards, so that the bone will come right by being helped with the hand; keep it in this position exactly, and tie the other end of the cord to the rack, so that the horse may not pull his leg back so as to dislocate the bone for an hour or two, till after it has been settled and dressed.

Then having ready melted pitch in a pot, dip a bit of a clout tied to a stick into the pitch, anoint the stiffing with it, to the breadth of three or four inches, and the length of ten; and immediately before the pitch can cool, having ready a strong piece of canvas cut fit for the purpose, and very well warmed by the fire, clap it so neatly upon the place that the bone cannot slip out again.

Take notice, that this plaster must not be long-ways towards the foot and flank; but cross-ways upon the joint, as it were about the thigh; for otherwise it cannot hold in the bone.

When you have laid on the plaster, anoint it all over with the melted pitch, and while it is warm, clap flax, the colour of the horse, all over the outside of the canvas.

Let the plaster remain on till it falls off of itself; but if the bone be out, then put in a French rowel, a little below the stiffing place, and let it remain fifteen days, and turn it once every day; at the end of fifteen days take it out, and heal up the orifice with green ointment.

STOMACH-SKINS; there are some foals under the age of six months, which, though their dams yield abundance of milk, decay, and have a cough, occasioned by certain pellicles or little skins that breed in their stomachs, even to that degree as to obstruct their breathing, and at last utterly destroy them.

To cure this malady, take the bag wherein the foal came out of the belly of it's dam, and having dried it, give as much thereof in milk as you can take up with three fingers.

This remedy is also good for all diseases that befall them while they are under six months old: but if you cannot have the bag, then take the lungs of a young fox, dry and powder them, and use it instead of the afore said powder.

STONE-BRUISE, a misfortune that befalls the cuds of a horse by divers accidents.

For the cure: take honey and fresh butter of each half a pound, melt them; to which add the juice of green coleworts, one pound; leaves of rue picked from the stalks, a good handful: black soap, four ounces, and one pound of bean-flour; stamp the rue in a marble mortar, then add the honey, and afterwards the juice of coleworts, butter, and black soap; mix them well without heat, and make a poultice with the bean-flour, and apply it cold with a hog's bladder, and keep it on with a bandage tied about the horse's back.

Hard swellings may be cured by this method; and removing the dressing once a-day, and the quantity here prescribed will probably be sufficient to perfect the cure, by being applied frequently.

But if the swelling be attended with a great inflammation, then add to the whole composition two drams of camphire, dissolved in three spoonfuls of the spirit of wine; but if by the bruise the tumour be seated in the ligaments that are above the stone, chafe the part with spirit of wine camphorated, and afterwards apply the forementioned cataplasm or poultice.

If you have reason to believe that there is matter generated in the stones, spread emplastrum divinum on very soft leather, about the bigness of the palm of your hand, and lay it upon the part affected, even where the matter seems to be seated, and then apply the poultice, and if the matter be either actually generated, or ready to be formed, the plaster will draw it.

You must take the plaster off once a-day and wipe it, but you need not change it; and by following this method the horse may be cured without gelding.

The horse must be let blood both at the beginning and end of the cure.

STONES-SWELLING, **STONES-HARDENING**, (in horses), a malady to which they are incident. See the article Cuds.

For the cure : take yellow wax, fresh butter, and oil of olives, of each half a-pound ; strong vinegar, half a pint ; boil them together till the vinegar be almost consumed, then take the vessel off the fire, and put in an ounce of camphire powdered ; make a poultice and apply it to the swelled cods ; let it lie on 24 hours, then lay on another poultice upon the first, without taking off the former or uncovering the part.

If the inflammation be but a simple one, it will assuage the swelling and abate the pain ; but if the swelling should continue after the heat and pain is removed, and the cods do hang down very low, it is a sign that the horse is troubled with a hydrocele, that is, when by a relaxation of the peritonæum, the cods are filled with water, which having been too long retained in the part, by reason of the great difficulty of expelling it through the pores, may corrupt and ulcerate the stones.

For the cure of this sort of swelling, or hydrocele, make a sort of gruel and barley-meal and vinegar, and when it is almost boiled, and half the quantity of chalk, with a sufficient quantity of oil of roses and quinces, and two handfuls of salt, apply this remedy as hot as you can endure it with your hands, and bind it on very carefully.

Or, boil a sufficient quantity of beans in lees of wine, till they are soft and tender, then pound them to a mash, to every pound of which add a quarter of an ounce of castoreum in fine powder ; incorporate them well together, and sew two pounds of them up in a bag large enough to cover the stones ; first anoint the cods with ointment of the oil of roses, and then lay on the bag as hot as you can suffer it to lay on the back of your hand, binding it on as well as you can ; let it lie on for twenty-four hours ; then heat the bag again in the same lees of wine in which the beans were boiled, and lay it on again ; repeat this continually till the swelling be abated.

If the peritonæum, or rim that holds the entrails, be relaxed, the guts will fall into the cods, which will appear visible. In this case you must first endeavour to put up the fallen guts, and then apply the following fomentation.

Take of the bark of the pomegranate and oak trees, green oak-apple, cyprus nuts, barberries and sumach, of each two ounces : anise and fennel seeds, of each an ounce, camomile, melilot, and pomegranate, flowers, of each a handful, and powder of crude allum four ounces ; put them into a bag large enough to cover the horse's cods (and if this quantity be not sufficient, double it) sew it up after the manner of a quilt, and put the first quantity with a quarter of a peck (or half for the double) of beans in a pot of shoe-wine, or some thick red wine, and boil them for the space of two hours : then apply the bag moderately hot to his cods or stones, cleverly fastening it on with a bandage, put round the flanks, and tied on the rump. Continue this application for some time, heating the quilted bag a-fresh every time in the same liquor.

But after you have put up the guts, the surest way is to geld the horse, for then the cods will shrink up, and the guts will not any more come down into them.

But if it be a rupture incording or burstness, which is when the rim, thin film, or caul, which holds up the entrails, is broken, or over-strained, or stretched, so that the guts fall down either in his cods or flank ; then use the following remedy :

Take common pitch, dragon's-blood, powder of bole armoniac, mastic, and frankincense, of each one ounce ; make a plaster of these, and lay it upon the loins of the horse, and on the rupture, letting it abide on till it falls off itself, and it will cure him ; but then you must at the same time give him strengthening things inwardly, of which there are many prescribed, as rupture-wort, crosswort, valerian, &c.

Or, carry the horse into a place where there is a beam over-thwart, and strew it thick with straw ; then put on four pasterns, four rings on his feet together, and he will fall, then cast the rope over the beam and hoist him up, so that he may lie flat on his back, with his legs upwards, without struggling ; then bathe his stones with warm water and butter melted together ; and

when they are become something warm, and well mollified, raise them up from the body with both your hands, being closed by the fingers, close together ; and holding the stones in your hand, work down the gut into the body of the horse, stroking it downwards continually with both your thumbs, till you perceive that side of the testicle to be as small as the other.

Having thus returned the gut to the right place, taking a list of the breadth of two fingers, and having anointed it very well with fresh butter, tie his stones close together with it, as nigh the body as you can possibly, but not too hard, but so that you can put your fingers between.

Then raise the horse, and lead him gently into the stable ; set him up and keep him warm, and let him not be stirred for the space of twenty-one days ; but do not omit the next day to unloose the list, and to take it away, and to throw a bowl or two of cold water upon the cods once or twice for that day and every day after : this will make him shrink up his stones, and by that means hinder the gut from falling down.

At the end of twenty-one days, in order to render the cure more effectual, take away the stone on the bursten side, and so he will hardly be bursten again on that side ; and during the cure, let him neither eat nor drink much, and give him his drink always warm.

STONE-BREAK, or English saxifrage, a perennial plant common in pasture grounds. The root has a sharpish and aromatic taste. The stalks are round, streaked, and reddish towards the bottom. The leaves are smooth, of a dark green, and divided twice, into long, narrow, sharp segments. The foot-stalks are membranaceous at the base. The flowers grow in loose umbels ; and of a pale yellow colour. The seeds are oval, streaked, and red at the top.

" Every farmer, says a correspondent of the editors of the *Museum Rusticum*, knows which sort of grass he would wish to have predominant in his meadows : it would surely be very easy for him to save some of the seeds of such grass, and propagate it apart till he had saved sufficient to sow, suppose an acre of land with it, pure and unmixed : when arrived at this point, he might propagate it as extensively as he thinks proper.

" I must not however forget the chief intended subject of my letter, which is, to recommend to your readers the saxifrage as a plant proper to be intermixed with the grass of their meadows.

" I have now in my holding above thirty acres of meadow land, which fortunately for me bears a grass that needs no improvement ; though this I in part attribute to my having drained my land properly some years ago, since which the bite is much improved.

" Amongst this grass in my meadows there grows a considerable quantity of saxifrage ; which in the opinion of all the dairy-men in my neighbourhood, is the reason my cheese is so particularly good.

" Now I should imagine that when a farmer has ploughed up a foul meadow, and intends sowing it with good grass seed, it would be no difficult matter to procure a sprinkling of saxifrage-seed to mix with it : this would certainly be of service ; and we should not despise this excellent plant, because it is common, and not far-fetched : there is great plenty of it in the Netherlands, in their finest cow-pastures ; and that I have often heard assigned as a reason for their having such quantities of cheese of a superior quality ; though I must at the same time own, I have in London tasted some Dutch cheese, stuffed full of cloves, which was not the best in the world ; but this might have been an accident, for they say their cheese is in general excellent.

" But, to return to my immediate subject, I would by all means recommend the propagation of the saxifrage plant, in meadows, not only on account of its great use in improving the quality of cheese, and butter also, which it does, but because it is a native of our island, and there is no danger of its succeeding to the farmer's wish ; which cannot be said of every plant recommended for cultivation.

" But it must be remembered, that I do not recommend it to be cultivated alone ; I never tried it in that manner : that it will thrive very well when mixed with good meadow grass, daily experience convinces me ; and this method it is I urge." *Museum Rusticum*, vol. 1. p. 472.

The burnet cultivated to so much advantage by Mr. Rocque

Rocque and others is a species of the faxifrage. See the article BURNET.

STONE, a hard solid body, neither malleable, fusible by fire, nor soluble in water, formed by succession of time in the bowels of the earth.

It has been argued, and is not yet determined whether stones are hurtful or beneficial to arable lands. Examples are not wanting on both sides of the question; though, in general, it seems rather to be carried for them. However, nothing can excuse leaving a stone in any ground so large as to interrupt the plough. If they are very large, they should be blown to pieces with gun-powder, and then be carried off. Some spots, very fertile in several kinds of grain, seem to consist of nothing but stones; and instances are given of fields being rendered barren by taking away the stones which covered them. Theophrastus accounts for this in a hot country, where it happened to the Corinthians, by saying, that the stones shelter the earth from the scorching heat of the sun, and thereby preserve its moisture. The same holds true even in our colder latitude, where the heat of the sun is less apt to hurt us; and Mr. Evelyn is clearly of opinion that husbandmen rather impoverish, than improve, those grounds which are almost covered with stones, especially where corn is sown, if they pick them off too minutely; because they thereby expose the land too much to the effects of heat and cold. Certain it is, that a moderate mixture of small gravel preserve the earth both warm and loose, and prevents too sudden exhalations. But it seems highly probable that there must be some farther reason, beyond what has yet been assigned for the benefit arising from the stones. The example already given of the stone used in Oxfordshire, and a remarkable incident which happened to M. Duhamel, gives great room to think that the stones which are thus beneficial, are of the lime-stone or calcareous kind.

"The stone which is used for building at Denainvillers, says M. Duhamel, is very hard. It bears polishing like marble, and is here and there intermixed with shells, some of which are filled with a kind of oker, and others contain a crystalline substance. This stone is very fit to make lime of. Some workmen, who were building about our house, cut pieces of this stone upon a grass-plot. When they had done their work, the rubbish was cleared away, and nothing was left upon the grass but the dust and very small fragments which had fallen from the stones in cutting them. The next year, the grass grew surprisingly thick in all the places where these stones had been cut, was much taller and greener than any where else, and preserved its vigour for several years. One would scarcely have thought that so hard a stone, reduced to powder, would have produced an effect like that of marble. The goodness of lime, as a manure, is perhaps, chiefly owing to the fineness of the powder, to which the lime-stones are reduced by calcination.

"This fact may help to clear up another, which cannot have escaped the notice of those who attended to the differences of soils. They must have observed some grounds so thickly covered with stones, that scarce any thing else is seen after a heavy shower of rain. Yet some of these lands are very fertile, and produce fine wheat. I know not whether I am mistaken, but I think I have observed that this fertility is found only in fields where those stones are calcareous. It is very probable that the dust which is formed by the mutual rubbing of those stones contribute to that fertility. *Culture des Terres, tom. V. page 220.*

The farmer may easily inform himself whether this be the case; and if it is, he has a certain rule to go by in the management of stones; viz. by trying with aqua fortis, or spirit of sea-salt, as mentioned before, whether they are calcareous or not: for every stone on which the spirit does not effervesce, is of no use, and therefore should be removed, as an impediment to the necessary labour. However, the prudent husbandman will make the experiment of clearing his land, first, on a small spot; that he may be sure of the success, before he embarks in a greater expence. See the article LIME.

STONE also denotes a certain quantity or weight of some commodities.

A stone of beef at London is the quantity of eight pounds; in Herefordshire, twelve pounds; in the north sixteen pounds.

A stone of wool, according to a statute made in the eleventh year of the reign of Henry VII. is to weigh four-

teen pounds, but in some places it is more, in others less; as in Gloucestershire fifteen pounds, in Herefordshire twelve pounds.

A stone, among horsemen, is the weight of fourteen pounds.

STONE-PICKERS, in general take almost as long time in emptying their baskets as in filling them: besides drawing them off is breaking into the day's work of a team. To prevent these inconveniences, one horse and a light cart, attending seven or eight women, boys, and girls may run over forty acres in about four days: four women at 10d. is 3s. and 4d. four boys or girls, at 6d. is 2s. The man is 8d. the horse 15d. wear and tear 9d. together 8s. a day, and for the four days is 30s. for the forty acres, or 9d. an acre for picking and carrying off. The pickers in this practice have nothing to do but fill their baskets; the cart and the man are always at hand to empty them: and a strong horse will draw a great many to the next hole, slough, or gateway.

STONY-LANDS, such as are full of flints, pebbles, or small fragments of free-stone.

These lands, in many places, yield good crops, and the general rule is, that in stiff and cold lands the stones should be as carefully picked out as possible, but in light and dry grounds they should be left. In Oxfordshire they have great quantities of a lean earth, and a small rubble stone, or a four sort of land mixed with it; this is sometimes very full of weeds, and sometimes very clear of them. If they are weedy they fallow them late; but if they are scary, as they call it, that is, if they have a sward upon them, they either fold them in winter, and add some hay-seed to the sheep's dung, to bring up the grass: or else they lay old thatch or straw and dung upon it: for they reckon that if those lands have no sward upon them, before they are fallowed, they will by no means be brought to bear a good crop, but a great deal of May-weed, and other useless weeds. In September, November, and December, they fallow as the sward directs them: if this be done in either of the two last months, they call it a winter fallowing; and never stir it again, till they plough it, and sow it with barley: and those lands are reckoned to do better than if finely tilled. They will bear wheat and messin in a kindly year, and large crops of barley, if they are well managed, and kept in good heart.

They always fallow those lands every other year, unless they sow peas upon them; sometimes they sow them with lentils; and when they are quite worn out, they lay them down for clover or rey-grass.

STONE-WALL. See FENCE.

STOOKING, SHOCKING, or STACKING, the setting the sheaves into shocks, the better to guard them from the rain.

A correspondent of the editors of the Museum Rusticum has given us the following method of stacking, or stooking corn to preserve it from the wet, and in which situation it may remain in the field six weeks or two months, without any danger from the inclemency of the weather.

"They set one sheaf upright, with the ears uppermost; and round that they place a circle of many other sheaves, with their ears uppermost, inclining on the first sheaf; and when so placed they look like the figure of an extinguisher.

"They then lay an horizontal circle of sheaves, with all the ears in the centre, and cover those ears with a loose sheaf or two.

"Thus placed, they are protected from all wet, and may remain in the field six weeks, or two months, as safe as in a barn; and this method of stacking has been adopted in Sussex, Surry, Kent, and many other southern counties, to the great benefit of the farmers and the public." *Museum Rusticum, vol. II. p. 35.*

In a subsequent number of the same work, the Rev. Mr. Comber, of East-Newton, in Yorkshire, has made some remarks upon the above method of stooking, and also described the method followed in Yorkshire:

"It is to be wished, says he, that this gentleman had been more particular in his account. He does not tell us whether this stack, as he calls it, is made immediately after the wheat is gathered, or after it has had field-room in some other manner, though this circumstance is very material towards a right judgment of its usefulness, and even of the expedition. He does not tell us, whether by a circle of many other sheaves he means a circle of one row of sheaves,

sheaves, or of more, though this circumstance too is very material.

"I will now give a short, but, I hope, sufficient description of the method of stooking used in Yorkshire, &c.

"Ten sheaves are disposed in two rows, each row leaning against the other: then two sheaves are laid on the top, so as to meet at the centre with their tails, and to slope downwards.

"Now to compare the methods, I must observe, first, that in your correspondent's the sheaves appear to be set so close as to exclude a free course of air, most essential to give, preserve, or restore dryness to corn; whereas in ours, the air has a free course, whether it bears against one or other end of the stook, or even against either side of it.

"Secondly, in your correspondent's method, only some loose ears are laid as a cover to the whole stock; and those cannot reasonably be supposed long to resist the beating of the rain, but to transmit it to all, or many of the ears below them, which they are supposed to cover: and if we consider what violent winds often visit us in and soon after the harvest, we shall readily allow, that these loose ears may reasonably be expected to be blown off, and become no cover; nay, to be blown about and away, and often totally lost; whereas in our method, the closeness and weight of two of the best sheaves in the twelve may reasonably be supposed to be a good cover, and to continue so, and hardly to be blown off by any wind, if carefully laid on; at least, not to be blown away, but so as soon to be replaced.

"Thirdly, the flat position of your correspondent's cover must make it extremely liable to receive all the rain that descends, and transmit it to what lies beneath; whereas the sloping position of our cap sheaves, neither exposes them to receive directly, nor to retain, nor transmit the rain to the corn below, but to throw it off, especially as the tails of the sheaves, in which the straw is thickest and strongest, receive the most of the rain, which can do them little or no harm, and especially if the tails of these sheaves be thrust closely together. In short gentlemen, your correspondent's method seems to threaten that dreadful malady, mow-burn, whilst ours gives the corn all possible guard against it, viz. access of sun and wind.

"It is of great consequence to the public, as well as individuals, to guard against every species of destruction to so valuable a crop as wheat is, in every stage, but more especially in its last, in which almost all the expence is over: therefore, the above gentleman's assertion, that his method of stacking is adopted in Suffex, Surry, Kent, and many other southern counties, made me more solicitous to examine it; and since, on a fair comparison with our Yorkshire method, it appears to have every disadvantage, I persuade myself I am doing my duty to my country, by shewing to many countries a much better method than that which they have adopted." *Museum Rusticum*, vol. II. page 250.

STOOMING of wine, is the putting bags of herbs, or other ingredients into it. See the article WINE.

STOOP, a post fixed in the earth.

STOT, a young bullock; a steer.

STOVER, fodder for cattle.

STOUND, a wooden vessel to put small beer in.

STOWK, the handle of a pail: also a shock of twelve sheaves.

STOWRE, a round of a ladder; a hedge stake; also the staves in the sides of a waggon, in which the eye-rings are fastened.

STRAIN, or **SPRAIN**, a violent extension of the sinews or tendons of some muscle, whereby the tendinous fibres are over stretched, and sometimes ruptured, or broken.

To form therefore a true idea of these disorders, let us first consider every muscle, and tendon, as composed of springy elastic fibres, which have a proper power of their own, to contract and extend themselves: or, to make their action more familiar, let us compare them to a piece of catgut, that we may the better judge with what propriety oily medicines are directed for their cure. Thus then, if by a violent extension of this catgut, you had so over-stretched it, as to destroy its springiness, or elasticity, and was inclined to recover its lost tone; would you for that purpose think of soaking it in oil? And is not the method of treating strains, or overstretched muscles and tendons, full as preposterous, when you bathe or soak them in oily medicines at a time when they want restringents to brace them up? Yet custom has so established this practice, and

fallacious experience seemingly so confirmed it, that it would be a difficult task to convince the illiterate and prejudiced, of the absurdity; who, by attributing effects to wrong causes, are led into this error, and the foils usurp the reputation that is due only to rest and quiet: they seem however to be aware of the ill consequences, by their adding the hot oils, as spike, turpentine, and origanum; which, though they in some measure guard against the too suppleing quantity of other oils; yet the treatment is still too relaxing to be of real service.

And indeed in all violent strains of either tendon or muscles, whatever opinion we may entertain of bathing and anointing with favourite nostrums, which often succeed in slight cases, where perhaps bandage alone would have done, yet it is the latter, with proper resting the relaxed fibres, till they have thoroughly recovered their tone, that are the chief things to be depended on; and frequently some months are necessary for effecting the cure.

All violent strains of the ligaments, which connect the bones together, especially those of the thigh, require time, and turning out to grass, to perfect a recovery. External applications can avail but little here, the parts affected laying too deep, and so surrounded with muscles, that medicine cannot penetrate to them. The sooner in these cases, a horse is turned out to grass, the better, as the gentle motion in the field will prevent the ligaments and the joint-oil from thickening, and of course the joint itself from growing stiff; nor do I believe that firing, so commonly practised in this case, is of half the consequence as rest, and turning out for a considerable time; which by the bye, is always advised at the same time the horse is fired. I could not avoid saying thus much, in order to shew the great advantages of rest in all strains, and that no horse should be worked till he is thoroughly recovered.

When a horse's shoulder is over-strained, he does not put out that leg as the other, but to prevent pain, sets the sound foot hardly on the ground, to save the other; even though he be turned short on the lame side, which motion tries him the most of any. When, trotted in hand, instead of putting his leg forward in a right line, he forms a circle with the lame leg; and when he stands in the stable, that leg is advanced before the other.

In order to cure this lameness, first bleed him, and let the whole shoulder be well bathed three times a day with hot verjuice or vinegar, in which may be dissolved a piece of soap: but if the lameness continues without swelling or inflammation, after resting two or three days, let the muscles be well rubbed for a considerable time, to make them penetrate with good opodeldoch, or either of the following mixtures:

Take camphorated spirits of wine two ounces; oil of turpentine one ounce; this proportion will prevent the hair coming off.

Or,

Take the best vinegar half a pint; spirit of vitriol, and camphorated spirit of wine, of each two ounces.

When the shoulder is very much swelled, it should be fomented with woollen cloths (large enough to cover the whole), wrung out of hot verjuice and spirit of wine; or a fomentation prepared with a strong decoction of wormwood, bay-leaves and rosemary, to a quart of which may be added half a pint of spirit of wine.

A rowel in the point of the shoulder in this case often does great service; especially if the strain has been very violent, and the swelling very large; but as to boring up the shoulder with a hot iron, and afterwards inflating it, is both a cruel and absurd treatment; and the pegging up the sound foot, or setting on a patten shoe, to bring the lame shoulder on a stretch, is a preposterous practice, and directly calculated to render a horse incurably lame; for it can only be necessary in cases the very opposite to this, when the muscles have been long contracted, and we want to stretch them out.

Where poultices can be applied they are at first undoubtedly very effectual, after bathing with hot vinegar or verjuice, and are to be preferred greatly to cold charges, which by drying so soon on the part, keep it stiff and uneasy: let them be prepared with oatmeal, rye-flour, or bran boiled up in vinegar, strong beer, or red wine lees, with lard enough to prevent their growing stiff; and when by these means

means the inflammation and swelling is brought down, bathe the part twice a day with either of the above mixtures, opodeldoch, or camphorated spirits of wine; and roll the part three or four inches, both above and below, with a strong linen roller, of about two fingers width, which will contribute not a little to the recovery, by bracing up the relaxed tendon; and perhaps is more to be depended on than the applications themselves.

As opodeldoch is variously made, and those usually sold in the shops do not seem so well calculated for horses, we shall insert the following, as better adapted to this purpose, and recommend it to be kept ready prepared for the use of the stable; it being not only very proper for the above use, but for bruises, cold swellings, benumbed parts, and for dispersing many other such sort of tumours: it may occasionally also be given internally for the gripes from wind, or taking cold; for the strangury also, and as a cordial; one ounce or more may be taken for a dose in a pint of ale.

Take Jamaica pepper, four ounces; Winter's bark, carraway seeds, laurel, and juniper berries bruised, of each two ounces; rosemary, marjoram, and lavender flowers, of each one ounce; rectified spirit of wine, three pints; let them digest in a warm place ten days, then strain off the tincture, and dissolve in it Venice soap, a pound and a half; camphor, three ounces; Barbadoes tar, four ounces; oil of turpentine, six ounces; oil of amber, two ounces; mix, and make a liniment.

In strains of the coffin-joint that have not been discovered in time, there will grow such a stiffness in the joint, that the horse will only touch the ground with his toe; and the joint cannot be played with the hand; the only method here is repeated blistering, and then firing superficially.

Strains of the back sinews are very common, and are easily discovered by the swelling, which extends sometimes from the back side of the knee down to the heel, but for the most part the horse sets that leg before the other. The tendon should be well bathed, three or four times a day, with hot vinegar: and if much swelled, apply the poultices above recommended, and when the swelling is down, bathe with the mixtures above, or with camphorated spirit of wine and oil of amber, in which is dissolved as much camphor as the spirits will take up, and roll up the tendon with a proper bandage, or laced stocking; which last, properly fitted to the limb, might be wore to great advantage, not only in these kinds of injuries, but in most others, where there is a disposition to the grease, or other swellings of the limbs, from weak and relaxed fibres. Carriers shavings wetted with vinegar have been found useful for this purpose; as has also tar and spirit of wine: but where the tendon has suffered by repeated injuries of this kind, the case will demand blistering, firing, and proper rest.

Strains of the knees and pasterns arise frequently from kick, or blows; if they are much swelled, apply first the poultices; and when the swelling is abated, bathe with the above, or the following:

Take vinegar, one pint; camphorated spirits of wine, four ounces; white vitriol, dissolved in a little water, two drams.

Or,

Take the whites of three or four eggs, beat them into a froth with a spoon; to which add an ounce of rock alum finely powdered, spirit of turpentine, and wine, of each half an ounce; mix them well together.

The following is also recommended by the French writers, and has been found very successful in some old strains, when other remedies have failed.

Take one pound of tar, and two of rectified spirit of wine, stir them together over a fire till they incorporate (but take care the flame does not catch the spirits); then add two ounces of bole finely powdered, and a sufficient quantity of oatmeal to bring it to the consistence of a poultice; to which add lard enough to prevent its growing dry; apply it, spread on cloth, twice a day.

As great weakness remains in the pasterns after violent strains, the best method is to turn the horse out to graze till he is perfectly recovered; when this cannot be complied with, the general way is to blister and fire.

When a horse is lame in the fistle, he generally treads on his toe, and cannot set the heel to the ground. Treat him at first with the vinegar and cooling restringents; but if a large swelling with puffiness ensues, foment it well with the discutient fomentation till it disperses; and then bathe the part with any of the above medicines.

A lameness in the whirle bone and hip, is discovered by the horse's dragging his leg after him, and dropping backward on his heel when he trots. If the muscles of the hip are only injured, this kind of lameness is cured easily; but when the ligaments of the joint are affected, the cure is often very difficult, tedious, and uncertain. In either case, at first bathe the parts well with the cooling medicines, four or five times a day; in the muscular strain, this method alone may succeed, but in the ligamentous, it is rest and time only can restore the injured parts to their proper tone.

Strains in the hock are to be treated by soaking the parts with coolers and repellers; but when the ligaments are hurt, and they are attended with great weakness and pain, use the fomentation. If a hardness should remain on the outside, it may be removed by repeated blistering; if within, it may be out of the power of any external applications to remove; however, the joint should be fired gently with small razes or lines pretty close together, and then covered with a mercurial plaster. To the discutient fomentation above mentioned may be added crude sal ammoniac, with a handful of wood-ashes boiled in it.

The blistering ointment for the above purposes may be found under the article SPAVIN; but the sublimate should be omitted.

The firing used for the strengthening relaxed sinews or tendons should act only on the skin, which by contracting and hardening it all round the sinews, compresses them more firmly like a bandage. See the article FIRING. *Bartlett's Farriery*, p. 224.

STRANGLES, a distemper to which colts and young horses are very subject; and begins with a swelling between the jaw-bones, which sometimes extends to the muscles of the tongue; and is attended with so great heat, pain, and inflammation, that sometimes, till matter is formed, the horse swallows with the utmost difficulty.

The symptoms are, extraordinary heat and feverishness, with a painful cough, and a great inclination to drink without being able; some horses losing their appetites entirely, others eating but little, by reason of the pain which chewing and swallowing occasion: when the swelling begins on the inside of the jaw-bones, it is much longer in coming to matter than when more to the middle; when it arises among the glands, and divides into several tumours, the cure is generally tedious, as it breaks in different places; and when it forms upwards on the wind-pipe and gullet, there is sometimes danger of suffocation, unless the swelling soon breaks. But the most dangerous kind is, when, besides the above symptoms, the horse runs at the nose; this by some is called the bastard strangles.

As this disorder seems to be critical, the most approved method is to assist nature in bringing the swellings to maturity, by keeping them constantly moist with ointment of marshmallows, and covering the head and neck with a warm hood. But as all swellings in glandular parts suppurate slowly, the following poultice may be applied hot twice a day; it is also a very proper one to ripen, or bring any other swelling to matter:

Take leaves of marshmallows, ten handfuls; white lily-root, half a pound; linseed and fenugreek seed bruised, of each four ounces; boil them in two quarts of water till the whole is pulpy, and add four ounces of ointment of marshmallows, and a sufficient quantity of hogs-lard, to prevent its growing stiff and dry.

In five or six days, by these means, the matter is generally formed, and makes its way through the skin; and if the discharge is made freely and with ease, the opening need not be enlarged, but should be dressed with the following ointment spread on tow, still continuing the poultice over it to promote the digestion, and prevent any remaining hardness.

S T R

Take rosin and Burgundy pitch, of each a pound and a half; honey and common turpentine, each eight ounces; yellow wax, four ounces: hogs-lard, one pound; verdigris finely powdered, one ounce: melt the ingredients together, but do not put in the verdigris till removed from the fire; and it should be stirred in by degrees, till the whole is grown stiff and cool.

If the fever and inflammation run high, and the swelling be so situated as to endanger suffocation, a moderate quantity of blood must be taken away, and the remainder diluted with plenty of water-gruel, or warm water, mashes &c.

The running at the nose, which often attends the strangles, is dangerous; especially if it continues after they have ripened and broke, as the horse will be greatly weakened thereby. To prevent this waste and decay, give him every day, for some time, an ounce of Jesuits bark; or a strong decoction of guaiacum shavings, which has been found extremely beneficial in restraining these glandular discharges when too liberal, and in drying up ulcers of all kinds in horses. [See the article GLANDERS.]

If a hardness remains after the sores are healed up, they may be anointed with the mercurial ointment; and when the horse has recovered his strength, purging will be necessary.

STRANGURY, a disease incident to cattle, consisting in a difficulty of making urine, attended with great pain. See the article KIDNEY.

This may happen to a horse divers ways; sometimes by hard riding, or much labour; sometimes by hot meats and drinks, and sometimes by an ulceration of the bladder, &c.

The first application necessary is to bleed largely, and after the operation give the following drink, and repeat it two or three times every two hours:

Take of Venice turpentine, well rubbed with the yolk of an egg, one ounce; of nitre, or salt prunella, six drams; of sweet oil half a pint; and a pint of white wine.

The horse should have plenty of marshmallow decoction, with an ounce of nitre, the same quantity of gum arabic, and two ounces of honey dissolved in every quart of it: for it must be remembered, that the more a horse drinks of this emollient decoction, especially when improved with nitre, gum arabic, and honey, the sooner he will recover: as it will greatly tend to remove the cause of the disease, and consequently to terminate its effects.

Some bathe the horse's loins with warm water, and then temperate bread and bay berries with butter; give him two or three balls of it for three days successively. Or,

You may use powder of flint-stone calcined, mixed with an ounce of the powder of parsley-seed, and as much of that of ivy-berries, and boil them a little in a pint of claret, and give the horse, and it will do. Or,

A quart of new milk, and a quarter of a pound of sugar, brew them well together, and give it to the horse to drink in the morning fasting, and keep him warm. Or, boil a good quantity of hog's fennel in the water you give him to drink, and it will cure him.

The following poultice applied a-cross the loins, over the kidneys, hath been followed by good effects.

Take a handful of garlic, fresh gathered, of mustard-seed and fresh horse-raddish root bruised, each half a pound; camphor, two ounces; green soap, enough to give the whole a proper consistence; spread it on a coarse cloth, and renew it every twenty-four hours until the horse stales easily.

STRAW, the stalk on which corn grows, and from which it is thrashed. See the articles DUNG and RICK.

STRAWBERRY-TREFOIL. See the article TREFOIL.

STRICKLE, the whet-stone placed upon the extremity of the shaft of a scythe.

STRIKE, a bushel, or four pecks of corn.

STRINGHALT, a disease in horses, consisting in a twitching and snatching up of the hinder leg much higher than the other.

It seizes them after a sudden taking of cold, after hard riding, or much labour; especially by washing him while he is hot, which chills his blood, and so benumbs his sinews, that it will sometimes take away the sense and feeling of a limb.

S T U

For the cure:

Take up the hinder vein upon the thigh; and underneath the same there lies a string, which you must cut away, and then anoint him with butter and salt, and he will do well.

STUBBLE, the stalks of corn left in the field by the reaper.

It has been a dispute among farmers, whether wheat-stubble should or should not be ploughed in. We shall therefore give the following remarks of a sensible Vale-farmer on this subject.

"We are far from being advocates, says he, for ploughing in stubble: yet our land is not light, but the contrary, and bears as good crops of wheat as any in the kingdom.

"As our soil is not light, it agrees very well with horse-beans, which we frequently sow after wheat; but if ever we let the stubble remain uncut till bean season, and plough it in, the consequences are surely fatal; it causes the earth to lie hollow; the bean plants to fall down; the sun and air get at the roots, and prevent the plant thriving; and the crop is always very greatly lessened: besides, the stubble, which with us is very strong, clogs the ploughshare, and gathers up in clods, which are a sure and a fatal shelter for many noxious insects.

"These facts, which every Vale-farmer is well acquainted with, induce us always to mow our stubbles, which we apply to many and various uses: if it is long, it serves very well for thatching: we litter our yards, stables, and cow-houses with it for making dung; we use it for drying malt; and a great deal is burnt by the poor cottagers, for warming themselves in winter, dressing their victuals, baking, brewing, &c. *Museum Rusticum* vol. III. p. 225.

STUM, the unfermented juice of the grape, after it has been several times racked off, and separated from its sediment.

STUMP, the part of any solid body, particularly of trees, &c. remaining after the rest are taken away.

A bare view of fig. 6. Plate XXIV. is sufficient to explain a very simple engine which Mr. Evelyn gives, for pulling up large roots.

The handle *A* turns the pinion of the spindle *B*, which has four or five teeth. These teeth turn the larger wheel *C*, which moves the cylinder *D*, on which the rope *E* is rolled as the root is drawn up; one end of the rope being previously fastened to the cylinder. The whole frame is let into a block of wood *F*, about four feet high and one in breadth; and the other end of the roller or cylinder is sustained by a lesser block of wood *G*. *H* is an iron plate which holds the wheel and pinion in the larger block. The cylinder, wheel, pinion, and handle of this machine should be made of good tough iron. The cylinder may be about four inches in diameter, and fourteen or sixteen inches in length. The rest is obvious: though I apprehend an improvement might be made, by adding a catch to secure either the handle or the cylinder, while the labourer (for one man will easily manage this engine) may be obliged to suspend his work, in order to clear away any obstacle that may have occurred. It would likewise certainly be right to place the wheels, and consequently the handle, somewhat higher than is here directed, to save the very great fatigue of stooping down continually while this last is turned.

Where the roots are very large, and obstinately tenacious, M. de Turbilly's advice, to blow them up with gunpowder, will be found very beneficial; especially if the above instrument cannot be had.

Where a place has been over-grown with wood, the earth is so thoroughly stirred by digging and pulling up the stumps and roots of the trees, that one ploughing in autumn is generally sufficient. The frosts in winter kill the weeds and break the clods; and after the second ploughing in the spring, these lands may be sown with expectation of an abundant crop: for the trees not having exhausted the earth towards the surface, but having on the contrary manured it with their leaves, a considerable produce may be expected for many years.

M. Duhamel mentions a small field, which had formerly been underwood, and being converted into arable ground, produced plentiful crops of wheat and oats for upwards of twenty years running, without being rested. It is true the soil was peculiarly proper for wheat, and would have been exhausted much sooner if it had not been a proper earth.

STUMPY,

S U R

STUMPY, full of stumps ; hard, stiff.

STURK, a young bullock ; a heifer.

STY, a cabin, or small building, to keep hogs in.

SUCCORY, or **WILD ENDIVE**.

SICHOREA or **WILD ENDIVE**, is by the Patriotic Economical Society at Hamburg, recommended as a fodder plant for cattle, more particularly cows ; equal, if not superior, even to the pimpinella. This plant is now become, all over Germany, an excellent addition to coffee ; which it greatly increases in strength, taste, and salubrity when but one part of its dried and pulverized roots, is added to two parts of ground coffee, and boiled together. These sichorea roots, ready prepared, sell there for eight English pence the pound ; and save one third of the coffee beans, without weakening, altering the taste, and wholesomeness of the very best Mocka-coffee ; but improving, on the contrary, all the inferior sorts of coffee, of the English, French, and Dutch West Indies. This beverage is, by this means, become universally preferred to tea, being cheaper, wholesome and more nourishing. See **CHICORIUM INTIBUS**.

SUCCULENT, juicy, moist.

SUCKER, a young twig, or shoot from the root.

SUCKLING-CALVES. See **CALVES**.

SUFFLATION. See **BLOWN** and **HOVED**.

SUFFOLK-GRASS, the same with meadow-grass or poa. See **POA**.

SULLAGE, a drain of filth.

SULL, a plough. See the article **PLOUGH**.

SULL-PADDLE, a plough-paddle.

SUMMER, the season in which the sun arrives at the northern solstice, and the days are at the greatest length.

SUMMER also implies the large piece of timber, or principal beam of a floor.

To SUMMER-LAND, or **To SUMMER-STIR**, to fallow land in the summer.

SUN-SCORCHED, a term used in some parts of England to express a distemperature of fruit-trees, owing to the sun's affecting them too forcibly on a sudden ; the consequence of which is the loss and withering of the fruit. Such trees are only subject to this, as are planted in places sheltered from the spring-sun, and open to that of the summer ; and may be always cured by proper waterings.

SURBATING, a term used by farriers to signify the sole of a horse's foot being worn, bruised, or spoiled by beating the hoof against the ground in travelling without shoes, or going in hot sandy lands, or with a shoe that hurts the sole, or the like. It also sometimes happens by over-riding the horse while young, before his feet are sufficiently hardened, or even by the hardness of the ground, and high lifting of his feet. The signs of this defect are his halting on both fore-legs, going stiffly, and creeping as if foundered.

There is nothing better for surbated feet than tar melted into the foot, or vinegar, boiled with foot to a proper consistence and poured into the foot boiling hot, with hurds over it, and splints to keep it in.

SURFACE-DRAINS. See **DRAINS**.

SURFEIT, a disease incident to horses and other cattle.

Surfeits arise from various causes ; but are commonly the effects of some diseases not attended to, or ill cured.

A horse is said to be surfeited, when his coat stares, and looks rusty and dirty, though proper means has not been wanting to keep him clean. The skin is full of scales and dander, that lay thick and mealy among the hair, and is constantly supplied with a fresh succession of the same, for want of due transpiration. Some horses have hurdles of various sizes, like peas or tares : some have dry fixed scabs all over their limbs and bodies ; others a moisture attended with heat and inflammation ; the humours being so sharp and violently itching, that the horses rub so incessantly, as to make themselves raw. Some have no eruptions at all, but an unwholesome look, and are dull, sluggish, and lazy : some appear only lean and hide-bound : others have flying pains and lameness, resembling a rheumatism : so that in the surfeits of horses, we have almost all the different species of the scurvy, and other chronical distempers.

The following method is usually attended with success in the dry species. First take away about three or four pounds of blood ; and then give the following mild purge, which will work as an alterative, and should be repeated once a week, or ten days, for some time.

Take succotrine aloes, six drams, or one ounce ; gum guaiacum, half an ounce ; diaphoretic antimony, and

S U R

powder of myrrh, of each two drams ; make into a ball with syrup of buckthorn.

In the intermediate days, an ounce of the following powder should be given morning and evening in his feeds :

Take native cinnabar, or cinnabar of antimony, finely powdered, half a pound ; crude antimony, in fine powder, four ounces ; gum guaiacum, also in powder, four ounces ; make them into sixteen doses for eight days.

This medicine must be repeated till the horse coats well, and all the symptoms of surfeit disappear. If the horse is of small value, two or three common purges should be given, and half an ounce of antimony, with the same quantity of sulphur, twice a day, or the alterative balls with camphor and nitre.

If the little scabs on the skin do not peel off, anoint them with the mercurial ointment ; during the time of using which, it will be proper to keep the horse dry, and to give him warm water. This ointment properly rubbed into the blood, with the assistance of purging physic, has frequently cured these kind of surfeits, without any other assistance.

The wet surfeit, which is no more than a moist running scurvy, appears on different parts of the body of a horse, attended sometimes with great heat and inflammation ; the neck often swells so in one night's time that great quantities of a hot briny humour issues forth, which, if not allayed, will be apt to collect on the poll or withers, and produce the poll-evil or fistula. This disease also frequently attacks the limbs, where it proves obstinate, and hard to cure : and in some horses shews itself spring and fall.

In this case bleed plentifully, avoid externally all repellers, and give cooling physic twice a week ; as, four ounces of lenitive electary, with the same quantity of cream of tartar ; or the latter, with four ounces of Glauber salts, quickened, if thought proper, with two or three drams of powder of jallap, dissolved in water-gruel, and given in a morning fasting.

After three or four of these purges, two ounces of nitre made into a ball with honey may be given every morning for a fortnight ; and if attended with success, repeated for a fortnight longer.

The powders above-mentioned may also be given with the horse's corn ; or a strong decoction of guaiacum shavings, or logwood may be given alone to the quantity of two quarts a day. These, and indeed all alterative medicines, must be continued for a long time where the disorder proves obstinate.

The diet should be cool and opening, as scalded bran or barley ; and if the horse is hide-bound, an ounce of fenugreek seeds should be given in his feeds for a month or longer ; and as this disorder often proceeds from worms, give the mercurial physic too, and afterwards the cinnabar powders, as above directed ; but as in general it is not an original disease, but a symptom only of many, in the cure, regard must be had to the first cause : thus, as it is an attendant on surfeits, fevers, worms, &c. the removal of this complaint must be variously affected.

In a mangy horse the skin is generally tawny, thick, and full of wrinkles, especially about the mane ; the loins and the little hair that remains in those parts stands almost always straight out or bristly : the ears are commonly naked and without hair, the eye and eye-brows the same ; and when it affects the limbs, it gives them the same aspect ; yet the skin is not raw, nor peels off, as in the hot inflamed surfeit.

Where this distemper is caught by infection, if taken in time it is very easily cured : and I would recommend a sulphur ointment as most effectual for that purpose, rubbed in every day. To purify and cleanse the blood, give antimony and sulphur for some weeks after. There are a great variety of external remedies for this purpose, such as train oil and gun-powder, tobacco steeped in chamber-ley, &c. Solleyfell recommends the following :

Take burnt alum and borax in fine powder, of each two ounces : white vitriol and virdegris powdered, of each four ounces ; put them into a clean pot, with two pounds of honey, stirring till they are incorporated : when cold, add two ounces of strong aqua fortis.

But.

But when this disorder is contracted by low feeding and poverty of blood, the diet must be mended, and the horse properly indulged with hay and corn. The following ointments are effectually used for this disorder, rubbed into the parts affected every day :

Take powdered brimstone, train oil, and tar, of each equal quantities : to which may be added ginger, or or white hellebore.

Or,

Take sulphur vivum, half a pound ; crude sal ammoniac one ounce ; hogs lard, or oil, a sufficient quantity to form into an ointment.

Or,

Take quicksilver, and oil of vitriol, of each one ounce ; hogs lard, one pound ; sulphur vivum, four ounces ; oil of turpentine, one ounce and a half.

These are both very powerful remedies for this disorder, and can scarce fail of success.

To the two first, occasionally, may be added a third part of mercurial ointment : but as sulphur is in general allowed, to be the specific in the itch, and being found both more safe and efficacious than mercury, so we apprehend it will sufficiently answer the purpose here ; for as this disorder seems best accounted for by Lewenhoeck, from certain small insects he discovered in the pustules, by the microscope, so it seems as if they were destroyed by the steams of brimstone, though only raised by the heat of the body ; for in the human body the itch may be cured by partial sulphureous unctions, on the legs only ; but where the mange proves obstinate in horses, let the parts be washed with sublimate water before the application of the ointment, and subjoin the internal use of sulphur, in order to diffuse the steams more certainly through the skin ; there being reason to believe, as in the itch, that the animalcula may sometimes lie too deep to be thoroughly destroyed by external applications only.

SURVEYING, the art or act of measuring lands ; that is, of taking the dimensions of any field, parcel, or tract of land, laying down the same in a map or draught, and finding the content or area thereof.

As this art is of the utmost importance to all owners and occupiers of land, we shall endeavour to explain it in the easiest and most intelligent manner. And in order to this we shall begin with the principles of the art, and proceed gradually to shew how all the ordinary figures may be measured, protracted, and cast up, with no other instruments than chains, compasses, and scales. We shall afterwards endeavour to explain, in a very easy and concise manner, the use of the plain table, and other instruments used in surveying ; so that any person, of a common capacity, and that understands the four first rules of arithmetic, may be able to survey and parcel out land, plot it, and give up its content with ease and expedition.

Of geometrical definitions, divisions, and remarks.

I. A point is that which hath no parts, either of longitude or latitude, but is indivisible, ordinarily expressed with a small prick, like a period at the end of a sentence.

II. A line hath length, but no breadth nor depth, whose limits or extremities are points. This is either straight or crooked.

III. A right line lies straight, and equal between its extreme points, being the shortest extension between them ; the crooked or circular not so.

IV. A superficies hath length and breadth, but no depth ; of this, lines are the limits.

V. A plain superficies is that which lieth equally (or evenly) between its lines.

VI. An angle is the meeting of two lines in one point, so as not to make one straight line ; and if drawn beyond that point, they will intersect or cross one another. This in vulgar English may be called a corner ; of which there are two sorts, one right, the other oblique.

VII. A right angle is that which is made by two right lines, crossing or touching one another perpendicularly, (or squarely), like an ordinary cross, or carpenter's square.

VIII. An oblique angle is that which is either greater or less than a right angle ; and this is of two sorts, obtuse and acute.

IX. An obtuse angle is greater than a right angle, like the left and right corners of a Roman X.

X. An acute angle is less than a right angle, like the highest and lowest corners of the same letter.

XI. A figure is that which is comprehended under one line or many : of this there are two kinds, a circle, and a right-lined figure.

XII. A circle is a perfect round figure, such as is drawn with a pair of compasses, the one foot being turned round in a point and the other wheeled about it. The point in the precise middle is called the center : the round line, the circumference or periphery ; a line going through the center, that divides the circle into two equal parts, is called the diameter : half of that line is a semi-diameter, or radius ; half the circle is styled a semi-circle ; the quarter, a quadrant ; any portion of it, cut off by a right line not touching the centre, is called a segment.

XIII. Right-lined figures are such as are limited by three right-lines, or more, and are either triangles or triangulate, that is, such as are compounded of, and resolvable into triangles.

XIV. Triangles are figures comprehended under three right lines, and (as Rasmus thinks that for a reason he gives lib. 6. pr. 6.) might be better called trilaterals ; but the name triangle, from the number of the angles, hath obtained.

Also from the nature and quantity of their angles, these triangles are distinguished into three sorts : 1. Rectangled, having one right angle. 2. Obtuse-angled, having one obtuse angle. And 3. Acute-angled, having all acute angles ; for no triangle can have more right or obtuse angles than one, because, by a well known old rule, no triangle upon a plain superficies can consist of three greater angles than such, as being jointly taken, are equal to two right.

These three sorts of triangles may, according to the length and proportion of their sides, be sub-distinguished into seven ; for each of them may have either two equal sides or none ; and the acute-angled may have all three sides or lines equal : but be triangles of what name or kind soever, they are all capable of being exactly measured by one plain rule, as hereafter shall fully appear.

XV. Triangular figures are such as have more angles, and consequently more sides or lines, than three ; and these are either quadrangular or multangular.

XVI. Quadrangular figures are such as have four angles, and as many sides, and these are either parallelograms or trapezias.

XVII. Parallelograms are figures that are bounded with parallel lines, that is, such lines as are every where of the same distance one from another, so as if they were infinitely extended, they would never meet, like the upright lines of the Roman H. These parallelograms are either rectangular or oblique angular.

XVIII. Rectangular parallelograms are such as have four right angles, viz. the square or quadrat, and the long square, otherwise called the oblong.

XIX. The square is that figure that hath four right angles, and four equal sides, like any of the six faces of a die.

XX. The long square hath also four right angles, and the opposite sides are equal, but the adjoining sides meeting at each angle, differ in length. Of this figure is a well-printed page in a book, and the superficies of a well-cut sheet of paper, or an ordinary pane of glass.

XXI. Oblique angled parallelograms are such as have oblique angles, viz. two acute, and two obtuse ; of these there are two kinds, the rhombus and the rhomboides.

XXII. The rhombus is a figure that hath equal sides, but no right angles, like the form of a diamond on the cards, or the most ordinary cut of glass in windows, whose opposite angles are equal.

XXIII. The rhomboides is a defective rhombus ; for if from any side of a rhombus we cut off a part with a parallel line, the remainder will be a rhomboides, which hath neither equal sides nor angles, but yet the opposite sides and angles are equal.

XXIV. The trapezium is a figure that is neither parallelogram, nor, consequently, hath equal sides or angles, but is irregularly quadrangular, as if drawn at adventure. Of this shape most fields prove, that seem to the eye to be squares or oblongs.

XXV. Multangular figures are such as contain more sides and angles than four, and they are either regular or irregular.

XXVI. Regular multangulars take their names from their number of angles; so a pentagon, hexagon, heptagon, octagon; eucagon, decagon, signify multangular figures of five, six, seven, eight, nine, ten angles, and consequently sides.

XXVII. An irregular polygon, or multangular figure, is that which hath more angles and sides than four, the sides and angles being unequal to one another.

Of geometrical problems:

I. *To draw a line parallel to another, at any distance assigned.*

Plate XXV. fig. 1. Open your compasses to the distances given, and chusing two points conveniently distant in the line given, as here at A and B, describe the arches C and D, to whose convexity, if you apply a rule, the parallel line is easily drawn.

II. *To raise a perpendicular upon a line given, or to cross that line at right angles in a point assigned.*

Fig. 2. Suppose the point C in the line A B were assigned for the perpendicular, open the compasses to a convenient distance, and mark out the two points E and F in the line A B, then opening them somewhat wider, you may, by setting one foot in E and F severally, describe the two arches cutting one another at the point D, from which, if you draw a line to the point, C, the work is done for the raising of a perpendicular; but if you be to cross the lines at right angles, you may continue the line from D through C at pleasure.

But if the said line A B had been given to be divided in the precise middle, by another line crossing it at right angles, the way is to set one point of the compasses in A and B severally; and having described two arches above the line intersecting one another at D, do the like below the line A B from the same points, and with the same extent of your compasses, then through the several intersections, a rule being laid upon them, a line may be drawn, cutting the given line exactly in the middle at right angles.

Note, That when one point of your compasses stands in A, you may make both the arches belonging to that center above and below the line; and then removing the compasses to B, you may cross them both.

III. *To raise a perpendicular at the end of a line.*

Fig. 3. Let O R be the line given, then to raise a perpendicular at R, make five little equal divisions, and taking four of them with your compasses, set one foot of your compasses in R, and with the other describe the arch P P; then take the distance from R to 5, and placing one foot in 3, with the other describe the arch B B, intersecting the former in the point S; then shall the line S R (being drawn by a straight rule) be a perpendicular to the line O R.

IV. *To let fall a perpendicular upon a given line from any point assigned.*

Open your compasses so as one foot being set in the assigned point, the other may go clear over the line given, and thereby describe an arch cutting the line at two points; then shall the half distance between those two points be the point to which the perpendicular may be drawn from the point assigned. But if you think it too much pains to find the point of half distance by trial, you may help yourself by the second problem: for if you describe two arches intersecting one another on the farther side of the line from the assigned point, placing (to that purpose) the foot of your compasses first in one of the intersections of the given line, and then in the other; you may, by laying a rule upon the assigned point, and the intersection of the two arches, draw a perpendicular from the said assigned point, cutting the given lines at right angles.

N. B. All in these problems, with regard to perpendiculars, aim at no greater matter than what may be performed in a mechanical way, with exactness enough, by the help of a small square exactly made; for if you apply one leg of such a square to any line, so as the angle of the square may touch the end of the said line, or any other point

where the perpendicular is to be raised, you may by the other leg draw the perpendicular. In the like manner to let fall a perpendicular from a point assigned, you need only to apply one leg of the square to the line, so as the other may touch, at the same time, the assigned point; whence you may draw the perpendicular by that leg that toucheth the point.

If the handle of your square be a little blunt, either through ill making or long using, you must allow for it when you apply to it a point in a line. And when you are drawing a perpendicular, you must stop before you reach the given line, and then by applying the leg of your square to that part of the perpendicular already drawn, so as part of that leg may pass clearly over the given line, you may draw the rest of your perpendicular as exactly as if the angle had been true. This same method is to be taken when a line is to be crossed by another drawn quite through it at right angles.

V. *An angle being given, to make another equal to it.*

Fig. 4. The angle X A D being given; and a line drawn at pleasure, as is the lowest from the point E, open your compasses to any convenient distance, and setting one foot in A, describe the arch B C. Then with the same extent setting one foot in E, with the other describe the arch C H, long enough to equal or exceed the other. Then taking the distance B C between the points of your compasses, set one in C, and with the other mark the point H in the arch C H, through which point H a line being drawn from the point E, will make an angle with the line E C, equal to the angle given.

Note, when we speak of the quantity of angles, their equality or inequality, we never regard the length of the lines; for if you extend or contract them at pleasure, the angle is still the same. But that is the greatest angle whose lines are farthest distant from one another at the same distance from the angular point, or the place where its lines meet.

VI. *Any three lines being given, (equal or unequal) so as no one of them be longer than the other two joined together, to make a triangle of them.*

Fig. 5. The lines A B C being given, set the line A from D to E; then with your compasses take the length of the line B, and setting one foot in D, describe the arch P O. This being done, take with your compasses the length of the line C, and setting one foot in E, with the other cross the former arch at P, from which intersection drawing lines by a rule to D E, the triangle is finished.

Note, that if all the sides, or two of them, be equal, the method is the same; but the labour less, because we need not take the same length twice over with the compasses.

VII. *To find the perpendicular of the triangle, in order to the measuring of it.*

Fig. 6. Let the line A B be accounted the base, and from the angle C, let fall a perpendicular, as was taught Probl. 4. upon that line at D, which is ready for taking off with compasses, and measuring on a scale; of which hereafter, in measuring the content of figures.

But if we have no occasion to draw the perpendicular, but only to know the length of it, (as it most frequently falls out in measuring) no more is needful, but to set one foot of the compasses in the angular point C, and extend the other to the base A B, so as it may touch it, but not go beyond it; then have we the perpendicular between the points of the Compasses.

VIII. *One side being given, to make a square.*

Fig. 7. The line C D being given, raise a perpendicular at C of the length, at least, of the given line; then taking the line C D between the feet of your compasses, set it upon the perpendicular from the angular point C to A: with the same distance, setting one foot in D, describe the arch O P. Lastly, with the same distance or extent, set one foot in A, and with the other describe the arch crossing the arch O P in N, from which intersection a
K line

line drawn by a rule to A, and another to D, finish the geometrical square or quadrat A C D N.

IX. *To make a long square, the length and breadth being given.*

This is so nearly like the former, that a particular figure is not necessary to explain it. Suppose each side of the square in the last problem to consist of 8 small equal parts, and you were to make a long square, whose length must be equal to a side thereof, viz. 8, and the breadth half so much: when you had drawn the line C D, for the length, and raised the perpendicular at C, you must take the shorter line given for the breadth, and set upon the perpendicular from C, upwards to a point, which for distinction we shall call the point E, imagining it so marked: with the same extent of the compasses describe the arch, placing one foot in D. Lastly, extending your compasses to the length of the line C D, set one foot in E, and with the other cross the arch aforesaid. Then a right line drawn from that intersection to E, and another from the same to D, complete the long square.

X. *To make a rhombus, the side being given.*

Fig. 8. If the angles be not limited, draw any oblique angle at pleasure, either acute or obtuse, as here, the angle B A C, which is acute. Then let the line O P be the length of a side, which being taken with your compasses, set it from the angular point A, in both lines to D and E, in which two points, place a foot of your compasses successively without altering them, viz. in D, to describe the arch F G; and in E, to describe the arch H I, crossing one another in the point K, from which right lines drawn to D and E, finish the rhombus D A E K.

Note, If any angle be given together with the side, to limit the shape and content, begin with that, and proceed as before; for you must know, that to make a rhombus (or rhomboides) like to another for figure, or equal to it in content, it is not sufficient to have the same sides: for the more oblique the angles are, the farther will the rhombus differ from a square, and the less will be the content. But you must have an angle given, or else a diagonal line, which is a right line passing through the rhombus from one opposite angle to another, and dividing the figure into two equal triangles. If the former, viz. an angle, be given, we have shewed what use is to be made of it. If the latter, i. e. a diagonal, together with the length of the sides, you may, by taking the length of your sides with your compasses, and setting a foot in the ends of the diagonal line, make a triangle on the one side of the diagonal, by Probl. 6. and then another on the other side by the same problem, the diagonal being a common base to them both; and this will give the figure exactly.

XI. *To make a rhomboides, the sides being given,*

Fig. 9. If neither angle nor diagonal be given, make any angle at adventure, as here A B C. Then supposing the lines given to be O P and O R, set the length of the longer upon the line B C, from B to D, and the shorter on the line B A to E. Then with the compasses extended from B to E, set one foot in D, and describe the arch F G. Likewise, with the compasses extended to the length of the line O P, setting one foot in E, with the other describe the arch H I, intersecting the former arch at K; from which the intersection lines drawn to D and E, finish the rhomboides.

XII. *To make a trapezium, the diagonal and lines in order being given.*

Fig. 10. Let the line H I be the diagonal of a trapezium whose sides are the lines A B C D; the side A being counted the first, as that which takes it, being from the point H, and the rest in the order as they are marked alphabetically.

Then with your compasses set to the length of the line A, place one foot in H, and with the other describe the arch E F. Next taking the length of the line B, with the one foot of your compasses placed in I, with the other make the arch G J, intersecting the former at K;

from which point of intersection, lines drawn to H and L, make the triangle H K L.

Then with the extent of the line C, set one of the feet of your compasses at L, and describe the arch O P. Lastly setting them to the length of the line D, and placing one foot of your compasses in H, with the other make the arch S R, intersecting the former at Q; so shall lines drawn from Q to L and H, make up the triangle L Q H, and finish the trapezium H K L Q.

We could have been much briefer in this problem, by referring to the 6th; but this being of very great and frequent use, we desired to be very plain.

XIII. *To make a regular polygon, otherwise called a regular multangular, or multilateral figure, consisting of many equal sides and angles, viz. above four a piece.*

Being satisfied what shall be the distance between the center and every angle, with that distance describe a circle, which being equally divided into as many parts as the figure must have angles (or sides, for they are equal in number) and lines drawn from the points of division within the circle from point to point, (ordinarily called chords) the polygon is finished, as in this diagram.

Fig. 11. Suppose an heptagon, or multangular figure of seven sides, and as many angles, be to be described, every angle being designed to be distant from the center A, seven eighths, or three quarters and a half of an inch; with that distance describe the circle B C D E F G H, which being divided into seven equal parts, and lines drawn from point to point, the heptagon B C D E F G H will be therein included.

We shall rather leave our reader to find out the points of division by many trials, than to puzzle him with the geometrical way for finding out chords to that purpose.

XIV. *Having the sides of the triangles whereof it consisteth, orderly given, to make an irregular multangular, or multilateral figure.*

This will be more fully handled hereafter, when I come to shew the method of drawing plots of ground. In the interim I will give you a specimen of an irregular pentagon.

Fig. 12. Having the lines of three triangles given, lay down the greatest of the first, viz. 20, from A to B for a base, and by Probl. 6, make a triangle of it, and the other lines 16 and 10, viz. the triangle A B O.

Secondly, You find by the number 20 over the first line of the second triangle, that it is the common base to them both; and therefore, by the same Probl. 6, make the triangle A B P of the lines, 20, 14, 18.

Lastly, finding the base of the third triangle to be the same with 18, one of the sides of the second make the triangle P B Q of the lines 18, 11, 12: so is the quintangular figure finished.

How every line is to be found in its due order in this, or any other sort of multangular figures, so as to give a true and exact account, not only of the superficial content, but also of the figure and situation, is to be taught hereafter in the doctrine and practice of Protraction.

How to find the superficial content of any right-lined figure, the lines being given.

As a foundation to what we shall say upon this subject, there are some few geometrical principles or theorems out of Euclid and Ramus, which we desire may be remembered; and because understanding is a great help to memory, we shall make use of a kind of ocular demonstration; which though not so strict and artificial as that which is to be found in the commentators upon Euclid in the quoted places, will be more serviceable because more easily understood.

Theor. 1. *Every parallelogram being of the same length with the base of a triangle, and of the same height with the perpendicular of that triangle, is double to it.* Euclid 41. 1.

Fig. 13. Here are two equal oblongs, or long squares, A B C D and B E F C, and within them two triangles inscribed, whose bases are of the same length, and their perpendiculars,

pendiculars, O P and Q R, of the same height with the oblongs. Now each of these triangles being parted into two right-angled triangles by their perpendiculars, then it is plain to the eye, and from the nature of diagonals, which ever divide a parallelogram into equal parts, that the two new triangles OPD and OPC, which makes up the first of the given triangles, are equal to the triangles DAO and OBC, which make up the remainder of the parallelogram A B C D. Therefore that parallelogram is double to that triangle which was to be demonstrated.

In like manner it is evident, that the parallelogram BEFC is double to the triangle COF, because C R Q is equal to B Q C, and Q R F is equal to Q E F.

Theor. 2. *All triangles having the same base, and lying between the same parallels, are equal.* Euclid 37. 1.

So in our last diagram, the two given triangles having bases of the same length, and lying between the same parallels, are evidently equal, because they are demonstrated to contain each of them the exact half of the parallelograms wherein they are inscribed; and the parallelograms being equal, their halves must be equal also,

Theor. 3. *The sides of the triangulate (that is, one that hath four or more sides) are ever two more than the triangles of which it is made.* Ram. lib. 10. prop. 2.

Fig. 10, 12. This is plain by inspection, if you view again the figures of the trapezium and irregular pentagon, in the 12th and 14th problems.

These theorems being allowed to be true, the doctrine concerning the superficial content of right-lined figures, might be reduced to a narrow compass; for he that knoweth how to husband these three theorems, may easily take up these corollaries, *ordine inverso*.

1. Any quadrangular figure, regular, or irregular, may by a diagonal be parted into two triangles; any five-sided figure by two diagonals into three triangles: and six-sided figures into four by three diagonals, &c. by Theor. 3.

2. It is no matter of what shape the triangle is, as to the rule for measuring; for whether it be right-angled, acute angled, or obtuse-angled, and whether it have three, two, or no lines equal, it is only the length of the base, and height of the perpendicular and is considerable by Theor. 2.

3. The true measure or content of any triangle, whether alone, or as part of any triangulate figure of 4, 5, 6, or more sides, (and consequently of the whole figure, by summing up the content of all the several triangles) is found by multiplying the whole base of the triangle by half the perpendicular, or the whole perpendicular by half the base; which being a rule of such infinite use in surveying, we desire it may be remembered; and that it may be understood, we shall give a plain example.

Fig. 6. Suppose A B the base of the triangle belonging to the 7th problem, to be 44, and the perpendicular C D to be 20: whether you multiply 44, the whole base by 10, the half of the perpendicular, or 20, the whole perpendicular by 22, the half base, the product gives the content 440, as is here apparent.

Having thus given a general method how all right-lined figures may be reduced to triangles, and so their contents found, we might pass to the next head concerning instruments, and their use; but because there are newer ways in measuring particular kinds of triangulate figures proper to those kinds, we shall briefly mention them.

I. To find the contents of a square, or long square.

Multiply the length by the breadth, the product gives the area or content.

$$\begin{array}{r} \text{Example of a square,} \left\{ \begin{array}{l} 17 \text{ inches length.} \\ 17 \text{ inches breadth.} \\ \hline 119 \\ 17 \\ \hline 289 \text{ square inches.} \end{array} \right. \end{array}$$

$$\begin{array}{r} \text{Example of an oblong,} \left\{ \begin{array}{l} 25 \text{ feet long.} \\ 13 \text{ feet broad.} \\ \hline 75 \\ 25 \\ \hline 325 \text{ square feet.} \end{array} \right. \end{array}$$

II. To find the area or content in measure of a rhombus

Let fall a perpendicular from one of the obtuse angles upon the opposite side; that side multiplied by the perpendicular, gives the area.

20 yards the side.

14 yards the perpendicular.

$$\begin{array}{r} 80 \\ 20 \\ \hline 280 \end{array}$$

III. To find the area of a rhomboides.

Divide it into two triangles by a diagonal drawn between either pair of the opposite angles, then from either of the other angles let fall a perpendicular upon that diagonal, then shall that diagonal, being multiplied by that perpendicular, give the area.

Example.

19 rods the diagonal.

5 rods the perpendicular.

$$\begin{array}{r} 95 \text{ square rods the content.} \end{array}$$

IV. To find the content of a trapezium.

Fig. 10. Divide it by a diagonal into two parts from angle to angle, as the trapezium, Probl. 12. is divided by the diagonal H L; then from the other two angles, which in that figure are marked with K and Q, let fall perpendiculars upon the diagonal, half the sum of those perpendiculars being multiplied by the diagonal, or common base, gives the superficial content.

Example.

Suppose in the trapezium before-mentioned the diagonal is 33, the perpendicular from K 13, and that from Q 15, the area or superficial content is thus computed:

13 chains the first perpendicular.

15 the second perpendicular.

28 the sum of both perpendiculars.

14 their half sum.

33 the diagonal.

$$\begin{array}{r} 42 \\ 42 \\ \hline 462 \text{ square chains the area.} \end{array}$$

V. To find the content of a regular polygonal, or multangular figure, otherwise called multilateral.

Draw a line from the center to the middle of any side; half of the perimeter, or of all the sides, being multiplied by that line before-mentioned, gives the content.

VI. To find the content of an irregular polygon; or many-sided figure.

Divide it into trapezia and triangles by diagonals, then find their content severally, and sum up all together.

Fig. 12. Suppose the polygon belonging to the last problem were given without the diagonals A B and B P; then by drawing those diagonals, the figure is divided into three triangles whereof two being upon the same base A B, make up a trapezium, whose content may be found just in the same manner as was taught even now in the fourth rule, having found the perpendiculars from O and P falling upon the line A B. Then there remains the triangle B Q P, whose content may be found by the general rule concerning triangles, having found the perpendicular falling from Q on the line B P; and then having added the content

content of that triangle to the content of the trapezium, you have the area of the whole polygonal figure.

Concerning chains, compasses, and scales.

I. Amongst the many sorts of my chains used for measuring land, three are most famous, bearing the names of their inventors, Mr. Rathborne, Mr. Gunter, and Mr. Wing, all of them ingeniously divided, and useful in their kind; but brevity will give us leave only to describe one, and that shall be Mr. Gunter's, being most in use, and easy to be procured.

This chain contains in length 4 statute-poles or perches, each perch containing 16 feet and a half, or five yards and a half; so that the whole chain is 66 feet, or 22 yards long.

The whole chain is divided into 100 equal parts or links, whereof 25 are a just pole or perch; and for ready counting, there is usually a remarkable distinction by some plate or largening at the end of every 25 links, but especially at the precise middle of the chain, which should differ from the rest in greatness and conspicuousness. Also at the end of every tenth link, it is usual to hang a small curtain ring; and if there be at every five links end a piece of wire made like the bow of a link, with a little shank an inch or less long, or some such distinction, it is still better.

When you are to measure any line by this chain, you need to regard no other denomination but only chains and links, set down with a prick of your pen between them; e.g. If you found the side of a cloie to be 6 chains and 35 links long, it is thus to be put down, 6.35.

But if the links be under 10, a cypher must be prefixed; so 7 chains 9 links must be thus set, 7.09.

In the using of this, or indeed of any chain, care must be taken both to go straight, and to keep a true account; for which purpose, it is good that he who goeth before, carry in his hand a bundle of rods, to stick down one at the end of the chain which leads, having first stretched it well, and that he who follows do not only gather up the rods to keep the account, but also at every remove, mark whether he sees the leader directly between his eye and the angle, or other mark he aims to measure to; and if need be, call to the leader to move towards the right or left hand, till he sees him in a direct line it.

II. Compasses are so well known, that we need not describe them; only they should be of brass, with steel points, small and neatly wrought, nine or ten inches long from the joint to the points, turning so truly upon the rivet, that they may be easily opened, and yet stand so firmly, that an arch or circle may be, without their shrinking, described upon a large radius.

III. Scales are certain lines divided into equal parts, upon plates or broad rules of brass or box, and they are of two sorts: 1. Plain. 2. Diagonal.

1. Plain scales are made up of two small lines parallel to one another at a little distance, and these are divided into great equal parts, which signify tens, and are noted 10, 20, 30, 40, 50, &c. according to the length of the lines.

They may be of any convenient length, but these great divisions are seldom more than inches, or less than third parts a piece.

Again, one of the great divisions is subdivided into ten equal parts by short lines, whereof that in the middle standing for 5, is longer than the rest.

Fig. 13. According to the numbers of these little parts contained in an inch, the scale is named, A, scale of 10, 11, 12, 16, 20, 24, 30, &c. in an inch. That short one which we give you the figure of A, is of 10 in an inch, so noted at the top, according as is usual upon the rules, and indexes of plain tables. The line marked O Q, separates units and tens; units being taken upward from that line, and tens downward; mixt numbers both ways.

As for example.

7 Is the extent of the compasses upon the scale A from the line O Q to K; 30 is their extent from the line so marked to O Q; and 27 is their extent from the line 20, to the short line K aforesaid.

Here note, that you must not expect to find the letters O Q or K upon the scales which you buy, being only marks used at pleasure, to make our meaning plain; and likewise that this scale of 10 in an inch, and others that are smaller are usually made, for more convenient use, so long as to con-

tain nine or ten of the great divisions, signifying tens; though the figure at A being designed for no other use than to help our conceptions, extends but a little beyond 30, that length being sufficient for my purpose in this place.

Fig. 14. These plain scales, especially the smaller sorts of them, such as 24 or 30 in an inch, are very proper for drawing figures upon paper, where the numbers represented by the lines are not above 100, for then every division may be counted as it is upon the scale, or above upon a long scale.

Also in the surveying of forests, chafes, and great commons, where the lines are vastly long, and the mistake of a few lines is not considerable, they may be conveniently used, accounting the tens and units to signify so many whole chains, and so estimating the parts of a chain with the compasses upon the small divisions, which a sagacious man may do very near upon one of the larger scales. But it would be much better for ordinary measuring, if the grand divisions of the scale were two inches apiece, for then the smaller divisions being of five in an inch, would be so large as to be sub-divided into five a-piece, which represents 20 links; and then the half one of those smaller divisions signifying 10 links, and the quarter 5, a very ordinary judgment may come very near to the truth by estimation.

2. But the diagonal scale is so well known to every mathematical-instrument-maker, so easy to be procured, and every way so fitted to Gunter's chain, that we cannot but highly commend it.

It is made, as appears by the figure B, upon eleven parallel lines equidistant, so as to include ten equal spaces, which are all cut at right angles by transverse lines dividing them all into four equal parts.

One of these transverse lines, viz. P R, where it toucheth the first and last lines, separates between the hundreds, or whole chains, and the tens representing 10 links apiece, the chains being numbered downwards on the left hand from P only to 3, but on the instrument itself they may go on to 9 or 10, but the tens upward from P to 10.

From the points of division into tens upon the first line, beginning at P, to the like points beginning at R in the last line are nine diagonal lines drawn, the first beginning at P, and ending at the first division above R. The second beginning at the first division above P, and ending at the second above R. In a word, they are all drawn from one division less from P, to one more from R; by which it comes to pass that every diagonal, by that time it hath passed from the first line to the eleventh, is a whole tenth part of an inch, which answers to ten links of the chain, farther distant from the line P R than at the points upon the first line whence it was drawn.

Every one of those diagonals is divided into ten equal parts by the long parallel lines running through the whole scale, and numbered on the top from 1 to 9. Whereby it is evident that the intersection of any of the nine parallel lines that are numbered at the head with any diagonal, must be farther distant from the line P R than the intersection of the line next before it with the same diagonal by $\frac{1}{10}$ of $\frac{1}{10}$, that is, by $\frac{1}{100}$, which answereth to a single link of your chain.

From what has been said, and inspection of the figure B, these things plainly follow; which, as so many clear instances, will help you to understand it fully.

The distance from P R, to the second division below it, answereth to two chains.

The distance from P R, to the eighth division upward, being taken (with compasses) upon the first line of the eleven from P to 8, answereth to 80 links.

Consequently the extent of the compasses from the second grand division below P, to the eighth of the less divisions upward, is proportionable to 2 chains 80 links.

The distance from P R to the first diagonal being taken upon the parallel line, noted with 9 above, answereth to 9 links: where note, that the first diagonal is not that which is noted with 1, but that which is drawn from the point P.

The distance upon the same line from P R to the diagonal that is marked with 7, is answerable to 79 links.

The extent of the compasses from the bottom of the figure upon the same line to the same diagonal, answereth to 3 chains 79 links.

In short, whole chains may be measured upon any line from P R, to the grand division noted with the given number,

number, decads alone, or chains and decads upon the first line of the eleven where the diagonals begin. Links alone, decads with links, and chains and decads with links, always upon that line upon which the number of the odd links stands at the head of the scale.

N. B. These directions will as well fit, if half an inch be only allowed for a chain, and consequently all the diagonals drawn within that extent, as is usual upon the other end of the same rule, the grand division for chains going the contrary way, and noted with numeral figures in order. It is therefore proper when you furnish yourself with scales, to have diagonal scales of both dimensions on the fore-side of your rule, and upon the back-side many plain scales of equal parts, with a line of chords.

How to cast up the content of a figure, the lines being given in chains and links.

Having described these plain instruments, and in some measure shewed the use of them in several instances, it were very proper in the next place to teach their joint use in measuring and protracting; but because we would have our young surveyor, before we take him into the field, able to perform his whole work together, we intend to shew him,

1. How he ought to make his computations; 2. The grounds or principles that will justify him in so doing.

For the first, take these rules:

1. Put down your length and breadth of squares and oblongs, and your base and half perpendicular of triangles directly under one another, expressed by chains and links with a prick betwixt them, as was taught before.

2. If the odd links were under ten, put a cypher before the numeral figure expressing them, (as there also was shewed) and if there be no odd links, but all even chains, put two cyphers after the prick.

3. Multiply length by breadth, and base by the half perpendicular, according to the rules for finding the content of figures.

4. From their product cut off five figures, accounting cyphers also for such, reckoned from the right-hand backward, with a dash of your pen, so shall those to the left hand signify acres.

5. If those five cut off were not all cyphers, multiply them by four, and cutting off five towards the right hand again, the rest will be roods or quarters.

6. If amongst these five figures towards the right hand that were cut off at the second multiplication, there be any figures besides cyphers, multiply all the five by forty, and cutting off five again by a dash of your pen, those on the left hand signify square perches, poles or roods.

A few examples will make all plain.

Quest. 1. *What is the content of a square, whose sides are every one of them 7 chains, 25 links?*

Length	7. 25.
Breadth	7. 25.
	<u>36. 5</u>
	1450
	<u>5075</u>
	5,25625
	<u>4</u>
	1,02500
	<u>40</u>
	1,00000

Ans. 5 acres, 1 rood, and 1 perch, as here appears.

Quest. 2. *In a long square whose length is 14 chains, and the breadth 6 chains 5 links, what is contained?*

Length	14.00
Breadth	6.05
	<u>7000</u>
	84000
	<u>8147000</u>
	4
	<u>188000</u>
	40
	<u>3520008</u>

Ans. 8 acres, 1 rood, and 35 perches, as the work makes it evident.

Quest. 3. *In a triangle, whose base is 3 chains, and half the perpendicular 98 links, what is the content?*

The base	3.00
Half perpend.	0.98

	<u>2400</u>
	2700
	<u>129400</u>
	4
	<u>117600</u>
	40
	<u>7104000</u>

Ans. 0 acres, 1 rood, 7 perches.

There are other ways of computation by scales, tables, &c. But that this is demonstrative, will appear by the following steps:

1. It is evident, that in this way of multiplication, the product is square links; for every chain being 100 links, it is all one to multiply 7.25 by 7.25, or 725 by 725 without pricks; for the pricks signify something as to conceptions, but nothing at all in operation. The product therefore of the first example was really 525625 links.

2. Every chain being 4 perches long, it follows that 5 chains, or 20 perches in length, and 2 chains, or 8 perches in breadth, make an acre, or 160 square perches; for 20 being multiplied by 8, gives 160.

3. From hence it plainly follows that there are exactly 100000 square links in an acre; for 5 chains multiplied by 2, is the same with 500 links by 200, which makes 100000. And he does not deserve the name of an arithmetician, that is ignorant of this old plain rule, when the divisor consists of 1 and cyphers, as 10, 100, 1000, 10000, 100000, &c. cut off from the right hand so many figures of the dividend as the divisor hath cyphers, accounting them the remainder; so shall the rest on the left side be the quotient. It is plain then that 525625 square links, make 5 acres, and 25625 square links over.

Thus we have made it clear to a very ordinary capacity, that as far as concern acres, the rules for computation are good. Now for roods and perches, though it might be sufficient to mention that known rule in decimal arithmetic, multiplying decimal fractions by known parts, gives those known parts in integers, due regard being had to the separation, we shall proceed thus: if 25625 square links, which remain above an acre, contain any quarter or quarters of an acre, then, if they be multiplied by 4, and divided by 100000, that is, five cut off from the product, they will contain so many acres as now they do quarters, or roods; for any number of quarters multiplied by 4, must needs produce the like number of units or integers, and the division only reduces them into the right denomination. Now, 25625 being multiplied by 4, and five figures being cut off from the product, the result is, 1,02500, that is an acre and above; which shews it was above a quarter before it was multiplied by 4.

And to find how much, that is, how many square perches are contained in this last remainder, you must consider this 2500, not as square links remaining above the rood or quarter, but as four parts or quarters of square links, or, which is all one, as the true number of square links multiplied by 4, and consequently being multiplied by 40, the fourth part of square perches in an acre, it must as often contain 100000 square links, or an acre, as the quarter of this number 2500, viz. 625, signifying square links, containing square perches; and so for 100000 divided by 160, the number of perches in an acre, gives 625, answering to one perch; and 2500 multiplied by 40, gives 100000, or one acre, the five cyphers being cut off.

2500	160	100 000625
<u>40</u>		<u>960</u>
100000		400
		<u>320</u>
		800
		<u>800</u>

How to measure a close, or parcel of land, and to protract it, and give up the content.

Hitherto we have been like children learning to spell, now let us set our syllables together : that is, let us make use of the instructions before given to measure a piece of land, to plot it, and to cast up the content.

All closes, or parcels of land, are either such as need not be plotted for finding their true measure, but the chain alone doth the work ; or such as cannot be conveniently measured without plotting or protraction.

Of the first sort are the square and long square, known before-hand to be such, or found so to be by such instruments as are not yet described, or by measuring all the sides and diagonals. These squares and long squares need no protracting ; for you need only to multiply the chains and links of the length by the chains and links of the breadth, and so proceed as in the first and second examples : but all others, whether triangles or triangulate, are to be protracted. We shall give examples therefore in the three sorts of figures, triangular, quadrangular, and multangular.

But before we proceed to particular instances, let the young practitioner remember,

1. To begin at some notable angle of the field where there is some house, gate, stile, well, or the like ; or if there be none, then to dig up a clod, drive down a stake, or at least, to observe what quarter of the heavens it pointeth towards, whether east, west, north, or south, and on your paper mark it with the letter A, or any other.

2. To go parallel to the side of the field, if pits, bushes, or the like, hinder not, and if they do, to allow for it, accustoming yourself to go either with your left hand towards the hedges, walls, or pales ; or with your right hand towards them : and when you go contrary to your usual custom, note it on your paper by some mark known to yourself.

3. To set down the chains and links of every side as you measure them, and trust not your memory. A black lead pencil will be very proper for this purpose.

4. To take care, if you have more scales than one upon your rule, lest you confound yourself by taking lines off of several scales, or measuring perpendiculars upon wrong ones ; for every line of the same figure must be made by the same scale, and the perpendiculars measured by it.

5. To make use of a scale of larger divisions when you measure small closes, and of smaller when you measure great ones.

6. To make your lines and points where angles meet, small, pure and neat.

7. To set on your chains and links at twice, when any line is too long for your scale.

These things being premised, proceed thus :

I. Suppose a triangular field is to be measured with the chain, beginning at the eastern angle A, fig. 15, and find the sides in their order and measure to be severally thus ; 2.29, 3.54, 4.07.

Making use of the less diagonal scale, because the other would make the figure too large, otherwise it were more proper for so small a close, with your compasses to take off the scale 4 chains and 7 links, and setting them from A to C, draw that line for the base, because the longest of the three ; then take 2 chains 29 links off the same scale, and set them in the eastern point, A, and turning the loose foot of the compasses above the line A C, describe, at that distance 2.29, the arch E E.

Next taking with your compasses upon the same scale the extent of 3 chains 45 links, place one foot in the point C, and with the other make the arch F F, intersecting the former in the point B ; and drawing the lines A B and B C, the triangle A B C is the plot of the triangular field measured.

But before you can give the content, you must find the length of the perpendicular, which is done by setting one foot of the compasses in B, and extending the other to the base A C, so as to touch it, and pass not over it, for then the length of the perpendicular is between the points of the compasses, and being applied to the same scale by which the triangle A B C was made, it appears to be 1 chain 42 links. With the half whereof multiply 4.07, the length of the base, the content appears to be 0 acres, 1 rood, 6 perches.

The base 4.07
Half perpend. 0.71

4.07
2849
28897
4
115588
40
6.23520

II. Suppose you are to measure a quadrangular or four-cornered field, begin as before at some remarkable angle ; and going round the close, find the sides to be 9.04, 6.72, 8.46, 7.28, and the diagonal from that remarkable angle to the opposite angle to be 10.02 ; we begin to protract it thus :

Fig. 16. Having by the help of your scale and compasses drawn the diagonal 10.02, from the remarkable angle A to C, the opposite angle, make a triangle of it, and the first and second sides 9.04 and 6.72, and another after the same method of that diagonal, and the third and fourth sides 8.46 and 7.28, so you have the trapezium ABCD.

Then by the help of your scale and compasses, you find the perpendicular of the triangle A B C to be 6.02, and of the other, viz. CDA 6.01, which added, are 12.03, whereof the half sum is 6.01 ; by which, multiplying the base 10.02, the content of the field will be 6 acres, 0 roods, 3 perches.

The base 10.02
Half perpend. 6.01

1002
60120
602202
4
108808
40
3152320

Before we pass any farther, let it be remembered,

1. Any quadrangular close, or parcel of ground whatsoever, having right lines, may be thus measured, protracted, and computed.

2. The odd measure above perches, is not valuable here, nor in the former computations, being always under a square perch ; but in multangulars, where there be many remainders, they must be summed up, and the perches contained in them added to the content before found.

3. This last, and the following figures, are made, that they might not be too large, by a scale of 400 in an inch, i. e. by the less diagonal scale, each chain and link being counted two.

III. Fig. 17. If this multangular figure be conceived to represent a close of seven sides, which is to be measured, begin at the remarkable angle A, and going round the close, find the sides will be 3.11, 2.49, 2.47, 1.77, 4.11, 2.29, 4.37.

Then measure the four diagonals, B D, D F, F B, and B G, in the order you will find them to be 3.45, 4.97, 4.13, and 4.36, which is as short a way as can be taken, to prevent unnecessary walks.

But when you come to protract by the help of your scale and compasses, first make the triangle B C D of the first diagonal, and the second and third sides. Then the triangle D E F upon the second diagonal, and fourth and fifth sides ; and upon same diagonal as a common base the triangle B D F of the first, second, and third diagonals.

Next of the same third diagonal, together with the 4th and 6th sides, make the triangle B F G, and upon the 4th diagonal, as upon a common base with the first and last sides, the triangle A B G. So is the whole close plotted.

And now it stands visibly reduced into two trapezias A B F G and B D E F, together with the triangle B C D, which we shall not now cast up, having so often shewn how such work is to be done.

But

But it must be acknowledged that this method of plotting parcels of land that have many angles, requires not only more care and pains, but greater skill and memory than to draw diagonals upon paper, when the plot is already taken by the plain table, or other standing instrument. We shall therefore, to help our young practitioner in this case, advertise him of two easy ways to help himself, so as to be out of danger of mistakes.

One way is, to divide the multangular field into two or more parts, as the last might have been by the diagonal B F; then might each part have been measured severally, as if they had been separated by a pale, or where sundry men's lands parted by a boundary.

Another way that much helps both the understanding and memory is, to draw a rude draught of the figure of the land you intend to measure, not only as to the sides, but also necessary diagonals. Then measuring the lines upon the ground correspondent to those on the paper, set the lines as you measure them upon the lines of the draught, as if it were the true ones, and when you have finished your measuring, protract it truly. Such as you see here, but it is better larger, to do your business; for it is not a pin matter how rude or false the lines or angles be, resemblance being all that is desired.

Concerning the measuring of circles, and their parts.

We have hitherto purposely abstained from the meddling with the circle and its parts, that we might lay those things close together without unnecessary mixtures, that are of greatest use.

It is very rare if a land-meter ever has occasion to measure any field or parcel of land, that will prove either circle, semi-circle, quadrant, or sector. Sometimes indeed there will be a little crook in an old hedge bowing like an arch; but we have never seen any offer to measure it as a segment, but always take it as an angle or angles.

Yet because it may be expected we should say somewhat of those things, we shall briefly do it.

I. To measure a circle in the more exact way, is, to square the diameter, and to multiply that square by 7854; so shall the content be in integers and decimals.

But the more usual and quick way, (and near enough for any use we shall make of it) is, to multiply the half of the periphery or circumference by the semi-diameter.

In like manner to find the content of a semicircle, quadrant, or sector, made up of semi-diameters, and arched lines, multiplying the half arch by the semi-diameter, gives the content.

Fig. 19. But that which falls out most frequently in mensuration, though seldom much regarded, except where a curious exactness is required, is that particular sort of segment which we call a section, less than a semi-circle, such as the figure A B C. And to find the content of it, the center of the circle, whereof this is a section, must be first found, as here at O, from which lines drawn to A and B, make up the sector A O B C: which being measured according to the last rule, and from the content thereof, the content of the triangle A O B subtracted, the difference or residue is the content of the section A B C.

But two questions may be here demanded:

1. How may the center be found? 2. How may such a portion of land be truly protracted and computed?

To the first we answer, that the most exact and artificial way is, by making a mark any where in the arch.

As for Example.

At the point C, and then, by a problem known not only to every surveyor, but to ordinary carpenters and joiners, for finding the center of a circle, whose circumference will pass through 3 given points that are not in a right line, as A C B, to find the center O. But if you know not how to do it so, cross the line A B in the middle, as here it is done by the perpendicular O C; so you may by a few trials find both the true extent of your compasses, and the point in the perpendicular that will fit your purpose near enough; for if a little error be committed in making up the sector, the most of it goes off again in the subtraction of the triangle.

II. For the latter, you may take this ready course: measure the length of both your lines, the chord and the arch, and their distance at the middle of them both; then when you come to protract, first take the length of your right line from the scale, and having laid it down, cross it

in the middle at right angles with a dry line, as in the last figure, so shall it intersect the line A B in the point E; then from the same scale take the measured distance between the two lines in the middle, and set it upon that dry line from the intersection at E, to the point C. Then, by trials, find a due place in the dry line O E C, and such a distance with you compasses, that the one foot resting in the line, the other may be described the arch A C B, and the section is protracted.

Concerning customary-measure, and how it may be reduced to statute-measure, &c contra, either by the rule of three, or a more compendious way by multiplication only.

Though the statute-perch or pole is 16 feet and a half, and no more, yet there are poles of larger measure used in many places, as of 18, 20, 21, 24, and 28 feet; nay, in some 22 feet and a half. It were therefore very convenient that our young surveyor were furnished with a chain fitted to the customary measure of the country where he lives. But because these are too large and cumbersome for small closes, it is very convenient, instead of one chain of 100 links, to make two of 2 poles a piece, each pole divided into 25 links, as that of 100 is; which two half chains may, in measuring large fields, be tied together by the loops with pack-thread, or joined by a buttoning key-ring for more speedy dispatch; but in smaller we may use the half chain of 50 links, only taking care that we count not half chains for whole ones.

And in these cases where the poles are large, and the closes small, it were still more convenient if you had a chain of 2 poles only, divided into 100 links. Only you must then take notice, that whereas working by whole chains and links, the first multiplication, after five cut off, gives the content in acres and parts. The like work by half chains and half links, will give the content in roods or quarters of acres, and parts of such roods.

But though it is no hard matter, for one that can find out the length of a link by dividing the number of feet in a chain by 100, and provide himself of good iron wire and curtain-rings to make it of, and a sharp edged-file, and round nosed plyers to make it with, to be furnished with such a chain; yet because every one cannot do this, we shall shew how you may easily, and yet very truly, reduce statute-measure into customary, that so the chain before described may do your business all England over.

Know therefore, for a ground to go upon, that acres bear proportion to one another as the square of their poles; and therefore if you multiply 33, the number of half feet in the statute-pole, by itself, which gives 1089, and also multiply the number of half feet contained in a pole of that measure you would reduce into; in the same manner you may, by the rule of three reverse, obtain your desire, making to that purpose 1089 the first number, the statute-measure the second, and the squared half feet of the pole given the third. As for example: suppose of a close measured by the statute pole, the length and breadth, and their product be as here

9.33L.
7.21B.

933
1866
6531

prod. 672693

represented in the margin. And it is desired that the content may be cast up according to the large Cheshire measure of eight yards, or 24 feet to the pole or rod. Then before you cut off any figures, consider that in the statute-pole are 33 half feet, and in the Cheshire pole 48; multiply therefore 33 by 33, and 48 by 48, and you will have 1089, and 2304, which, together with the said product, may be thus placed: 1089, 672693:: 2304, and so multiplying 672693 by 1189 and dividing their product, being 732562677 by 2304, the quotient is 317952; from which, if 5 figures towards the right hand be cut off, the content, by this customary-measure of 24 feet to the pole, will be 3 acres, 0 roods, 28 perches, as here appears:

3|17952

4

171808

40

28|72320

But if the lines on the land had been measured according to that custom of 24 feet to the pole, and the content must have

have been found according to statute-measure, then we must have multiplied the product by 2304, and have divided that latter product by 1089. And in the same method you may proceed in all or any of the rest. But the truth is, that though this may be very exact, plain, and comprehensive, suiting all the customary measures before-mentioned without fractions, it is something tedious, except the practitioner knows how to relieve himself by a large table of logarithms, which we cannot stand here to treat of. Therefore, to contract the work a little, take notice, that all the customary poles being mentioned, saving only those of 20 and 28 feet, which we suppose are somewhat rarely used, having never heard nor read of them, but in Mr. Holwell; all the rest are capable of being divided into half yards: and therefore, if instead of squaring the half feet, you square the half yards of both poles, and work with them, you will attain the same end without any regardable difference, the small diversity that there is, being generally in the useless remainders, not at all affecting the desired quotient that gives the answer near enough for use.

As for Example.

If we had squared 11, the number of half yards 11 in the statute-pole, which would make 121, and also 16 the number of half yards in the Cheshire pole, which would make 256, and then multiplied the first product 672693 by 121, the second product would have been 81319853, which being divided by 256, the quotient would have been as before 317952. And this way is in a manner co-incident with Mr. Holwell's first method.

Take notice also once for all, that whether you use either of these or the following methods, you need not reduce the particular squares, triangles, or trapezia's severally; but sum up all their products together and then reduce all at once.

But if you would reduce statute-measure into customary by multiplication only, take notice of this present table following:

The content by the statute-pole being multiplied by	$\left\{ \begin{array}{l} .84027 \\ .68062 \\ .61734 \\ .53777 \\ .47265 \\ .34725 \end{array} \right\}$	Gives the content by the pole of	$\left\{ \begin{array}{l} 18 \\ 20 \\ 21\frac{1}{2} \\ 22 \\ 24 \\ 28 \end{array} \right\}$	Feet
---	--	----------------------------------	---	------

The use of this Table.

When you have multiplied lengths by breadths, or bases by half perpendiculars, multiply these products by the decimal fractions answering to the customary-measure, into which you would reduce statute-measure, and from that latter product, first cut off five places towards the right hand, as not to be regarded, being only parts of a square link, then cutting off five more, and proceeding to multiply by 4, and then by 40, as hath been often shewn, you will have the content by that customary-measure.

Example.

Suppose the length of a close measured by Gunter's chain and multiplied by the breadth measured also by the same, produced 672693 square links; and it is desired that the content may be given in Cheshire measure of 24 to the pole; you must multiply 672693 by 47265, 317948 the decimal fraction answering to 24 feet, and 4 from that product, being 31794834645, cut off and cast away 5 places, and the rest being 171792 317948, are in the usual way easily reducible 40 into 3 acres, 0 roods, and 28 perches, as here appears, agreeable to what it amounted to in 2871680 the former method.

But if you measured by a chain of customary-poles, and desire to know what the content is in statute-measure, this following table is for your purpose.

Feet.	18	1.19008
The content measured by the pole of	$\left\{ \begin{array}{l} 20 \\ 21 \\ 22\frac{1}{2} \\ 24 \\ 26 \end{array} \right\}$	being multiplied by $\left\{ \begin{array}{l} 1.46921 \\ 1.61983 \\ 1.85950 \\ 2.11570 \\ 2.87970 \end{array} \right\}$ gives the content by the statute-pole.

To understand which, take this example.

Suppose the length and breadth of a long square being measured by a chain of 24 feet to the pole, and multiplied together, make their product 317952, let this be multiplied by 2.11570, which answereth to 24 feet, and the latter product will be 67269104640; from which, if you cut off and cast away 5 places towards the right hand, the remainder is 672691; which, in the usual way, is easily reduced to 6 acres, 2 roods, and 36 perches.

One thing more, and we have done with this business of reduction. If the content to be reduced be cast up into acres, roods, and perches, reduce all into perches, and then in other respects work as before, either by the Rule of Three, or by this last method of multiplication only. So shall you have the content in square perches, according to the measure desired, which you may reduce into acres by dividing them by 160; and if any thing remain, that remainder being divided by 40, will give you the roods in the quotient, and the latter remainder the number of square perches.

For trial of which rules, remember the answer of these two following questions wrought all three ways.

Quest. 1. How many acres, roods, and perches according to the pole of 18 feet, contained in 5 acres, 3 roods, and 11 perches statute-measure?

Ans. 4 acres, 3 roods, and 22 perches, as here appears.

How to measure a piece of land with any chain of what length soever and howsoever divided; even with a cord or cart-rope, being a good expedient when instruments are not at hand of a more artificial make.

If you can procure a chain, and find it is not divided as before hath been shewn, but into feet or quarters of yards, or any such vulgar divisions, make no reckoning of the divisions at all, but measure it as exactly as you can find out the true length of the whole chain; and if it fit none of those lengths mentioned before, nor any of their halves, make it fit by taking off a link or two, or piecing it out with a string; then dividing the length of that chain by 100, or the half of it by 50, find the true length of a link according to our artificial divisions, and having got a long stick or rod, set as many of those link-lengths upon it as it will hold; then may you measure all the whole chains by your regulated chain, and the odd links of every line by your divided stick or rod, as is manifest in this example following.

Being far from any instrument, and requested by a friend to measure him a close, you must procure a pair of compasses, an ordinary carpenter's rule of two feet, divided into inches and quarters, and also with a piece of an old chain seemingly divided into feet, measure it by the rule, and finding it to be 45 feet long, and some odd measure, piece it out with a pretty strong cord that will not stretch much, to 48 feet exactly; then will it serve for half a chain of 24 feet to the pole: this 48 multiply by 12, the number of inches in a foot, and that product being 576, divided by 50, the number of links in half a decimal chain, and the quotient is 11.52 inches, or 11 inches and an half, and a trifle over: dividing therefore a long stick throughout into such parts, each containing 11 inches and a half, besides the breadth of the nicks, you are provided of tools to measure lines to a link with exactness enough.

In like manner you proceed with a cord or rope, having fitted them to some known length or other: and then for protracting, it were easy with the compasses to make a plain scale of a large sort, either upon paper or an even piece of wood. This for once may serve a man's turn well enough.

Besides, there is a way of measuring the perpendiculars of triangles and trapezias upon the ground itself, so as prevent the necessity of a scale; for if you have a little square with a hole in it to turn upon the head of a little stick, which you may fix where you please, as you are measuring the base of a triangle, or the diagonal of a trapezium, you may by a very few trials find the place where the one leg will be just in the line you are measuring, and the other point at the angle from which the perpendicular falls on it; and then the space between your stick and that angle, truly measured, is the perpendicular.

If you have not such a square, a square trencher, or any end of a board that hath one right angle, and two true sides, will supply the want of it.

And we shall make bold to add, that this is a good way to measure a trapezium, though it be protracted afterwards; for by measuring the perpendiculars as aforesaid, and observing at how many chains and links end the said perpendiculars meet the common base, the whole trapezium may be truly protracted without going about it; this little square competently supplying the place of a instrument, which is usually called a cross or square, made up, as it were, of two small indices, like those for a plain table, but much less, with four-sights and back-sights; and cutting one another at right angles put together; and having an hole in the center.

Concerning dividing of land artificially and mechanically.

I. To divide a triangle into any parts required; divide
7 M the

the base as the demand imports, then shall lines drawn from the points of division to the opposite angle, finish the division of the triangle.

Example.

Fig. 20. A C, the base of the triangle A B C, being divided on 12 equal parts, a line drawn from the angular point B to the point 6, divides the triangle into two equal parts; 2 lines drawn to 4 and 8, divide it into three equal parts; two lines drawn to the points noted with 3, 6, and 9, divide it into four equal parts; and so lines drawn to 2, 4, 6, 8, and 10, divide it into six equal parts.

Also it is very obvious, that if the same triangle were so to be divided, that the one part should be double to the other, a line drawn from B to 4 or 8, doth the work, or if it be required to divide into two parts, so as the one shall be triple to the other, a line drawn from B to 3 or 9, completes the work. So also a line from B to 2 or 10, divides it into two parts, whereof the one is quintuple, or five-fold, to the other, and a line from B to one or 11, divides it into two parts, whereof the one is 11 times as large as the other.

Farther yet, if it were required this triangle should be so divided that the two parts should in quantity bear proportion as 5 and 7, a line from B to 5 or 7, will answer the intention.

The divisions will indeed be sometimes a little more intricate than this, yet no such, but that the seeming difficulty may be easily overcome by observing the following method:

Suppose a large triangle of common land to be divided amongst three tenants, A, B, and C, according to the quantity of their tenements, A, having 19 acres of land to his tenement, B 13, and C 7, the base of the triangle being found by measure to be 17 chains and 17 links; and the demand is, where the point of the division must be placed in the base, so as lines drawn from thence to the opposite angle, shall truly limit each man's part.

To answer this, let us add 13 and 07 to 19, and they give 39, so is the work plainly reduced to the rule of fellowship; and therefore to find every man's distinct portion, we need only to multiply the base by his particular number; and divide that product by 39, the sum of all their numbers.

$$\begin{array}{r} \text{A} \\ 29 \cdot 17.27 :: 19. \\ \hline 19 \end{array}$$

$$\begin{array}{r} 15543 \\ 172 \\ \hline \end{array}$$

$$\begin{array}{r} 39) 32813 (841\frac{1}{3} \\ 312 \\ \hline \end{array}$$

$$\begin{array}{r} 161 \\ 156 \\ \hline \end{array}$$

$$\begin{array}{r} 53 \\ 39 \\ \hline \end{array}$$

$$\begin{array}{r} 14 \end{array}$$

$$\begin{array}{r} \text{C} \\ 39 \cdot 17.27 :: 7 \\ \hline 7 \end{array}$$

$$\begin{array}{r} 39) 12086 (309\frac{1}{3} \\ 117 \\ \hline \end{array}$$

$$\begin{array}{r} 389 \\ 351 \\ \hline \end{array}$$

$$\begin{array}{r} 38 \end{array}$$

From these operations it is plain that if we set off from the angular point where the base begins, 8 chains, 41 links, and a little above the third part of a link upon the base for A, and were that ends, 5 chains and 75 links and $\frac{1}{3}$ of a link for B, and consequently leave between this second division and the other end of the base 3 chains and almost 10 links for C; lines drawn from those points of division to the opposite angle, will give each man his due.

What has been said touching the division of triangles upon their bases, will, with a little variation, serve for the

dividing of all sorts of parallelograms, whether squares, long squares, rhombuses, or rhomboides; all the difference is, that, instead of drawing lines from points in the base to the opposite angle, you must draw parallel lines from points in one opposite side to another, as will be sufficiently plain by this one instance.

Fig. 7. Suppose the square figure to represent a close of six acres, and you are to cut off an acre at the side A C; having set off the 6th part of the line C D, from C towards D, and also from A towards N, a parallel drawn between those points, take off exactly a 6th part of an acre.

If it be not thought convenient, as in some cases it is not, to cut off a piece so long and narrow, you may by the Rule of Three find what other length of any greater breadth will limit an equal quantity to it. Or you may multiply the breadth by 2, 3, or any other, and divide the length by the same number that you multiplied the breadth by. Or lastly, if you set out a double proportion that is $\frac{2}{3}$ or $\frac{3}{2}$, from C towards D, and from the point where it falleth draw a line to the angle A, you will have a triangle equal to $\frac{1}{6}$ of the square A C D N.

But to return to triangles, the most simple and primitive of all rectilinears, and therefore the most considerable in this case of partition, as giving laws often to the rest, it may fall out that a triangle must be divided, by a line from some point in a side, so as that line may either be parallel to some other side, or not parallel to any.

Fig. 21. Let A B C be a triangle given, and it is required to cut off $\frac{1}{3}$ by a line parallel to A B. First, on the line A C describe the semi-circle A E C, whose diameter C A divided into five equal parts according to the greater term, upon three of those parts, the lesser term, erect the perpendicular D E, which cutteth the arch line in E, then let the line from C E from C to F, and from thence draw the line E G parallel to A B; so will the triangle C G F contain $\frac{1}{3}$ of the triangle A B C, as was required.

Fig. 22. Now, for the latter case, when the line of partition goes not parallel with any side, take this example:

Let A B C be a triangle given to be divided into two parts, which shall bear proportion to one another, as 3 and 2, by a line drawn from the point D in the base, or line A C.

From the limited point D, draw a line to the angle B; then divide the base A C into five equal parts, and from the third point of the division draw the line to E parallel to B D. Lastly, from E draw the line E D. So shall the trapezium A B E D be in content as 3 to 2, to the new triangle D E C.

We shall have now done with the division of triangles, when we have added the three following advertisements:

1. You must be sure to take very exactly the distance of every point, where a dividing line cutteth any side, to one of the ends of the same side, as in this last figure, the distances B E and A D; which distances being applied to the scale by which the triangle was protracted, will shew at how many chains and links end you are to make your dividing line on the field itself.

2. The proportions by which you are to divide, are not always so formally given as in the former examples, but are sometimes to be found out by arithmetical working, as in this case.

Suppose a triangular field of 6 acres, 2 roods, and 31 perches, must be divided so as the one of the two parts shall be 4 acres, 3 roods, and 5 perches, and the other, consequently, 1 acre, 3 roods, and 26 perches; reduce both measures, into perches, and the one will be 705, and the other 306. Their sum is 1011, which, by their common measure, being reduced into their lowest terms of proportion in whole numbers, will be 5, 2, and 7, which shews that the triangle being divided into 7 equal parts, the one must have 5 of those 7 parts, and the other 2. And observe that it be sufficient to find the common measure between the sum of your terms, and either of the terms; the method whereof is shewn in every arithmetic-book for reducing fractions into their lowest terms.

But the reader may multiply either of the parts; as suppose 705, by the length of the base, which we will suppose to be 8 chains and 75 links, or 87 links; and that product divided by 1011, the content of the whole close in perches, gives the rule of three direct, 625 links, or 6 chains and 1 pole, the true distance from either end of the base, that his mind or occasions may direct him to begin with, to the point of division; for the division must be not only for pro-

proportion or quantity, but also as to position or situation of parts upon the paper, as it is required to be on the ground.

3. In these and all other divisions of land, where a strict proportion in quantity is to be observed, you must have respect to the rules given hereafter concerning measuring of uneven ground, especially if one part prove much more uneven than another: and if there be any useful pond, or well, to draw your line of divisions through it; but if it be an useless pond, lake, or puddle, or if there be any boggy or barren ground, that must be cast out in the divisions, measure that first, and subtract it from the content of the whole close, and then lay the just proportion of the remainder on that side that is free from it, that the other may have its just part also, besides that which is useless.

What hath been said, with an ordinary measure of discretion, may sufficiently instruct a young artist to divide triangles, parallelograms, and regular polygonals, in an artificial way; but because many closes and open grounds are trapezias, and many irregular polygons, and even those that are regular enough, may fall under an irregular division, in regard to the quality of the land, woods upon it, or quarries in it, or the conveniences of ways, currents of water, situation in respect of adjacent lands, &c. we shall propose a method, which, though it hath somewhat of the mechanic in it, will be singularly useful in such cases.

Let A B C D be a trapezium to be divided betwixt a young heir and his mother, so as his part may be double to her's. Having by the diagonal B C divided it into two triangles, you will find the content of the triangle A B C to be 138550 square links, and the triangle B C D to contain 103468, in all 242018 square links, which, if reduced, as hath been formerly taught, would amount to 2 acres, 1 rood, and 27 perches.

But for the present work, they are in a better order already. Dividing then 242018 into three parts, each of them is 80676 and $\frac{2}{3}$, two therefore of those third parts must contain 161353 and $\frac{1}{3}$, which $\frac{1}{3}$ being inconsiderable, regard them not.

Then if you resolve to lay out the double part towards the line B D, strike at adventures the line E F, and measuring the trapezium bounded by that line, and the opposite side B D, together with the interjacent parts of the line A B and C D, which you will find to contain 119140 square links: but because it should have been 161353, subtract 119140, out of 161353, and their difference is 42214, and perceiving that the lines A B and C D are very near parallel, and finding their distance where they are cut by the line E F, to be 326 links, or 3 chains and 26 links, divide 42214 by 326, and the quotient is 129 links, and almost half, at which distance draw the line G H parallel to E F; so shall the trapezium G B D H be the heir's part.

Another way whereby the same thing may be performed is this. Finding the triangle A B C to contain 138650 square links, subtract it out of the heir's part, viz. 161353, the difference 22803, shews how many square links must be taken out of the triangle B C D, and added to the triangle A B C; which to perform with all necessary exactness, suppose the side or line B D to be the base which by measure proves to be 344 links, or 3 chains and 44 links. Say by the Rule of Three direct, if the whole content of the lesser triangle, viz. 103468, give 344, what shall 22803 give? So will the result be 75 links, and somewhat more than $\frac{1}{2}$, or a link, for 22803 multiplied by 344, gives 7844232, which being divided by 103468, the quotient is 75 $\frac{181132}{103468}$; or according to decimal division, 75.8131, which is somewhat more than 75 links and $\frac{1}{2}$, wherefore extending your compasses upon the scale to almost 76 links, set that distance upon the line B D, from B to I, and draw the line C I: so shall the trapezium A B I C be double to the triangle I C D, within so small a matter as is not worth regarding, though the land were a rich meadow.

We hope it will be unnecessary to tell any man of sense, that if he please he may begin with the less part, and take out that; or if there be many partners, he may divide betwixt any one and all the rest, putting their parts together, and then by the same method sub-divide amongst them till each hath his due share; not to spend many words in telling him he must subtract where he hath, by separating a line at adventures, or by choosing out a triangle, taken too much, as we added when we took too little. Nor lastly, that these methods are not only applicable to tra-

pezias, but to any triangular figure whatsoever, whether regular or irregular.

Concerning the boundaries of land, where the lines to be measured must begin and end.

If there be no agreement between the parties concerned, for if there be, that must be observed, reason and custom are the surveyor's guide.

The farmers speak loudly, that when a piece of arable or meadow land, is let for a year to be sown or mown, no more should be measured, nor expected to be paid for, either to the letter or workmen, than the plough or scythe can go over. So also when a parcel of land is let for pasture by measure to a farmer, it seems very reasonable, that all, and only so much should be measured, as is useful to that purpose.

But commons to be inclosed are usually measured, except it be otherwise agreed, to the uttermost bounds of every man's particular proportion, without any allowance for ditch or fence, every man being to make them upon his own of what breadth he pleases. Nor is this unreasonable, for it is as good for one as another, and the rate paid to the lord is usually very little, sometimes nothing.

It is also very usual in measuring betwixt lord and tenant, in cases of leases for lives, and long terms of years, to extend the lines to the utmost bounds of the tenant's claim, taking in the very walls, hedges, and ditches: but this is accounted very hard, and oft proves very unequal among the tenants of a lordship, some being forced to make much more waste of their ground this way, than others that hold as much or more. But where the custom obtains, the surveyor must observe it; for it is others work to appoint what must be measured, and his only to measure truly what is so appointed. A good landlord may, and will be apt to consider it in his rates, and a bad one it is like will be tenacious of a custom to his own advantage.

Lastly, in case of a sale by measure at a rate agreed upon per acre, no boundaries being specified in the bargain, the rule is to extend the lines to the quick wood-row, that is, to the place where the quick wood actually groweth, or where, according to custom, it ought to be set.

Containing a description of the plain table, the protractor, and lines of chords.

Though what hath been already said, may competently suffice to instruct the young artist in measuring a close of land, yet to advance him a degree higher in useful knowledge, we shall take occasion to describe unto him the plain table, which consists of several parts.

1. The table itself which is a parallelogram of wood fourteen inches and a half long, and eleven inches broad, or thereabouts, and for necessity may be made by an ordinary countryman workman of one board; but for a neatness, convenience of carriage, and freedom from warping, it is usually made of three little boards, joined together sideways, with a ledge at each end to hold them fast together; and upon the middle board a socket of brass fixed with three screws, and with a fourth to be fastened on the head of a three-legged staff; of which anon.

2. A frame of wood fixed to it, so as a sheet of paper being laid on the table, the frame being forced down upon it squeezeth in all the edges, and makes it lie firm and even so as a plot may be very conveniently drawn upon it. This is usually made with joints for more easy carriage, but a plain one may suffice. Upon one side of this frame should be equal divisions, for drawing upon parallel lines both long-wise and cross-wise; as occasion may require, over your paper, and on the other side the 360 degrees of a circle projected from a centre of brass conveniently placed in the table.

3. A box with a needle and card, to be fixed with two screws to the table, very useful for placing the instrument in the same position upon every remove.

4. A three-legged staff to support the head being made so as to fill the socket of the table, yet so as the table may be easily turned round upon it, when it is not fixed by the screw.

5. An index, which is a large ruler of wood, or rather brass, at the least sixteen inches long and two inches broad, and so thick as to make it strong and firm, having a sloped edge

edge, by which we draw the lines, called usually the fiducial edge, and two sights of one height, whereof the one hath a slit above, and a thread below, and the other, a head above, and a slit below, so set in the ruler as to be perfectly of the same distance from the fiducial edge. Upon this index it is usual to have many scales of equal parts, and there might be a diagonal scale if the instrument-maker please; and lines of chords of sundry length; but if you have such a scale as before described, you need not to have them here.

The protractor is an instrument so well known and so easy to be made and procured, that we shall be very brief in the description of it. As it is usually made, it consists of two parts, a scale and a semi-circle, but the scale is no necessary part of it, but serving, if you be not otherwise provided, for other uses before-mentioned in the case of plain scales.

But the semi-circle is more essential, and it may be made of brass, or other metal of any convenient size, as four inches, more or less, for the straight side, this semi-circle being bounded as all others are by two lines, the one right or straight, the other circular.

The right line is divided in the precise middle, by a point which is in the center, upon which the circular boundary is drawn, and two other arches concentric with it.

The center when the semi-circle goes alone without the scale, should be guarded with two little lips, on each side one, or a little loop, for more convenient turning the instrument about upon a pin fixed in a paper.

The arched or circular edge is divided into 180 degrees, or equal parts, numbered by tens, upon the upper concentric arch from 0 to 180, and in the lower from 180 to 360. So that by applying the straight edge of the protractor twice to any line keeping the center right upon a pin fixed in the line, that is, with the semi-circle first above it, and then below it, contrarily you may draw a whole circle by the guidance of the arch, or set out any number of degrees, as will appear more plainly hereafter.

A line of chords is a line divided into 90 unequal parts, whereof 60, and the radius upon which the circle was drawn, are equal, and the divisions upon that line are equal to the next extent in a right line, of so many degrees from the beginning of the quadrant, as answer thereunto.

When lines of cords are cut upon wood, it is both usual and necessary that there be two studs of brass, the one at the beginning and the other at 60 degrees, with little holes for the feet of the compasses, when you take the extent of the radius to preserve the line, from being wounded by the compasses; and being thus fenced, it will for need do the work of a protractor, but not altogether so commodiously.

How to take the true plot of a field by the plain table, upon the paper that covers it, at one or more stations.

There are three ways or methods for doing this work, two more usual and ordinary, the third more unusual and extraordinary, though now pretty well known to most surveyors, and in late books published. The first performs the work by measuring every line from the instrument to every angle, and is a very sure substantial way where it can be done, as it ordinarily may in most closes.

The second doth it by measuring only the station or the distances, and it is very quick, but not sure and exact as the other; yet if managed by a skilful artist, that knows how to plant this instrument, so as to avoid making acute angles unnecessarily, it will come near enough the matter in many places; as in measuring for workmen, that take the mowing or reaping the fields by the acre, or when tythes are let a small value per acre, as in poor barren parishes they usually are.

The third is the way of circulation or perambulation, the instrument being oft to be planted, and the plot to be measured about; by which not only difficult closes, but even the thickest woods, yea, bogs, meers, and pools of water, may be plotted, which by neither of the other methods can be performed.

In all these methods, two things are to be performed.

1. At every angle where there is no perspicuous mark already, as a tree, bush, stile, &c. one must be placed, as white paper, or such like; or else some one must go from angle to angle, and remain there as your mark to look at, till you bid him remove to another; only when angles are near you, this labour may be spared.

2. Whenever you have occasion to plant your instrument more than once, as it will often fall out in the first method, and ever in the two latter, you must be sure it stand just as it did the first time for situation; for which your needle, if well touched and hung, will be a good direction, but is not thought sufficient without back-sight and fore-sight. The first method is this.

1. When you go about to plot your parcels of land, find such a place in it, if possible, from whence you can see all the angles, and in that place plant your instrument covered with a sheet of paper, and turning it about till the needle playing at liberty, hang over the flower-de-luce, or any other notable place that you make choice of, screw it fast. Then choosing any convenient place in your paper for a center; and to represent your station, or place where you fix your instrument, make a prick with the small point of your compasses; to which prick applying the fiducial edge of the index, which is easily done if you keep the point of your compasses resting in it, direct the index, by the sight to all the angles; and when through the slit, or long sight, you see the opposite thread, cut the mark in the angle, draw a neat dry line along the fiducial edge, to or from the center; then measuring from the instrument to every angle, set the measure by a scale and compasses from the center towards the angle upon the line that points at it, making a prick in the line where the chains and links, reckoned from the center, truly end; then shall lines drawn by a straight line from prick to prick, give you the perfect plot upon your paper, which you may divide, as hath been before shewed, into trapezias and triangles, and so find the true content. To make which plain, mark this example:

Fig. 24. Suppose *ABCDEFGH* to be a field, having planted the plain table, as before directed, at a convenient advantage, so as to see all the angles, as at *I*, a prick to represent the station in the little circle \odot marked with *I*, upon which laying the fiducial edge of my index, and directing the sights to all the angles, draw dry lines towards *A*, and all the rest of the angles in order from the center; and then measuring upon the ground from the instrument to the angle *A*, and find it to be 3.45, which set from the center to the point *A*, and so upon all the rest, according to their due measures, and then black lines drawn from point to point, as from *A* to *B*, from *B* to *C*, &c. limit the true figure of the field according to the scale used, viz. of 400 in an inch.

And now before we pass to farther varieties, let the reader take notice of these following things.

1. From henceforth we shall forbear to take any notice of the measures of lines measured from the instrument to the several angles, having so often shewed how to measure by a scale.

2. When we speak of measuring from or to the instrument, we always mean from or to that part of ground that is perpendicularly under the head of the instrument where you are to draw your plot, which will ever be enclosed with the three legs of your staff.

3. That it is usually the quickest way to measure first from the instrument to the first angle, and then back from the second angle to the instrument, and so the rest in order, still one from the instrument, and the other to it.

4. It is no matter at all whether your plain table be placed towards the middle of a field, as was represented in this figure, or at an angle, as will appear hereafter.

5. In all workings by this instrument, you must have a care that the instrument be not moved out of its due place, till you have finished the work of the present station; for which purpose, cast your eye now and then upon your needle, observing whether it continue to hang directly over the same point you set it at when you began your work, and to rectify your instrument if you see cause. But because all tables have not needles, and where needles are, they are not accounted very accurate, make use of the following help.

When you have planted your instrument, and made a point or prick in your paper, representing your station, set the fiducial edge of your index to it, and turning it softly about till you find one remarkable thing or other upon one side of the close, and another on the opposite side, as you look through the sights of your index, which we call fore-sight and back-sight, draw a remarkable line with ink, or rather with a black-lead pen quite over your paper, which in this figure is represented by the black line *K L*; and then if you suspect that by any accidental jog, or other casualty

casualty, the instrument is any thing removed, you may easily try, and rectify it by applying the fiducial edge to the same line, and making use of fore-sights and back-sights again, upon the same marks which you before observed upon upon the opposite sides of the close.

But if there be no convenient place for the placing of your instrument, whence you may see all the angles of the field, more stations must be made use of: thus,

Fig. 25. Let A B C D E F G H I K L M N be a field whose angles cannot be all seen from any one angle, or other place in it. Plant your instrument at the angle A; and if it have a needle, mark what degree of the chord it cuts, or turn about the table on the head of the staff, till the needle hang over some remarkable place, as suppose the flower-de-luce, and screw it fast; then setting up a stick with a white paper or cloth on the head of it, where you intend your second station, as here at Q, make a prick or point in your paper, to signify the point A upon the paper on the table: to which point you must apply the fiducial edge of the index, and when you see the white at Q, so as looking through the slit you see the thread cut it, draw the line O P quite through the paper with a black-lead pen, and then keeping the fiducial edge still upon the same point, and turning it round by degrees, look at the angles B C D E F L M N, still drawing dry lines with the points of your compasses, and setting on the measures from the station A, to every angle measured to or from, as in the last example.

Then remove your instrument to the place of your second station, having set up a mark at A, and laying the fiducial edge to the line O P, turn about the table upon the head of the staff, till, through the slit of the back-sight, you see the thread cutting the mark at A, and then screw it fast; so will the needle, if a good one, hang directly over the same point that it did at the first station: but however that be, fore-sight and back-sight will do the business; for which purpose it is good to take back-marks as well as fore-marks at every station, as was taught in the example of a single station, only taking notice that the back-mark, when the instrument is planted in an angle, must needs be out of the field; as suppose here at O.

Having measured the distance between the first and second station, and finding it to be 7, 10, set it upon the line O P, from A to Q; where make another point to represent the second station, and turning about the index with the fiducial edge upon that point, and so looking through the sights at the angles G H I K, draw lines towards them on your paper, and having measured between every one of those four angles, and the instrument, set those measures, as you did the other, with your scale and compasses, from Q towards every angle upon its proper line; and then having the drawn black bounding lines from A to B, from B to C, and so round about the close, the protraction is finished.

But here to make this figure yet more advantageous, remember the following advertisements.

1. Sometimes a station is so taken, that you may measure towards two angles at once, as here from Q to G and H, in which case you are to set down the chains and links where the first angle falleth, but still be proceeding to the farther angle, causing the remainder of the chains at the fore-end to advance beyond the former angles; so going on with whole chains so far as you can, to which the odd links at the end are to be added.

2. If at any of your stations, as suppose A, you can see an angle, for example E, to which you cannot measure in a direct line without passing the boundaries of your parcel of land given to be measured, you may notwithstanding take in that angle by a straight measured line, as we have done, provided it may be lawfully done without trespass, and conveniently without troublesome passing of fences, otherwise it must be taken from another station.

3. One of your stations was here taken at an angle, and the other within the body of the field, to shew the variety of working taught by other authors, and that it is no great matter where you make your stations, so you can see the angles; else it has been full as convenient to have taken the first station also within the body of the field, as suppose at R.

4. Though this figure represents to your eye only two stations, A and Q, your fancy may multiply them at pleasure; for suppose the angle H could not have been seen from A to Q, how easy had it been to have set up a mark at S, and then to have removed the instrument thi-

ther, observing the same directions that were given at the removing from A to Q?

II. In the second method the instrument is to be planted twice, or oftener, as occasion requires, the rules for removal of the instrument fore-sight and back-sight, and measuring the distance of stations, being the same as formerly taught; but instead of measuring to and from every angle, we only view each angle through the sights from two stations, having applied the fiducial edge to the points representing those stations, and having drawn lines with the point of your compasses, or a protracting needle, the intersections represent the angles, from which the boundary-lines may be drawn; so is the field protracted. Which, that the reader may understand, let him note these three figures:

Fig. 26, 27, 28. In these three figures the angles are marked alphabetically, A B C D E F, &c. and the stations by a small point in a small circle numbered, 1, 2, or 1, 2, 3, according to their number and order.

Fig. 26. The first of these figures represents the plotting of a field at two stations within it, from both which all the angles may be seen.

Fig. 27. The second performs the same work by two stations taken without the field, by which art a close may be measured, though the present possessor will not give us leave to come into it.

Fig. 28. The third shews how the work may be performed at three stations or more, when two such places cannot be found whence to view all the angles; which last having more of difficulty than the two former, though indeed not very much, and the explanation of that will sufficiently help to the understanding of them, we shall a little explain the meaning of it in these particulars.

1. From the first station, taken according to the former directions, you see the angles A B C D F G K, and accordingly draw lines upon your paper towards them from the point representing that station, by the fiducial edge of your index with the point of your compasses.

2. Having removed the instrument to the second station, and in so doing, observed the rules before given, you will thence see the angles A B C D E F G H I K, and draw lines upon your paper towards them from the point representing the second station. And now viewing your work, you find upon your paper intersections for the angles A B, D F, G K, but only single lines towards the angles, C E H I; therefore,

3. Removing the instrument regularly as before, to a third station, you will thence see those four angles C E H I; and drawing lines towards them, you will have intersections for them also; so that having drawn the lines A B, B C, &c. from one intersection to another, you have the field perfectly protracted. For these bounding lines from angle to angle, do not only signify the boundaries of a piece of land given to be measured, limiting the figure or shape thereof, and are to that purpose given in this and all other surveying-books, but also are the true distance by a scale from angle to angle for the plot upon the paper; we mean by the same scale by which the stationary distances were laid down upon their own lines. And this holds true in all kinds of true plotting, whether in this method or any other.

III. The third method is that of circulation; and this hath several varieties, according to these three following cases:

1. When the distance from angle to angle, without any exception, is measured quite round the plot, either within or without.

2. When the distance is taken only between some more notable angles, and the perpendiculars of the rest measured as you pass along their bases, within the plot, proper for plain solid ground.

3. When the like is done without the plot, as in case of plotting thick woods, meers, pools, bogs, &c.

The first of these are very easy, consisting in nothing but planting the instrument at every angle, either within or without, as necessity and convenience determine it, observing the former directions for planting and removing the instrument, and also for measuring the stationary lines on the ground, and protracting them on the paper, as is manifest in this example.

Fig. 29. Let A B C D E F be a park, pond, or close, to be protracted, first plant your instrument at A, and direct the sights to a mark in the angle B, drawing a dry line from a convenient point on your paper towards B, on the ground,

ground, then having measured by your chain the distance AB, set it by a scale upon the correspondent line from A to B, drawing a black line between them with ink or a lead pen, the extremities whereof are the points A and B on the paper, and the little pricked line that goes beyond B, represents the remainder of the dry line drawn at random, as to length, with the point of the compasses.

Then setting up a mark at A, if there was none before, remove your instrument to B, and laying the fiducial edge to the line A B, turn about the instrument upon the staff, till, through the sight, you perceive the thread cutting the mark at A, and the needle directly over the same point that it was when it was planted at A; and so screw it fast.

Your next work is to lay the fiducial edge to the point B, and direct the sights to C, drawing a dry line towards it, and setting the distance B C, measured by the chain from B to C.

In this manner you are to proceed, surrounding the close till you come at last to A, where you begin, by planting the instrument at every angle, using the help of back-sight, and your needle, as at B, and then from the point representing your present station, directing the sight to the next angle, as you did from B to C.

In the second case, we do not plant the instrument at every angle, but at the more considerable, taking in the smaller by their perpendiculars from the base as we pass along; of which the following figure may be an instance.

Fig. 30. Let A B C D E F G H I K L be a close to be measured; by planting the instrument only at A C F and K, we have the main substance of the close in the trapezium ACFK: and for the five small triangles which must be added to the trapezium, they may be easily protracted by the help of such a little square as was formerly mentioned; for by finding at how many chains and links distance from A upon the ground, the perpendicular B b falleth upon the line AC; and having measured the length of that perpendicular, and taken in between the compass-points of the scale, we erect a perpendicular of that length at b, which is the point upon the paper, where so many chains and links determine, as were measured upon the ground, from the angles A, to the place where the perpendiculars fell on A c, viz. at b. Just in the same manner we raise the perpendiculars D d, and G g, I i; and then by the help of the perpendiculars, we draw the boundary lines AB, BC, CD, DE, FG, GH, HI, IL, KL, LA: which, together with the line EF between the angles E and F, give the true plot of the field in one large trapezium, and five small triangles ready for casting up.

The third case is like the second, so that there needs no new direction concerning it, but to annex one plain diagram; all the difference consisting in this, that because we cannot go within it, being supposed to be some pool, bog, or thicket, we must of necessity go on the out-side, and consequently all the triangles made by inward angles, and their lines upon the measured bases, must be excluded, by the boundary-lines, from being any parts of the plot.

Fig. 31. Supposing A B C D E F G H I K L M N O P to be a great pool, though here be fifteen angles, plant your table only five times, viz. at A E F H and M, and upon the dry lines AE, FH, HM, and MA, raise their perpendiculars in their proper places, and also of a right height, by which, and the five stationary angles, we may draw the bounding-lines of the plot, excluding all the triangles as foreign to it, they being no resemblances of any part of the pool, but of land adjacent.

Concerning the plotting of many closes together, whether the ground be even or uneven.

Though we do not design to make the reader able to survey lordships and forests, much less to draw maps of countries, but to measure a parcel of land with truth and judgment, yet we would have him so expert, as not to be puzzled, if any should desire him to draw a true map of a tenement or small demesne, consisting of several closes; for which purpose, let him observe the following method:

Fig. 32. Suppose A B C D E F G H I K L M to be a tenement or small demesne, divided into fourteen closes, to be measured and protracted according to their several shapes

and situation; first draw the plot of the whole by the method of circulation, planting your instrument either at every angle, or only at the most considerable, either within or without, as you find most convenient. This being done, a line from B to M gives the triangle ABM from the first close. In the next place go round the second close beginning at M, then to B, and so about to M again: and then for the third close, plant your table at C, and go round to B, the line B C being protracted already, and so of all the rest, still observing which are common lines belonging to several closes, representing the fences, that you may avoid the trouble of measuring those lines oftener than once, and lay every part of every close in its due place; and be sure to keep the instrument throughout the whole work to its true position, by needle, fore-sight, and back-sight.

There are divers other ways of doing this work, but none more sure or plain, especially if the ground be uneven; for in that case, if you protract according to the length of lines measured from your station to the angles, you will put your closes into unproportionable shapes, except you reduce hypotenusal lines to horizontal, by instruments, or otherwise, which is somewhat troublesome; and the like may be said when you plot with the chain only. Indeed the method of measuring only the stationary distances were very proper for setting out the figure of each particular close, provided the distance of the stations be large, and taken, if possible, upon pretty even ground, which sometimes may be done, though most of the close be uneven; and the work so ordered, as not to make too acute angles; but because this requires skill and care, we advise the young artist to use the circling way, as generally most commodious.

It is convenient when you plant your table, that the needle hang just over the north point of the compass under it in the box; then may you by the lines overthwart the frame of the table, easily draw two lines quite through the plot, cutting one another at right angles, the one pointing at north and south, and the other at east and west. And if you mark the two and thirty points of the compass upon the place where they intersect, and draw the forms of the houses, woods, and other remarkable things upon the demesne, and the course of brooks and rivers running through it, it will add to your commendation.

And so it will also, if you take in such parcels of land bounding it, whether common or peculiar to other men, as will make your plot look handsomely, like a perfect square or oblong. But however that be, you must be sure to protract truly all lanes going into it, or through it, and all closes of other men's mixed with it; and also all considerable ponds, ways, and out-lets, with the names of the closes, and quality of the ground, whether meadow, pasture, arable, &c.

Concerning shifting of paper.

In work of this kind, it sometimes happens through the multitude and largeness of fields, that one sheet will not hold your whole plot; in which case you may help yourself by shifting paper, as we call it: thus,

Fig. 33. Let A B C D represent the sheet of paper that covers the table, upon which the plot of the large piece of land E F G H I K should be drawn: having finished your first station at E, and the second at F, and find your paper will not receive the line F G, draw it so far as it will go to the edge of the paper, and planting your table again at E, proceed in your circulation the contrary way to K and I, where you will find yourself again at a loss for your line I H, but draw it also to the edge of the paper; then with the point of your compasses striking the line P O parallel to the edge of the paper B C, and the line Q O parallel to D C, and cutting P O in Q, throw it aside for a while, covering the instrument with a new one, which mark with the figure (2) for your second sheet.

Fig. 34. Upon which second sheet, the leading part whereof is represented by the three lines meeting in the angular points, A and B, draw P O parallel to A B the leading edge of the paper, and crossing it at right angles in the point O, by a parallel to B C, viz. the line O R, being of the same distance from B C that Q O in the former sheet was from D C; then with a rule and a sharp pen-knife

knife cut off the end of the first sheet at the line P O, and applying the edge of it to the line P O of the second sheet, so as it may touch that line all along, and the line Q O of the former touch the line O R in the latter, so as to make one line with it, draw the lines P G, being the remainder of the line F G, and the line O H, being the remainder of the line I H, and from their extremities the line G H. And if the plot required it, you might proceed on in the second sheet, and annex a third and a fourth, &c. as there is occasion.

These sheets may be pieced together with mouth-glew or fine paste, applying the edge of the former as you did upon the table, to the line P O of the latter.

And note here once for all, that when we speak of applying the edge of the paper to a line, we mean the precise edge cut by the line P O; but when we speak of drawing lines to the edge of the paper upon the table, we hope none will think us so absurd as to mean the edge that is concealed under the frame; but that the meaning is, that the lines must be continued on the paper till they touch the frame.

Concerning the plotting of a town-field, where the several lands, butts, or doles, are very crooked: with a note concerning hypothecusul, or sloping boundaries.

Fig. 35. Suppose A B C D E divided, in the manner of a common field, into seven parts or doles, belonging to seven several men: first, plot the whole, as before hath been taught, then measuring from A to B upon the land, note down, as you go along, at how many chains or links, or both, the division is between dole and dole, and accordingly mark them out by the help of scale and compasses in the line A B on the paper-plot. In the very same manner you must measure and mark out the lines O C and E D; which being done, take the paper from the instrument, and laying it before you on a table, with the side A E towards you, the compasses must be so opened and placed, as by a few trials they may, that one foot resting upon the table, the other may pass through the points of division upon all the three lines, viz. A B, O C, and E D, as in this figure they do.

If the content of any one or more of these parts, butts, or doles, be desired without plotting, it may easily be done, without your plain table, thus: take the breadth by your chain at the head, middle, and lower end, and adding these numbers together, the third part of their sum is the equated breadth; by which multiplying the length measured down the ridge or middle, the product gives the content.

But both in this case, and that mentioned before, the figure of a plot may be somewhat disordered, not only by the unevenness of the ground within, but also by the great declivity of the ground where the boundary lines go, either of the whole plot, or particular parcels. For whereas in plotting, every line is presumed to be horizontal or level, that it may pass from angle to angle the shortest way, and that every part may be duly situated, and none thrust another out of its right place, if it be not level, but falling down towards a valley, or rising up hill, or compounded of both, a line over such ground will be false as to the plot, and therefore must be reduced to a level, and so taken off the scale, and protracted. For the doing of this, there are several instruments very proper, especially Mr. Rathburn's quadrant upon the head of his peracter, and divers others. But suppose our country friend to have no other but such as we have already described, we shall shew him a plain easy way much used by practical surveyors.

Fig. 36. Suppose A B C to be a part of a hill falling within your plot, your boundary line going crookedly from A to B, following the surface of the ground. To find the horizontal line, equal to A C, cause one to stand at the point A, the foot of the hill, and to hold up the end of the chain to a convenient height, and gently ascending the hill, you must draw it level, and make a mark where it toucheth the hill, observing the number of links betwixt your assistant's hand, and that place where he must take his second standing, and hold it up as before, and so draw it out level again, till it touch the place where he must take his third standing, noting the links as before, and so proceed, till at last, from his fifth standing, you draw the chain level to the highest point within your plot, viz. the point B. And now as the pricked lines of this figure put together are evidently equal to the line A C, so are the links noted down at every station, when sum-

med up, equal to the horizontal line of that part of the hill.

In the very same manner, only inverting the order, you may find the horizontal lines going down hill, where that is most convenient: and if there be both ascents and descents in one line betwixt two angles, the horizontal lines of both must be found and joined together in protraction.

All this concerning declivities of rising or falling ground, is to be understood when they are considerable, and a very exact plot required; for small ones, especially when much exactness is not expected, are not regardable.

Concerning plotting a piece of ground by the degrees upon the frame of the plain table several ways, and protracting the same.

Hitherto we have shewn the use of the plain table as such; and our directions have been near as plain as the instrument itself. We will now shew how the plot of a field may be taken by the degrees on the frame by two methods, whereof the one is proper for an ordinary close; where all the angles may be seen from one station within it, the other fitting any parcel of land, though much larger, whatever be the figure of it.

For the former, take this example.

Fig. 37. Let A B C D E represent the figure of a field to be plotted by the plain table in rainy weather, put on the frame without a paper, the graduated side upwards, and plant it in some convenient place, whence you can see all the angles, as at O; then placing the index upon the table, so as the fiducial edge may, at the same time, go through the center upon the table, and the lines upon the frame of the table cutting it perpendicularly at 360, where the degrees begin and end, and 180, the exact half, turn about the table upon the staff-head, till through the sights, the side marked with 180 being next your eye, see the angle A, and then screw it fast, observing where the needle cutteth, and by back-sight causing a mark to be set up in the line C D at the point F, that the instrument may be kept firm from moving, or be rectified if it be moved, during the work. And now the line A O F passing upon the land from the angle A, directly under the sights of the instrument to the mark at F, is, as it were, the prime diameter whence the degrees of the angles are to be numbered, and accordingly you must mark the angle A in the table hereafter to be exemplified with 360 degrees. Then turning the index with the fiducial edge upon the center, till you see the thread cutting the mark at B, the said edge will cut upon the frame at 76 deg. 15 min. which note down for that angle. The like must be done, turning the sight to C D and D, but not to F, for there is no angle; but only a mark in the boundary, and you will find the index to cut for every angle as we have marked them within the pricked circle of the last figure, viz. 157 deg. 35 min. for C, 225 deg. 20 min. for D, and 278 deg. and 50 min. for E.

Then measure, or cause to be strictly measured by others, the distances betwixt the place where the instrument

stands, and every angle, and you will find them to be as set down upon the pricked lines in the little circle, viz. A 4 chains, 20 links, B 4 chains, 3 links, C 3 chains, 84 links, D 5 chains, 35 links, E 5 chains, 6 links. And now your table both for lines and angles is thus perfected, and the work is ready for protraction within doors.

	D	M	C	L
A	360	00	4	20
B	76	15	4	03
C	157	35	3	84
D	225	20	5	35
E	278	50	6	06

Your judgment will easily inform you, that in such weather we shall hardly stand to make our table neat and formal, but any thing, how rude soever, that we can understand, doth the feat. A Welsh slate with a sharp stile, or for want thereof, a black-lead pen, and a smooth end of an hard board like a trencher, is more convenient at such a season, than pen, ink, and paper. But of all, we would commend for expedition a red-lead pen, whereby you may mark out every angle neatly with one touch upon the table itself, just where it toucheth the frame by help of the fiducial edge, and close by it the length of the line from the center to that angle: all which may be easily cleared off by a wet sponge or cloth so soon as you have protracted.

Fig. 37. Now to protract our observation; draw upon a paper the line A F at adventure, so it be long enough, and stick a pin in it at pleasure for the center O, upon which place the center of the protractor, so as the straight side may just lie upon the line A F, the limb or arch-side being upwards towards B; by help whereof make a prick or point on the paper 76 degrees 15 minutes for B, and at 157 degrees 35 minutes for C, according to the number nearest to the limb.

Then turning the protractor about on the pin with the arch or limb down towards D and E, till the diameter lie again just upon the line A F, number downwards from the right hand towards the left, by that rank of figures that are nearer to the center, beginning 190, 200, &c. and over against the places where 225 degrees 20 minutes and 278 degrees 50 minutes fall, prick the paper at the side of the limb, and through those four points draw so many several lines, upon which, and also upon the line A O, mark out by what points the true measure of every line, by a scale, from the center, and from those points drawing the lines A B, B C, C D, D E, and E A, you have the true plot of the field.

Having proceeded in the field as before, and made your table for lines and angles, or done that which is equivalent by a red-lead pen, draw the line A F, and having extended the compasses to the radius, or 60 degrees, on a line of chords, set one foot towards the middle of the line A F, and with the other describe a circle like that in this figure of a five-angled field, but much larger, according to the length of the radius: then extending the compasses from the beginning of the line to 76 degrees 15 minutes, set one foot in the intersection of the circle by the line A, and with the other foot make a mark in the circumference of the circle upwards, towards the right hand, and through it draw the dry line B O.

In the next place subtract the angle 76.15 from 157.35, where the index cut for the angle C, and there remains 81 degrees 20 minutes, which take off the line as before, and set it upon the circumference from the intersection by B O, toward the end of the diameter marked with F, and through the point where it falls, draw the dry line C O.

In like manner subtract 157 degrees 35 minutes from 225 degrees 20 minutes, and the difference is 67 degrees 45 minutes, which set from the intersection by the line C O, downwards past the prime diameter A F, and through the point where it falleth, draw the line D O.

Lastly, having subtracted 225 degrees 20 minutes from 278 degrees 50 minutes, there remains 53 degrees 30 minutes, which must be set downward towards the left-hand from the intersection by D O; and through the point where that falleth, draw the line E O. And now having set the particular measures upon every line, and drawn the boundary lines, as you must have done if you had used a protractor, the plot is finished.

But for better assurance that you have done your work well, take the measure of the remaining angle A O E upon its proper arch, viz from the intersection of the circumference by A F, to the intersection by E O, and applying it to the line of chords, you will find it to be 81 degree 10 minutes, as it ought to be, for it should be the complement of 276 degrees 50 minutes to 360.

And for farther satisfaction, sum up the degrees and minutes of all the five angles, which for plainness-sake we have noted in every one of them on the outside of the circle in the figure so often referred to, and their sum is 360, as it ought to be,

76. 15
81. 20
67. 45
53. 30
81. 10
—————
360.000

The reader may now expect that we should teach him how to take a plot at two or more stations, when all the angles cannot be seen from one: but because this is so easy from the principles already laid down, to any that is ingenious, and in part rendered unnecessary by the method presently following, we shall only give this general hint.

When you have from one station taken in all the angles you can see from thence, and then are to remove to your second station, do just as you would do if the table were covered with a paper; only it is at your choice, whether you would guide yourself for back-sight by a line that may be rubbed off, drawn upon the table itself, from the center to the degrees, on the frame along the fiducial edge, or by noting only what degrees it cuts on either side of the

center, the edge passing through it, that by the help thereof and the needle, the instrument may be placed in the same line and situation as before, for taking in the rest of the angles, if it can be; if not, another station must be taken after the same manner.

Fig. 38. Let A B C D E be the figure of a field to be plotted, the weather being bad; send your assistants to find the length of every side, beginning at A, who return you such an account of every side, in chains and links, as are noted upon the figure, and in the table following, viz. A B 3 chains 73 links, B C 4 chains 91 links, &c. In the mean time you are to find the angles; in order to which plant the instrument at B, and laying the index on the center, look at C, and find the index cutting 10 degrees 15 minutes, and looking at A, it cuts 126 degrees 45 minutes; out of which if you subtract 10 degrees 15 minutes, there remains 116 degrees 30 minutes for the angle A; but because it will not be so convenient to subtract there, you may set them down thus:

B A 126. 45 the meaning whereof is, that B notes the angle, and C A the lines meeting there, cutting such degrees on the frame; and the reason why A is set above, is for more ready subtracting afterwards; then removing to the angle C, and thence looking at B and D, you will find the index is cut as it is here expressed. C B 153. 10.
D 15. 40.

In like manner at D thus, C 96. 05.
E 28. 50.

At E thus, E D 141. 20.
A 11. 45.

And lastly, at A thus, A E 98. 30
B 9. 20

This being done, you may retire under covert, and by subtraction find 116 degrees 30 minutes for the angle B, 137 degrees 30 minutes for C, 67 degrees 15 minutes for D, 129 degrees 35 minutes for E, and 89 degrees 10 minutes for A, as you will find them on the figure, and in this table, together with the length of the lines.

An.	D.	M.	Side.	Ch.	L.
A	89	10	A B	3	73
B	116	30	B C	4	91
C	137	30	C D	4	88
D	67	15	D E	9	64
E	129	35	E F	2	29

Note, that there is a way to find the angles without subtraction, if at every station you lay the fiducial edge over the center, and the divisions 180 and 360, turning about the head of the instrument upon the staff, till through the sights you see one of the neighbouring angles, for the index turned upon the center to the other angle, will give you the quantity of the angle you are at, but this exact planting at every angle is more tedious than the other, and therefore not so fit for wet weather. But now to protract this plot:

First, by your scale, rule, and compasses, draw the line A B in length 3 chains 73 links, ending at the point B; then laying the center of your protractor upon the line A B, so as the center of it be upon the point A, and that end of the diameter from which the numbers are reckoned on the arch or limb towards B, make a point for the angle A at 89 degrees 10 minutes, by the direction whereof, and the point A, draw the line A E, which according to your scale, must be two chains 29 links.

In like manner placing the diameter upon A E, just as it was upon A B, and the center upon the point E, mark, out by the limb, for the angle E, 129 degrees 35 minutes by which draw the line E D, 6 chains 64 links.

In the next place, bring the center of the protractor to the point D; its diameter lying on the line E D, and its limb towards A, by which prick out 67 degrees 15 minutes for the angle at D, and draw the line 1 chain 88 links.

Lastly, The center being at C and the diameter upon the line D C, in such manner as before at other angles, prick out by the limb or arch 137 degrees 30 minutes, and draw the line C B, for at B your plot should close; and if rightly done, the angle at B will be 116 degrees 30 minutes, and the side B C 4 chains 91 links, which you will find it to be by measure.

But if you plot by a line of chords, you are not bound to this order, but may go from A to B, and so round that way if you please, which you could not so well do with a protractor, without reckoning the numbers backward, yet it must be granted that a line of chords neither doth

doth the work so quickly nor conveniently: this is the way.

When you have drawn the line A B of a proper length, set the compasses to the radius, and placing one foot of the compasses in the point B, and with the other describe an arch of a competent length, beginning at that side of the line A B that is designed not to be the inward side, and upon this arch, 116 degrees 30 minutes must be set; but because the line of the chords give only 90, set them first on from the line A B, and then take off the remainder 26 degrees 30 minutes, joining them to the 90 upon the arch, making a point, through which the line B must be drawn of a due length. In the like manner you must do at C E, but the angles at A and D need no such piecing, being capable of being measured out by a line of chords at once.

Nor do your angles only give you trouble in this kind of work, but your lines also will be often found too short to receive the touch of an arch upon the radius, especially if the line of chords be large, and your scale little; and so it may often fall out when you use the protractor upon such short lines as A E and C D of this last figure: in which case a rule must be applied to them, and they must be extended to a due length, that the arches may meet them without the figure. And if those extensions of lines, and describing of arches, spoil the beauty of your plot, the matter is not great, it is so easy to be retrieved; for if you lay on a clean paper, and prick through every angle, lines drawn between those points will give you the plot neat and perfect.

The artist sometimes loseth his labour of protraction through some error in the field, so that his plot will not close; it is therefore proper to know before you begin that work, whether it will or no; for which purpose if we take a number less by two than the number of angles in the plot, and thereby multiply 180, that product being found to be equal to all the angles, the plot will close: this appears by our plot in the present work; the multiplier being 3, because the angles are 5, and the multiplier must be two less than the number of angles.

	Deg. Min.
180	89 . 10
3	116 . 30
540	137 . 30
	67 . 15
	129 . 38
	540

This kind of trial is grounded upon two principles of Euclid and Ramus, mentioned in the beginning of this article, shewing that in all plain triangles, all the angles taken together are equal to the right angles, and that the sides, consequently the angle also, of every triangle figure, are more by two than the triangles of which it consisteth.

Concerning taking inaccessible distances by the plain table, and accessible altitudes by the protractor.

Fig. 39. The substance of what is to be said for the first of these, is gathered from the instructions given for plotting a field, by measuring only to stationary distance: but to make the case more plain to an ordinary capacity, suppose the line A C to be the unknown breadth of a river, over which a bridge of boats is to be laid, and the general, that the may in form himself what number of boats and planks is necessary to be brought down, commands you to tell him the true distance from A, where he is at present, to C, a little boat-house on the other side of the water.

To satisfy his demand, plant your table covered with a paper at A, causing one to set up a mark at B, at a good distance from you, along the bank of the river, the farther the better, if distance do not hinder sight: then having chosen a point to represent A, and laid the fiducial edge upon it, direct your sights towards C and B, and strike lines towards them. Which done, set up a mark at A, and from thence measure to B, 6 chains 32 links, and so plant your instrument at B, laying the fiducial edge to the line A B, and turning about the head of the instrument upon the staff, till through the sights you see the mark at A, and then screw it fast.

In the last place take 6 chains 32 links off your scale and set it on the line A B, from A to B, and laying the fiducial edge to the point B, from thence direct the sights to C, and draw the line B C, meeting or cutting the line A C in C; so shall the space A C measured on the scales viz: 8 chains 29 links, be the distance desired, and because the chain is 22 yards long, if you multiply 8.29 by 22, the product is 182 yards and $\frac{3}{8}$ of a yard, which by reduction is some little more than 13 inches and $\frac{3}{4}$ of an inch.

Now, to take the height of a tree tower, or steeple by a protractor, without any arithmetical operation, hang a plummet with a fine silk thread at the center of it, and hold it steadfastly with that end to your eye, where the numbers begin, then look straight along the diameter, still removing backward and forward as there is occasion, till you see the top of the tree, tower, or steeple, and the thread at the same time fall upon 45 degrees, so shall the distance from your eye to the tree, tower, or steeple, measured in an horizontal or level line, together with the height of your eye above the bottom of it, be equal to the height of the object.

If either for convenience of sight, or any other reason, you think proper to set the other end of the diameter to your eye, then the thread for the above trial must fall upon 135 deg. instead of 45.

Of casting up the content of land by a table.

1250	0	02
625	0	01

This table consists of three columns, the first containing links, the second roods, or quarters of acres, the third perches; and the use of it is thus:

Suppose a field to be 7.25 chains and 25 links long, and 5.50 five chains 50 links broad, these by multiplication make 36250 398750, whereof 5 figures being cut off towards the right hand, the figure 3 signifies acres, and the rest, 3.98750, viz, 98750 denote parts; and to reduce them into roods and perches, first subtract from 98750 the greatest number of links in the table that can be subtracted from it, viz. 90000, and put down for it three roods 24 perches, which you find over against it in the annexed columns, and the remainder being 8750, look in the table, and find over against it 14 perches, which by addition makes 3 roods 38 perches; so is the whole content of the field 3 acres, 3 roods, 38 perches.

A R P

3 3 24

14

3 3 38

But note here, that if the remainder after the first subtraction cannot be found in the table, you may take the nearest to it, so the error will be but part of a perch.

As for Example.

7.75 being the half perpendicular, and 9.23 the base, give for their product 6.78405. The 6 signifies acres, and from the rest 70000 being subtracted, to which 2 roods 32 perches answer, there resteth 8405; which, because you cannot find in the table, you must take the nearest, which is 8125, to which 13 perches answer; so the whole content of that triangular close, is 6 acres, 3 roods, and 5 square perches, and a little better.

SUSSINGLE, or *Surfingle*, the girt which comes over the saddle, and binds it firmly to the horse.

SWAMP, a hollow, watery place, in any part of a field; a bog. See BOG.

SWANG, a fresh piece of green sward lying in a bottom among arable or barren land.

SWARD, the surface of the ground.

SWARM, a large number of bees, seeking a proper settlement. See the article BEES.

SWATH, or *Sewath*, a line of grass, &c. cut down by the mower.

SWATH-BAUK, a swarth, or line of new mown grass or corn.

SWATH-RAKE, a rake about two yards long, with iron teeth, and a bearer in the middle; to which a man fixes himself with a belt, and when he has gathered as much as his rake will hold, he raises it and begins again. This instrument is in some counties called a dow-rake, and much used in Essex for gathering barley after mowing.

To **SWEAL**, to finge, or burn off the hair, &c.

SWELLED-LEGS in a Horse, an infirmity he is sometimes subject to, by hard riding or much labour, when he is too fat, or carelessly put to grass, or set up in the stable too hot, whereby he takes cold, which causes the blood, grease, and humours, to fall down into his legs, and to make them swell.

Sometimes it comes by long standing in the stable, when the planks where his fore-feet stand, are higher than where his hinder legs are; which uneasy posture makes the blood settle in the hinder legs, whereby they are unhappily brought to swell.

There are several prescriptions for the cure of this malady.

Some use nerve oil, black oil, soap, and boar's grease melted, and anoint the place therewith; or else bathe his legs with butter and beer, or with butter and vinegar melted together.

Some bathe them in water in which sage, mallows, and rose-cakes have been boiled, putting in butter and salad oil; or boiling rosin, frankincense, and fresh grease, of each a like quantity, then strain it, and use it once a day, as there is occasion.

You may also wash the horse's legs in cold fountain water, or the horse may be left every day to stand up to the knees in running water, till the swelling is assuaged.

Others bathe the horse's legs with sheep's foot oil, train oil, or urine and salt-petre mingled together, and wetting hay ropes in the same liquor, roll them from the pastern to the knee; but care must be taken not to bind them too hard.

Others boil primroses, violet-leaves, and strawberry-leaves, of each a handful, in new milk, adding nerve-oil, petroleum, and populeon, of each an ounce, and anoint the horse with this for four or five days successively.

Others boil pitch, virgin's-wax, rosin, galbanum, myrrh, zedoary, bdellium, Arabian storax, and the juice of hyssop, and when it is cold, they add bole-ammoniac and costus finely powdered; these being well incorporated with the other ingredients, they boil them all over again, and when they use it, they spread it on a plaister and wrap it about the swelling, letting it remain there till it drops off of itself.

But when a horse's legs are much swelled, because of the scratches, boil a handful of bay-salt, a quarter of a pound of soap, with a good quantity of foot, and a good handful of milletoe chopped, in a quart or more of urine, and with this bathe his leg, very warm, twice or thrice a day, and wetting a cloth with it, wrap it close about his legs, and it will assuage the swelling.

SWELLED PIZZLE, IN HORSES, is a kind of hardness which proceeds from the parts being bruised by riding, and is cured in the following manner:

Take holly-hock, house-leek, and a little plantane, stamped together with fresh butter, and anoint his pizzle with it twice a day, and if the pizzle be sore, you must caulk him, and wash his sheath and pizzle very well with white-wine vinegar; and if there be any cankers, or holes in the yard, then you must put some burnt allum to the vinegar, and wash it very well; and he will mend without fail in three times dressing.

SWELLED VEINS; that which the French call varice, is a crooked vein, swelling with corrupt blood in the temples, biley, or the legs of an horse.

For the cure:

Open the skin of the horse, and burn it with a hot iron; then rub and chafe it well for ten days with milk and oil, and if the disease is not removed, let him bleed, and this will effect the cure:

A poultice to dissolve a swelling in Horses.

Take garden orrice-roots, and white lily-roots, of each an ounce; marshmallows, pellitory, penny-royal,

origanum, calamint, and rue, of each a handful; camomile, mellilot, and elder-flowers, of each half a handful; green aniseeds, common fennel, and cummin-seeds, of each half an ounce; boil all these together to a mass, in water and white-wine vinegar; then pound them in a stone mortar to an even smooth mass, adding to them of the meal of lupines, and of beans, of each an ounce and a half; oil of camomile an ounce and a half, oil of orrice the same quantity; mix them well in the mortar, and then heat them again, and apply this to the part affected, in greater or lesser quantity, according to the heat of the part.

This is a medicine extraordinary useful in all tumours, and is the more necessary, since tumours or swellings are so frequent in horses, by reason of hurts and bruises they are so often liable to, which if not timely taken care of, and that judiciously, do degenerate into incurable fistulas, and cancerous ulcers; for it is allowed by all surgeons, that the safest way to cure all swellings (to which they give the name of tumours) except such as are malignant, is by dissolving them, if possible, which is the most successful, and which ought to be used as soon, and as much as possible; but if that cannot be done, then you ought to endeavour to ripen them as soon as possibly can be.

Another for mollifying, softening, ripening, and bringing to suppuration, a swelling.

Take the roots of marshmallows, and those of white lilies, of each a quarter of a pound; the leaves of groundsel, common mallows, brank-ursin, and violet-plants, of each a handful; the flour of linseed and fenugreek-seeds, oil of lilies, and goose fat, of each three ounces; wash the roots and slice them, then boil them in water, and after some time put in the leaves, and boil all till the whole mass becomes perfectly tender and soft: then strain out the decoction, and pound the substance that remains in a stone mortar, with a wooden pestle, till it comes to be a pulp; then put both the decoction and pulp into a skillet, mixing with them the flour or meal of fena-feed, and fenugreek seed, oil of lilies and goose fat; boil all together over a moderate fire, stirring the ingredients from time to time, till the mass is become of a sufficient consistence.

This is a very useful medicine, because dangerous consequences do frequently happen to swellings, or tumours, in horses, that will not be discussed, that is, not go away of themselves, or that such a poultice has been wanting to bring them to a speedy suppuration.

For if a swelling or tumour that cannot be discussed, should remain too long before it be brought to a suppuration or ripening, it generally putrifies and turns to a fistulous ulcer, which, very rarely, admits of a cure.

SWILL, a vessel to wash in, standing on three feet.

SWINE Early in the morning, when you untye them, give them drasse, pulse, or other garbage, with swillings in the troughs; and when they have eaten it, drive them to the field, where they may graze and root for their food. Marshy grounds are the best, where they may get the roots of sedge-reeds, rushes, knot-grass, &c. which is wholesome for swine; and at the fall of the leaf it is best to drive them to hedges, where they may get haws, hips, sloes, crabs, &c. which are very wholesome: then the poorer sort will gather their fruits, and keep them safe, to feed their swine with all the winter. In the evening drive your swine home, and fill their troughs with swillings, &c. and when they have filled their bellies, stye them. Once a fortnight give them in the swillings some raddle or red oker, which prevents the measles and other inward disorders. The cure for the measles is, to mix red oker with old urine, till it be thick: let there be about an ale quart of it: then mix it with about a gallon of warm whey, and give it the swine to drink in the morning. If the swine vomit up their meat, give them split beans to eat, which will strengthen their stomachs. If your swine are bitten by dogs, to prevent the imposthumation of the sore, you shall anoint it with vinegar, soap, and tallow, mixt together, and it will cure the part. See the article HOG.

SWINE-CRUP, a hog's-fly.

SWINE-

T E A

T E A

SWINE-HERD, a keeper of swine:

SWINHULL, a hog's-sly.

SYCAMORE, the name of a tree well known in many parts of England. It grows to a large size; the wood is soft and very white, and therefore valued by the turners; but is not esteemed very valuable for other purposes. However, as this tree will thrive better than most other sorts

near the sea, it is frequently cultivated to screen plantations of other sorts of trees from the spray of the sea.

Mr. Young, in his *Annals of Agriculture*, vol. VII. says, the sycamore is the only tree which grows erect, and resists the wind and spray of the sea.

SYTHE. See SCYTHE.

T

TABERN, a cellar.

TAGGE, a sheep of the first year.

TAIL-SOAKED, a disease incident to cows, by which the joint of the tail near the rump, will, as it were, rot away. The cure is generally performed by cutting a deep gash into the part affected, then rubbing a handful of salt into the wound, and binding it up with a rag. Others mix foot and a clove of garlick with the salt.

Wild TANSEY. See the article SILVER-WEED.

TAPPING-OAKLINGS. See OAK, TIMBER, ORCHARD &c.

TARES. See the articles VETCHES, CORN, &c.

TEAM, a number of horses or oxen drawing at once the same carriage.

To TEAM, to pour or lade out of one vessel into another.

TEAZLE, or FULLERSTHISTLE, a species of the thistle cultivated for the use of clothiers, who dress their cloth with them.

The teasle is propagated by sowing the seeds in March, upon a dry soil. About one peck of the seed will sow an acre; for the plants should have room to grow, otherwise the heads will not be so large, nor in so great quantity. When the plants are come up, you must hoe them in the same manner as is practised for turneps, cutting down all the weeds, and singling out the plants to about six or eight inches distance; and as the plants advance, and the weeds grow again, you must hoe them a second time, cutting out the plants to a wider distance; for they should be, at last, left at least a foot asunder; and you should be particularly careful to clear them from weeds, especially the first summer: for when the plants have spread so as to cover the surface of the ground, the weeds will not so readily grow between them. The second year after sowing, the plants will shoot up heads, which will be fit to cut about the beginning of August; at which time they should be cut and tied up in bunches, setting them in the sun, if the weather be fair; but if not, they must be set in rooms, to dry. The common produce is about an hundred and sixty bundles, or staves, upon an acre, and they will sell for about one shilling a slave. *Miller's Gard. Dict.*

M. de Chateauvieux extended the New Husbandry even to the culture of the teasle, or fuller's thistle, which grew to a surprising height, and produced an extraordinary number of the finest and best heads that the fullers in his country had ever seen.

"I am well informed, says an ingenious correspondent of the editors of the *Museum Rusticum*, that the principal place in the kingdom for the cultivation of the teasle, is about Wrington in Somersetshire, many of the inhabitants of that, and the neighbouring parishes, being chiefly employed therein; and from these places the cloth manufactories in the counties of Gloucester, Somerset, and Wilt, are supplied, and even a great many packs carried annually into Yorkshire.

"The land most suitable for this plant is that of a thin, sweet surface, and marley bottom, though a clay or stone-trass bottom will do, and produce large crops: rich loam, or strong clay, is very improper, as on them the plant is

apt to grow luxuriant, and thereby cause the heads to be large and coarse-hooked, and, in a moist summer, subject to mildew and rot before they blossom and are fit to cut.

"As to situation, a southern aspect, on the decline of a hill, is to be preferred, though any other will do: but upland ground is to be most esteemed, more especially in an inclosed country, that the wind may assist in carrying off the natural humidity of the plant in moist seasons; which sometimes, in low and small inclosures, is retained so long as to cause the heads to taint, and become rotten.

"Having made choice of a piece of ground; (an old lay is preferable) in February cause it to be ploughed in ridges of three bouts each, at a depth suitable for a crop of beans, taking care that the furrows be laid straight and as even as may be; the middle of the ridge highest, and a fresh furrow ploughed in the furrow between each ridge; after which let a man go along each ridge, and with a mattock, hoe, or spade, raise earth in small clods, at suitable distances from each other, to produce earth, when meliorated, to heat or cover the seed.

"Having done thus much, let it remain as it is until the time for sowing the seed, which will be about a week or ten days in April, as then the earth is generally moistened with rain.

"At this time cause a middle-sized harrow to be drawn over the land once or twice in a place, to fill the crevices between each furrow, and level the surface; after which sow the seed broad-cast, in the proportion of two bushels on an acre; then harrow it in, the same as turnep seed, and let it remain until the plants are come up, and grown into six or eight leaves each; when some person or persons should go over the field with a hoe, and cut out the plants where they are too thick, to the size of about two feet from each other every way, if the ground be in heart; if it be thin poor land, sixteen or eighteen inches distance is sufficient.

"After this they may remain until the latter end of August, when they must be gone over as before, with this difference, the person should have a spade made about four inches broad, and eighteen inches long in the bit, or pan, with a tree in it of three feet six inches long: with this tool the workman must go backward, and turn the whole surface over, about two inches deep, in long spits, turning the spade from the plant, to turn the spit so as no earth may fall into the heart of the plant: but it would be advisable, at the time of first sizing the plants, to leave more than are necessary to stock the ground, to have some to fill up the vacancies where any may happen to die, which is often the case during the succeeding winter, and more especially should it prove frosty.

"Having done thus much, in this state they are to remain during the winter; only care must be taken that no cattle get into the field, especially sheep, which will eat out the cabbage of the plant, and spoil it.

"About the latter end of the succeeding February, the plants should be digged between, as in August, being very careful that none of the earth falls into the middle of them; and in May, when the plants begin to shoot into spindle,

spindle, the ground must be dugged over again, with this difference, instead of being laid plain, it must be raised into small hillocks about each plant, to strengthen them in the ground, so that the wind may not blow them down when loaded with heads.

" This being done, they are left till the season for cutting, which will be a work of some time, as the heads become fit, which is known by their blowing: it is to be observed, that the blossom first appears near the bottom of the head, in small, pale, blue flowers: and when these appear to have blown somewhat more than half way up, such head is fit for cutting, which is generally done in this manner; a man has a knife, the blade about two inches long, with a string in the haft to put over the hand, and a pair of strong gloves to defend him against the sharp prickles on the stalks.

" Being thus equipped, he must go along each furrow, and cut with one hand, putting them into the other, till he has as many as he can easily gripe; when cutting one which is a little more ripe than the others, and the stem about eighteen inches long, he binds the handful together with it, (the others are generally cut about nine inches long); which done, the handful is tossed to some open spot, in order to be carried to the place for drying, which is done in the following manner:

" Some small poles of ash, willow, or any straight-growing wood, about the size of a hedge-stake, and ten or twelve feet long, must be procured, at the great end of which, about eighteen inches from it, a hole must be made, and a peg put through, to extend three or four inches on each side. The poles thus prepared, the handfuls of teazles must be put on them, by running the small end through the handful, until the pole be filled: in this condition they must be set on one end to dry; but it is to be observed, that they should be carefully carried into a house or shed every night, and brought out at days; and in the house set so as for the poles not to touch each other, lest they taint, which for want of a free circulation of air, they are very subject to, and more so if it be close moist weather.

" When they are dry, so as to be free from moisture, they may be carried into some upper room, and placed up close together: over a cow-house, or place where cattle are fed in winter, is to be preferred, because their breath is supposed to help to brighten them in colour: wherefore they are the better esteemed, and supposed to be more tough in hook than otherways they would.

" When they have by this means acquired from the gradual moisture of the air an additional elasticity to the hooks, and are brightened in colour, which will be completed a little after Christmas, the time that generally the heads are sorted, and made out in the following manner. The handfuls are brought from the storehouse into some large room, usually a barn-floor, where they are untied, one at a time; and generally made four sorts of. The largest heads which are sound, and are such as grow on the middle stem of each branch, are thrown for the first sort, and called kings. The next smallest which are sound, and are commonly such as grow as side heads on each branch, are thrown for a second sort, and are called middlings. Another, or third sort, are such of the largest, or those which grew on the middle stem, as are damaged by the mildew, wet, or other accident; and which would have been kings, had not such defect rendered them unworthy that appellation. These therefore are thrown to a third sort, and denominated scrubs. These last, or fourth sort, is the refuse of all, and are such as are too small, or too much damaged for any use; and are therefore thrown away.

" When a quantity is thus separated, they are made out in the following manner: the persons who do it, put of the kings ten in each handful. First, six of the larger, in the manner of a fan extended, and four lesser of the same sort, in the bosoms of the six; and then bind their stems together with a spleet of willow, or some tough wood, by wrapping it about them three or four times, and tucking the end under. When the kings are tied up in handfuls in this manner, a straight stick of about three-fourths of an inch diameter, and two feet six inches long, is split to within four inches of one end. Twenty-five of these handfuls are put on this stick, alternately head to stem; letting two of the middle stems of each handful to be in the cleft, to hold them secure; then a small wreath, made of spleet, is slipped on the upper end of the staff, which holds

it together, and keeps the whole from falling about. In like manner are the scrubs, or third sort, also made out and put in staves. But of the middlings, or second sort, double the number of heads are put in one handful, by making two fan-like rows of six each, and four in their bosoms on each side; and these are put into staves of three feet long each, split as the former, and thirty handfuls in each staff. When they are thus made out, they are fit for sale, and are to be laid by for that purpose in some convenient place, where they may not be bruised. Thirty staves of the first and third sort are accounted a pack; and forty staves of middlings make also a pack.

" An acre of land, if well grown, and what is deemed a full crop, often produces nine packs of kings, nineteen of middlings, and two of scrubs. The common price per pack of the first sort, is twenty, the second sort fourteen, and the third sort eight shillings. But in a French war, they are generally double these prices.

The expence attending a crop per acre, are,

	l.	s.	d.
1st, Rent of the ground for the crop, which is one year and a half	—	5	0
2d, Ploughing and sowing	—	0	15
3d, First dressing or delving	—	1	0
4th, Second delving	—	0	10
5th Hilling	—	0	15
6th, Cutting and carrying home	—	1	15
7th, Tythe	—	0	5
8th, Clearing off the stalks, and binding them in bundles	—	0	5
9th, Making out, at two shillings per pack, spleets, staves, and wreaths included	3	0	0

All which make the total expence, attending—
ing one more acre of teazles — £13 5 0

" This, exclusive of seed, which is not often bought, because enough may be saved in making out the crop in winter: but if the seed be bought, it is generally valued equally with wheat. Therefore, if two bushels be sown on the acre, ten shillings may be added as the medium price; which makes the whole expence of one acre thirteen pounds fifteen shillings, if it should produce thirty packs. But such produce is not always the case, for twenty is to be esteemed a middling crop.

" With respect to crops of corn, raised amongst the plants, it is practised in many places; and indeed it has been mine to plant field beans, or garden beans, at about three feet distance singly from each other, in a promiscuous manner over the teazle land: which crop of beans, by the cultivation necessary for the teazle, is greatly forwarded in growth, and often produces from four or five and six stalks from one bean, well loaded with cods. This crop is no injury to the teazle crop the first year, and frequently pays the expence of labour attending the whole.

" The crop, which generally succeeds the teazle, is wheat. The ground, by being frequently delved and kept clean, during the teazle crop, becomes very fit for this grain, and generally produces very large crops. Forty bushels per acre is not uncommon, though the land in itself is often such as is not annually worth more than ten shilling per acre. Hence, I think, it is evident, that a crop which well shades the ground, (in summer) and that has been two or three times turned and cleaned from all weeds, before such shading, greatly fertilises the land on which it grows. But I have frequently observed an error, to which the occupiers of such land are too liable after these fertilising crops. This error is the ploughing away (by over-cropping) the profits which would ensue. If after its being thus fertilised by the crops of teazles, it were to be laid down with suitable artificial grass-seed, sown amongst wheat and properly managed afterwards, it would, I am experimentally sensible, be a lasting improvement." *Museum Rusticum, vol. III. p. 237, and vol. VI. pag. 1.*

To TED, to spread abroad new-mown grass, which is the first thing done in order to its being dried, and made into hay.

TEDDER, or TETTER, a rope with which a horse is tied in the field, that he may not pasture too wide.
To TEEM, to be pregnant; to engender young.
TEETH are little bones in horses' jaws, which serve not only to facilitate the nourishment, but likewise to distinguish the age of horses.

A horse

A horse has forty teeth, including the tushes, which are distinguished as follows.

Twenty-four of them are called grinders, which are placed at the bottom of the mouth, beyond the bars, twelve on each side of the channel, viz. six above, and six on each side.

These teeth continue, and do not fail to give place to new teeth in their room, so that they are of no use in distinguishing a horse's age.

However, they are subject to wolves teeth.

With reference to the other sixteen, twelve of them are called in their infancy, milk or foal teeth, and the remaining four go by the name of tushes.

The twelve foal teeth are short, small, and white; and are seated on the fore part of the mouth; six above, and six below.

These change and cast, to give place to others; which, in process of time, become long, large, and yellowish.

These new teeth are distinguished by the different names given them, according to their putting forth, and it is the manner of their coming forth, that gives us to know the first years of a horse.

Now of these twelve, four are called nippers, four are called middling teeth, and four go by the name of corner teeth.

The four nippers are seated on the fore part of the mouth, two above, and two below.

When a horse has put forth these, we conclude that he goes from two and a half to three years.

The middling teeth are placed near the nippers, or gatherers, one above, and one below, on each side of the jaws.

They come out and appear between three and a half and four years.

The corner teeth are placed yet more forward in the mouth, one above and one below, on each side of the jaws.

These begin to shoot between the fourth and the fifth year, and are got above the gum at five years.

When surmounting the gum at that age, they become hollow, and mark commonly till seven or eight years.

By marking we mean, that in the hollow or cavity of the corner teeth, a little black speck is formed; which, from it's resemblance, we call the bud or eye of a bean.

But when the horse passes six, the cavity begins to fill, and the black mark disappears by degrees; yet this diminution of the cavity and the mark continues from six till seven and a half.

At eight years the cavity is filled up, and the black mark gone, and in regard that the tooth is then full, even as if it had been shaved, we then say that the horse has razed; which happens a little before the eighth year, and after that the horse does not mark; so that the surest knowledge of his age is then took from his tushes.

The tushes are placed beyond the corner teeth upon the bars, two on each side below, without being preceded by any foal teeth.

The two under tushes cut sometimes at three years, sometimes at three and a half, sometimes at four; but the two upper tushes appear sometimes at four, sometimes at four and a half; sometimes before, and sometimes after the corner teeth, without any certain rule; and till the age of six they are chamfered within.

About ten years of age the two under tushes appear much worn, which serves for that age.

After that they grow out in length, and become bare of flesh, because the gum shrinks and retires; and at last, about the fifteenth or sixteenth year, the horse shells.

A horse is not capable of any great fatigue till his tushes have cut the skin.

Most of the Dutch horses are very sick when their tushes come forth; mares have them but seldom, and when they have them they are but very small.

TENDRIL, the clasper of a vine, or other climbing plant.

TENEMENT, any thing, as a house, &c. held by a tenant.

TENURE, the manner in which tenants hold their lands, &c. of their lord.

THATCH, straw laid on the top of a building, rick, &c. to keep out the weather.

THEAVE, or TIER, an ewe of the first year.

THETCHES. See the article VETCHES.

THICKET, a close knot, or tuft of trees; a close wood.

THILL-HORSE, or THILLER, the last horse in a team; the horse that goes between the thills or shafts.

THISTLE, a well known prickly weed growing in corn-fields.

Wherever thistles grow naturally, it is a sure sign that the land is strong: but they are, at the same time, a great annoyance to every plant intended to be cultivated. The best way to destroy thistles is to cut them up by the roots before their seeding time, which is in the autumn; for cutting them off too young, will only make them branch the more: or, which Mr. Lisle prefers, to pluck the thistles up by hand, when the ground is reasonably moist before they are grown to the size at which they are usually cut. They may then be easily drawn up with their root by the thumb and two fingers; and the weeder may guard against their prickles by putting on a glove, or false fingers, made of hard leather. Chalking of land is a good way to destroy this very noxious plant: but thorough tillage, summer fallows, and repeated good harrowings, are the most effectual of all.

By an excellent regulation in France, a farmer may sue his neighbour who neglects to thistle his land at the proper seasons; or may employ people to do it at the other's expence. And it were to be wished, that a similar law was enacted here, to prevent this wide-spreading mischief, occasioned by the seeding of this pernicious weed; among which may be reckoned; besides its choking the young corn, that if wheat, in particular, be not well thistled; the reapers take up the grips so tenderly, lest they should prick themselves, that, by their loose handling of them, they sometimes leave upon the ground corn enough to sow the whole field.

THISTLING, the action of cutting or pulling up thistles, in order to destroy them.

THRASHING, the action of beating out the corn;

Though the flail be the best instrument yet known for threshing the corn, because it separates the grain from the straw and husks very effectually and expeditiously; yet as it always bruises a great many seeds, even so as to render them incapable of growing, it were much to be wished that some method could be found, by which this essential inconvenience might be avoided. Some engine or other, provided with a number of flails, or other pieces answering the same end, might surely be made to move by water, wind, or a horse, so as to perform the business of thrashing still cheaper and more expeditiously, and with less damage to the health of the husbandmen, which is frequently thought to be injured by the dust, &c. which arises in the common way of thrashing, as well as by the very great laboriousness of the work. This well deserves the attention and endeavours of skilful mechanics. At all events, the thrasher ought not to wear thick iron-clouted shoes whilst he is at work, especially if he is to thrash new corn, and particularly wheat; because they will be apt to bruise it. His shoes for this purpose should be soled with an old hat, or some other soft substance.

Mr. Mortimer esteems it a day's labour for a man to thresh four bushels of wheat or rye, six bushels of barley, five bushels of oats, or five bushels of beans and peas, if the corn thrash well. But Mr. Lisle says a good thrasher assured him that twelve bushels of oats or barley are reckoned a good day's threshing: that this very man had thrashed fourteen bushels of oats daily and winnowed them, for several days together; but that those oats yielded indeed extraordinary well: and five or six bushels of wheat are a very good day's thrashing; and if the corn be clung, and yields ill, sometimes three bushels are as much as can be thrashed in a day. He rates the common price of thrashing at eight-pence for a quarter of corn; and observes, which may account for the difference between the estimate and Mr. Mortimer's, that six bushels of wheat of the growth of a warm gravelly vale are as easily thrashed in a day, as four bushels of the produce of cold hilly land; because the stroke of the flail must be forced down stronger to beat out the grain of this last, than it need to be for the former: and also, that as the straw of corn of the growth of a light soil is shorter than that of a strong clayey ground, more sheaves, and consequently more ears of this first sort, may be laid together on a floor of equal extent, than can be of the last, whose longer straw requires proportionably more room.

The worse the wheat is, though it be never so dry, the rougher it will feel when handled; because thin and coarse wheat is not so plump and globular as fine wheat, but is apt to be pitted and wrinkled, which of course renders it less slippery. It will handle cooler out of a stack two years old, than it will out of the one that is only a year old; for in that time the mists and rimes, especially in a hilly country, will be driven into the stack.

Mr. Lisle, who makes this remark, adds from his own experience, that wheat thrashed in damp weather generally yields but little flour, with a great deal of bran, when it is ground; and that if it be put into sacks, it will grow musty in less than three weeks, let the weather be ever so dry afterwards: but if it be thrashed when the air is perfectly clear and dry, it will keep well in sacks, for a long time; especially if these are laid upon trellises high enough to secure them from the dampness of the ground or floor.

For the keeping of meal, in general, there is no better way than first to bolt it, and clear it from the bran, which is very apt to corrode and putrify it, and make it musty; then to tread it down as hard as possible, and head it up closely, in clean, dry, tight, and well bound casks, which must be laid in a cool dry place.

The beards of barley come off best, in thrashing, when the swarths of this corn have taken the dew before their being housed. It will keep well in the mow, unthrashed, for one year; and for making it into malt, which must be done before the heat of the summer comes on, it should not be kept above a year and a half, or at most two years: otherwise it will be filled with weevils; unless it has been previously cured in a stove or kiln.

Oats being defended with a double husk, are the grain least subject to harbour vermin. The best way to keep them after they are thrashed, is to dry them well on a kiln, and then to barrel them up in clean close casks; but they should not be thrashed earlier than Christmas, because they are not fit for keeping before that time.

Beans and peas always thrash best after they have sweated in the mow, which they are very apt to do, because, as the whole crop of either of them never ripens all together, the green parts heat, and communicate their ferment to the whole heap. The danger to be guarded against here is, that the ripe so heated do not give fire to the green, by which both might be either rotted or consumed; to which the bigness of their leaves, and hardness of their stalks, which continue moist and sappy a long time, will also contribute very much. For this reason farmers generally choose to stack them without doors, rather than to house them; that they may be the more thoroughly dried by the sun and air. But the best way of all is to kiln-dry them, or dry them well in the sun; after which they will keep many years, without turning or any other care, though they be laid ever so thick in the granary. As beans are a very large seed, and consequently full of moisture, it is found best to let those that are intended for keeping sweat in the mow till March, when they may be thrashed without danger: for beans never give again, after they have once been thoroughly dried.

Peas are, of all grain, the most subject to rottenness and imperfection, because they are the most apt to breed worms, weevils, and mites, by reason of the lusciousness and sweetness of their grain. The better they are dried either in the kiln or sun, the former of which will generally be found most effectual in this country, the longer they will keep sound, and the fitter they will be for the food of cattle, by helping to make them thirsty; it being a just observation, that if cattle drink well, they will feed well. What is intended for the food of men should not be dried too much; because that would make the peas require double the time in boiling: nor need they be thrashed for this use, but as they are wanted; or else they may be put into close casks, and headed up. In granaries, they keep best in thick heaps, or in bins: spreading of them thin upon the floor being apt to dry them too soon, and to take from them much of their sweetness and goodness.

Vetches wanted for sowing immediately after they are cut, may be thrashed very well on a hurdle, with a cloth; though they may then be too soft, notwithstanding their being ripe, to be thrashed on a floor, where the flail and the thrasher's feet would bruise and break them.

When a careful husbandman opens and spreads his sheaves, he will pick out of them at least all the largest and most apparent weeds, before he begins to thrash. As he proceeds

in his work, he will from time to time remove all the long straw from the corn beaten out of it, which last always lies underneath, with a prong or fork, and then the pieces of straw, broken ears, &c. with a wooden rake. He will then shovel the remaining grain up on one side of the floor, and repeat this till he has thrashed out enough to make what is commonly called a clearing.

The heap is then passed through a wide sieve, which retains only the bits of straw, and such fragments or ends of the ears as have escaped the flail. These frequently contain very good corn; though the farmer seldom grudges giving them to his poultry, or binding them up with straw intended for fodder. A few of them inclosed in a small truss bound at both ends, the better to keep them in, will entice horses to eat heartily of this straw, which affords them good nourishment: and M. Duhamel judges that they would also be excellent and profitable winter-food for sheep, when there is a scarcity of grass.

A great deal of labour may be saved in the using of this sieve by fastening a loop to its rim, and resting it thereby on a hook suspended by a rope. This will sustain half the weight of the corn, and the winnower may easily give it the necessary circular motion. But yet a more convenient method, is to place a square sieve, of wire is best, with thin boards for its sides, upon two polished rods of iron, to throw the corn up into it with a shovel, and to push it backward and forward upon these rods, on which it moves easily, and will sift a great deal of corn in a short time.

For separating the chaff, which is the next business, the casting shovel is much more expeditious than either the wicker fan, or the common winnow with sails. When this shovel is used, the wind must blow through the barn, either in at one door and out at the other, or in at a window, and out at the opposite door. The winnower then, placing himself under the wind, and close to the heap of corn that is to be cleansed, takes it up, one shovelful after another, and, with a circular motion, throws it scattered in the air, against the wind, towards the opposite side of the barn. The best grains, which are the heaviest, go farthest; the lesser fall short of them; and the very small, shrivelled, and much damaged, with the seeds of cockle, darnel and several other weeds, fall still nearer to the man who throws them; while the lighter seeds of other weeds, with the bits of straw, chaff, dust, &c. are blown from all the rest, by the wind. From time to time, the winnower quits his shovel, and sweeps away the second sized corn, which would be too much intermixed with the smallest, if the heap was left alone, and suffered to accumulate till the end of the winnowing; and when the whole is done, he shovels up the finest grain. The least of all, which borders on the chaff, &c. is also then collected, and the three sorts, after being sifted or screened, to cleanse them from any remaining dust, are laid up separately; the first for sale, the next for domestic uses, and the third, if the farmer can afford it, chiefly for the food of poultry. The short straws and chaff are sifted in a pretty fine sieve, to clear them likewise of dust, and are frequently given to oxen and cows.

Mr. Lisle observes that the seeds cannot be separated from any grain by the common fan, but that it may be done with the screen; of which he therefore advises the constant use for all sorts of corn designed for sowing.

Though wind is in all cases, the chief agent in the cleansing of seeds, which being intrinsically heavier than their coats or husks, are by the same force applied to both, carried to different distances, in proportion to their weight, and thereby consequently separated; yet the natural action of this assistant is liable to many inconveniences: it blows not constantly: but frequently disappoints the winnower in his time of greatest need: when it does blow, it is not always in the best direction to answer the situation of his barn; and without doors it is intirely useless to his purpose, if it be not attended with fair weather. Besides, when its force can be applied in the best way, it is even then not equal; but generally acts by sudden blasts, which, as is well known, disorders the whole work, and occasions a considerable waste of seed.

The Dutch avoid these inconveniences by using a machine (Plate XXVI. fig. 1.) which creates an artificial wind, uniform and steady in its action, and always ready at command.

The fan, (fig. 2.) which is the acting part of this engine, produces a wind proportioned to the velocity with which

which it is turned on its axis, and therefore capable of several degrees of strength, as best suits the purpose of the winnower.

The fan is inclosed in a large case or box, K L, and occupies one half of it; which is represented separately, and in a different view, in fig. 3. It is suspended freely on its axis, and turned by the handle A. The other half of the box is empty, and receives the seed as it falls down from the hopper B, to the sloping floor visible at C, along which it slides out at D, while the force of the wind which is confined within this winnow, and always acts in the same direction, viz. lengthways of the machine from A to E, carries the chaff, light and rotten grains, dirt, &c. out at E. In this passage, the wind meets the seed constantly falling from the hopper, and impels it more or less towards the end E, according to its weight. Good seed never goes quite so far, but comes down within the box.

The hopper here is ingeniously contrived to save labour. It hangs by strings upon four pegs, and moves with such ease, that the necessary motion may be communicated to it by the same hand that moves the fan, without any hindrance to the workman. To this purpose, a triangular board f, is fixed upon the handle of the fan, and turns with it. The angles of this board, in their rotation, press against the lower end of a little lath, incurvated as in the figure, which moves freely upon a peg at g. This end accordingly recedes from the pressure towards H, and consequently the upper end moves the contrary way, towards I, and by a string fastened from it to the hopper, draws this last after it, out of its natural situation. When this pressure ends, and the sides of the little triangle are next the lath, the hopper hangs freely, returns to its former place, and takes the lath along with it, till the next angle of the little triangle begins to act; and so alternately as long as the fan moves. As the hopper is thus in continual motion, the seed sheds down, and is winnowed as it falls.

The next care is to cleanse the corn from all foreign bodies, which could not be carried off by the wind, such as stones, bits of earth, &c. These are separated by running the grain through a sieve wide enough to let it pass with ease, while bodies of a larger bulk are retained: and it is likewise often necessary afterwards to use a fine sieve, which lets through only the dust, seeds of weeds, and other bodies smaller than the corn.

Mr. Marshall, in his *Rural Economy of Yorkshire*, vol. I. p. 281. speaks of a winnowing machine to the following effect:

"This excellent machine is well known as a curiosity in most parts of the kingdom. But the county of York being the only one in which its use has been established in common practice, it merits in this place particular notice.

"We are probably indebted to the Chinese, or other Eastern nation, for the invention of this machine. I have seen it upon an India paper drawn with sufficient accuracy, to shew that the draughtsman was intimately acquainted with the uses of it. The Dutch, to whom the invention has been ascribed, imported it, in all probability, from the East Indies. Be this as it may, it indisputably came from Holland into this country.

"Its first introduction into the Vale was by a gentleman of this neighbourhood, about five-and-thirty years ago. But the introducer committing this complex machine to the care of servants, without paying attention to it himself, it was, as might be expected, soon thrown aside as useless.

"Some time afterwards, however, it fell into the hands of a sensible substantial yeoman; who, with the assistance of a friend, discovered its usefulness, and reduced it to practice.

"My father, who had made himself master of the excellencies and defects of this pattern, made one from it, with some improvements. This was the first which was made in the district, and perhaps the first which was made in England.

"The utility of it being seen by some discerning individuals, several others were constructed under my father's direction. But, notwithstanding many of them were kept in common use, and visited as subjects of admiration, it was some fifteen or twenty years before they grew into popular estimation.

"Within the last ten or fifteen years, the making of them has been a principal employment of wrights and carpenters. At present there is scarcely any man, whose farming is considerable, without a machine fan."

"The construction of this machine has undergone several alterations, and some few improvements may have been

made in it; none of them, however, of moment, except that of changing the materials of the sails, from boards to sheet-iron. Its complexness is the only bar to its popularity.

Mr. Young, in his *Annals of Agriculture*, vol. VI. gives a description of a mill, for separating the grain from the ear in place of thrashing, by Mr. William Winlaw, to the following effect. See Plate XXVI*.

"This mill was tried in June, 1785, in the presence of many gentlemen, and gave the greatest satisfaction.

"Upon trial there was passed through the mill one bushel of the heads of wheat in one minute, with very moderate labour to the man that turned it; and, by experiment, it is found that four bushels of the ears will yield one bushel of clean grain; allowing that a man will thrash six bushels in a day, of eight hours work: the mill will clear that quantity in twenty-four minutes, and to a greater degree of perfection than can possibly be done by the flail, for it separates every grain from the ears.

"The saving of corn, by using the mill in preference to common thrashing, being proved, the straw also is in a preferable state after it is cleared of the ears; it need not be handled a second time to prepare it for the market, as it is all combed clean and fitting for use, without any further time being bestowed in preparing it. The expence of repairing or relaying the barn-floors should also be a consideration of the farmers, which the use of the mill entirely removes, besides thrashing instruments, &c.

"It requires very little practice to enable any person to manage the mill. The dart painted on the fly directs which way to turn the handle, it being pointed as it should be turned. The hopper, which serves to feed the mill, is regulated by the two round pins, to which the cords are fixed. The screw at the bottom of the frame is to adjust the distance of the inner nut from the outward cone; for if it is screwed upwards too much it will bruise the grain; if lowered down too far it will admit the ears to pass without effect. The cross bars, which support the axis on which the fly and pinion are fixed, are moveable upwards and downwards, as occasion requires. When the screw at bottom is turned to the right it moves the nut upwards, and give less space. The wedges must be slackened above to admit the axle to rise upwards or downwards, as may be found necessary. These wedges may be slackened or tightened with great ease, and without any danger of injuring the mill.

Directions for combing the bottom of the sheaves, and stripping the ears from the straw. (See Plate XXVI.)

The frame of the comb is made in form of a cross, with a comb fixed to every limb, that four persons may work at once, if requisite, according to the figure in the annexed plate. The teeth or prongs are made of steel, and of an angular form, set at such convenient distances as to strip the ears clean; if set too wide apart they will pass through without effect, and if too near together will not admit the straw to go between.

The objection made by some gentlemen, against the mill coming into general use, is, their fear of not finding employment for their threshers.

Answer. If gentlemen and farmers pay proper attention to improving their waste lands, and other necessary improvements requisite in husbandry, they will be at no loss to find employment for their threshers.

The improvements made of late years in our cotton manufactories, by the help of useful improved engines, is sufficient to confute the notion which many people have, that those improvements are hurtful to the labouring interest of the kingdom, when it is plainly proved that the contrary

trary is the fact, many thousands of poor people being employed by their means, who would not have had it in their power to get employment otherwise; consequently they would have been chargeable to their respective parishes, who now are useful members of society."

As the farmers in many place feed their cattle, and particularly their sheep, in the winter, with half-threshed straw; and as new straw is good food for horses, which are induced to eat it very readily when it still contains some grain; there is, in this respect, an advantage in thrashing the corn only by degrees; besides, that the grain itself is allowed to improve in its quality when preserved in the ear, so as attain the most perfect maturity, to sweat out its moisture, and to acquire a degree of hardness which fits it for long keeping. About three months after it has been cut, is generally reckoned the best time for threshing wheat that is intended for keeping; and accordingly our prudent husbandmen make this the business of winter, when their presence is least wanted in the field. But, on the other hand, feed wheat cannot well be too soon cleared from the chaff, as M. de Chateauvieux's experiments have proved; and the best way of doing this, is by striking the ears against a beam. By this method the husbandman will obtain a fine, long, unbruised straw, fit for binding up his next year's sheaves, for thatching, and for various other useful purposes. Of this he should always save, and stack, as much as he can spare, when it proves long and good, for wheat straw will keep perfectly well a year or two; and if there be no occasion for it in that time, it will make litter and dung at last. Barley straw is likewise very serviceable for thatching or to throw over stacks of barley, or peas, till they can be thatched: but oat straw is of no great use, unless it be to cover an oat-rick, peas for fattening hogs, or corn for fowls. In general, an empty space should be left in the barn, if it can be done conveniently in harvest time, to receive the litter, and foddering straw that is threshed out before cattle come to fodder; or it should be laid under some cover, for otherwise it will rot.

THRASHING-FLOOR, the floor on which the corn is thrashed. See the article **BARN**.

THRAVE, a shock of corn consisting of twenty-four sheaves.

THREAF, a handful, a bundle, a pottle.

TROATING, the action of mowing beans against their bending, which is never done but in a thin crop.

THROATWORT, the name of a perennial weed common in pasture grounds. The stalk is cornered and undivided. The flowers grow in bunches at the top of the stalk. They are erect, of a beautiful purple colour, and divided in the middle into five acute segments.

TICHING, setting up turfs in such a manner as they may be dried by the sun, and fit for being burnt for their ashes upon the land.

TIKE, an insect found in dogs, sheep, cows, &c.

TILLABLE, arable, fit for the plough.

TILLAGE, the act or practice of tilling, or cultivating land. See the article **PLOUGHING**.

"I was much pleased, says a correspondent of the editors of the *Museum Rusticum*, with an account which I received about six weeks ago, of a peculiar management of tillage at Market-Weighton, in the East-riding of Yorkshire, given to me by a sensible man of veracity, who was born and bred a farmer in that neighbourhood.

"The inhabitants of Market-Weighton have, it seems, five fields, two of a sandy soil, and three of a strong clayey soil; the former, as will easily be conjectured, destined to rye, and the others to wheat. Their sandy lands are disposed to four swathes breadth; and finding by experience that considerable parts of each land, towards each furrow, are starved by the coldness of water dripping from the higher parts of the lands, they have for many years altered their former method; and only ploughed the half of each land, viz. the two middle swathes: so that they have now excellent rye growing on the higher and dryer half of every land, and excellent meadow growing on the lower and wetter half, which being just two swathes, is moved with great ease and exactness.

"It will, perhaps, be thought by some, that by making narrower lands, they might have more dry land, and consequently more corn. But I apprehend, these industrious husbandmen find by experience, that when they make their lands narrower, and consequently with less descent, the water stagnates in the higher parts, and consequently spoils their whole crop. Nor could they, I suppose, sow more

corn on their lands; in their present disposition, with convenience, as their present method allows them just one swathe on each side.

"They have rye and meadow in one of their two sandy fields every other year; and a fallow the next year. The having half of the field in grass; affords good grass for their sheep, &c. in that year; and allows them to keep a good stock thereon; and this stock, in return, manures the ground considerably, both the fallow and the sward. One of their wheat-fields affords them plenty of worse or spring corn; and thus they are supplied with wheat, rye, spring corn, meadow, and summer grass, from their five fields, which in any other management they could scarcely be.

"It is observable also, that by this management they only plough as much as four fields, and consequently can afford one fifth more ploughing to every piece of ground in tillage, than they otherwise could, on supposition that their fields are all of the same extent.

"These provident people, gentlemen, have another piece of management well worthy the attention of others. They have two great fairs for sheep; one in spring, and the other in autumn. They hold the former of these fairs in one of their fallow fields, which is to be ploughed up in spring. The concourse of sheep, horses, &c. manures this field surprisingly, and then they turn in the dung before it be evaporated or baked. Their later fair is held on the other fallow field, which is soon to be sown with hard corn. And here they receive equal benefit.

"Whether they have their spring fair on the rye or wheat field, I know not; but I apprehend them to have it on the former, as rye is sown sooner than wheat; and the time of sowing might be too late for their autumnal fair.

"Whoever has seen the useless nastiness which is made by sheep at fairs, in the streets of great towns, will think this management of the Market Weightoners highly deserving of imitation: especially in the latter end of the year, when the rains bring in much soil with the sheep.

"I would, however, venture to recommend one improvement to these sensible people, viz. after a certain number of years to plough up one of their sandy fields entirely, and to cross-plough it, and endeavour to mix the soil of the ridges and furrows thoroughly together, and then to make the furrows where the ridges were, &c. and to sow down the outward swathes of each land with seeds proper to the soil. The advantages hence resulting, are so obvious, that it would be an affront to their understandings to insist upon them." *Museum Rusticum*, vol. VI. p. 83.

TILLER, a branch or stem of corn.

To **TILLER**, to spread or shoot out.

TILLS, tares, or vetches.

TILTH, or **TILT**, the condition of the earth after ploughing, &c.

TIMBER. Mr. Marshall, in his *Rural Economy of Midland Counties*, gives the following treatise on timber.

Mr. Laking, of Hall End, whose landlord (living at a distance) has judiciously entrusted him with the care of his woodlands, obligingly shewed me a young oak wood, of about seven acres, which he recollects to have seen planted with acorns.

"He was, at the time of planting, a child. He is now near seventy. He thinks it is about sixty-three or four years ago.

"The inclosure was in grass. A hole was opened by a kind of scoop or gouge, run obliquely into the surface, so as to raise up a tongue of turf; under which the acorn was placed. The sward was not broken, neither by the spade, the plough nor the hoe, nor does he believe that any kind of nursing, except keeping up the fences, was used.

"In about thirty years, it was coppiced, that is, partially cut down as underwood; leaving timber stands.

"It has since been coppiced twice: the last time about twelve years ago; when the timbers were thinned, in a manner that does Mr. Laking great credit.

"The weedlings were sold for rails, chiefly, at a good price.

"Mr. Hill, in whose farm this wood stands, does not recollect the exact produce of these seven acres: but another piece of somewhat more than four acres, planted about the same time, has, he says, already paid its owner upwards of 400l. as nearly as may be 100l. an acre; and the timbers,

timbers, still too thick, are some of them worth 20s. to 25s. a tree: from forty to fifty feet high, and from six to ten inches timber girth.

"There is a strikingly exact proportion between the size of the tops and the thickness of the stems: How injudicious to suffer trees to crowd each other! Mr. L. seems fully convinced of this; and is meditating another thinning. His ideas are very just in this respect. He is equally aware of the mischiefs ensuing from the lashing of tops, and of the utility arising from young plants standing sufficiently close to draw each other up straight; as well as to rot off the lateral shoots of the stems.

"The soil is a hungry clay, worth about 7s. or 8s. an acre; the clay continuing a considerable depth. How judicious to plant such land with oaks. The trees are clean and full of growth.

"Mr. Laking also showed me a small plantation of his own; about twelve or fourteen years old. The ground was sown with wheat, harrowed, and the acorns dibbled in by women, soon after the wheat was sown. The plants have never been touched. They are, however, getting very unsizeable; beginning to be drawn up too slender; and, no doubt, want weeding. They were never hoed, except partially, and Mr. L. seems to think cleaning the land is not of great use. The subsoil is a bed of fine clay: the plants are clean and thriving.

"Lady Robert Bertie has a piece of oaks getting up, by the side of Shortwood. Mr. Hill says, he sowed the acorns, about sixteen or seventeen years ago: he also sowed some ash keys, at the same time; but few of the ashes have got up, and the oaks are too thin. The acorns and keys were sown broad-cast, and harrowed in with wheat.

"Mr. L. says this piece was sown with tree seeds about fourteen years prior to the last sowing; but a rabbit-warren then lying contiguous, the plants were all cut off.

"It is in vain to attempt to propagate wood, in the neighbourhood of warrens; whether of rabbits or hares."

Mr. Marshall, observes, "1784, July 25. This summer, the oak puts on an unusual appearance. The spring shoot having been taken off entirely from most individuals (see his 29th minute) by the chafer, the Midsummer shoot (or more accurately speaking, a fresh shoot) has supplied its place; the trees now appearing in the colour and softness of May.

"The leaves, however, as yet, are small, thin, and faint; unable, probably, to draw up any considerable supply of sap: and even supposing them to acquire, before autumn, their natural size and texture, the loss of time, and the extraordinary check the sap may have received during the disfoliated state of the trees, will probably prevent them, this year, from forming their ordinary increase of wood: a circumstance which may, hereafter, be easily proved, by examination."

In Minute 140 of the same vol Mr. Marshall says, "1785, April 21. The purchasers of the Merevale timber began to fell, yesterday: although the Grosbery has barely foliated, and the hawthorn but just beginning to open. And it is the opinion of experienced timbermen, that some of the trees in Statfold wood (about fifty years younger) would likewise run.

"Query, is this early rise of sap owing to the specific nature of the trees of this district; or to the nature of the soil or climature? or are woodmen in other districts ignorant as to the circumstance of the bark of old trees running so much earlier than that of younger wood?

"It is observable, that young trees, and even the young wood of old trees, retain the leaves longer than the older branches of aged trees: the sap having, perhaps, a less free circulation, neither rises nor falls so rapidly, as it does in old wood; in which the ducts are become large, and in which the flesh of the bark may have lost, in great part, its elasticity."

In Minute 141, he says "The lag is a common blemish of timber trees in this country: a defect which I do not remember to have met with in any other; unless it be included, elsewhere, in that of shakey. It is a cleft, or rift, reaching sometimes from the top to the bottom of the stem, and, perhaps, to near its center.

"This defect is believed to be caused by frost. No other ground, however, is produced for this opinion, than the evidence of an old man, who lives (or lived) in the neighbourhood of Sutton park (in which the lag is very prevalent) and who says that, in the hard frost, he has, in the

night, heard the trees burst, with reports as loud as those of a gun; and that, on examination, he has found cracks in them large enough to thrust in his hand.

"If this be a fact, it is an interesting one. It is, at least, probable; and is, indeed, the only rational account that, perhaps, can be given of this too well ascertained effect."

In Minute 142, he says, "April 28. Two of the purchasers of the Statfold oaks began felling to-day.

"The tops run perfectly well; but the lower parts of the stems move with difficulty. This may seem a paradox. Yet the fact is so notorious that an old bar-kpeeler will have it, the sap enters as the top.

"The buds are just beginning to swell: the small twigs are full of sap: and no wonder they are so; for the buds not being yet opened, the sap has yet no vent, and there is, of course, a surcharge. This surcharge necessarily takes place at the extremities of the boughs; which might be termed the bottom of the containing vessel; while the roots and the stem might be said to act the part of a tunnel, down which the sap, collected by the fibrils, is poured."

In Minute 143, he says "May 1. This morning, spent two or three hours in Statfold wood.

"In one set of workmen, there are nine fellers to seven peelers, and, in another, three fellers to four or five peelers. But stocking (see vol. I. p. 102.) requires a greater proportion of fellers than axe-felling, in the more usual way.

"The minutiae of stocking are these: the horizontal roots having been bared with a mattock, are cut through with falling axes (see as above); and one end of a rope having been previously, or while the surface roots were cutting, fixed judiciously to a bough in the head of the tree, and the other end of the bottom of the neighbouring tree, in a proper direction, the tap and other downward roots, if not very large, are broken off, by means of this purchase; tearing out the crown of the root entire.

"Much judgment and circumspection are requisite in letting down large spreading trees. Two of those already fallen are much injured by rents below the crowns, and a third is cleft halfway down the stem, by injudicious management.

"The mischief is sometimes done by a spreading bough catching a standing tree; but more frequently, by a heavy arm falling uppermost, and dashing to one side when the tree takes the ground. The worst rent (of a valuable tree) was caused by two boughs, standing forkwise; one of them dashing to one side, the other to the opposite side of the stem, while a third took the ground.

"The preventive is, to cut off or cripple the dangerous boughs, while the trees are standing: an expedient which has a doubly good effect; as is not only guards against the splitting, but inclines the tree to fall, with greater certainty, toward the desired point.

"A log of wood, judiciously placed at the foot of the falling tree, assists in giving it a proper bias. And wedges, driven in behind, have a similar effect.

"It is very observable, that the largest trees, of this wood, have the smallest tap roots: their horizontal roots being numerous, and lying quite up to the surface; while those of the stunted inferior trees are all tap or downward roots; lying deep in the ground; having few horizontal ones.

"In this instance, the topsoil is good, with a hungry, gravelly, yellow loam, for the subsoil.

"These stunted trees are an evidence that, in situations where the subsoil is of an inferior quality, oaks, though raised from the acorn in the place where they are intended to grow up, should be tapped.

"One of the largest trees, in this wood, is much depreciated by having its stately stem fouled and rendered coarse, by rotten and small boughs sticking out of it, from top to bottom. Its purchaser allows it would have been worth more by two guineas, had the stem been clean. One hour's work, or half that labour, bestowed upon it a hundred and twenty years ago, would have given this desirable quality.

"What a mistaken idea that timber trees should not be touched with a pruning instrument! It is injurious, no doubt, to take off principal boughs, after the tree is full grown, or even in the latter stages of its growth; but to suffer the stem, while young, to remain foul with dead stumps, and small branches, is unpardonable."

He says, in Minute 144. "May 14. The felling of the Merevale timber was finished yesterday. Scarcely one tree in ten with a perfectly sound bottom. Many of them

hollow at the heart, a considerable way up, and the entire stems of course tainted. What a dear bargain ! How injudicious to suffer timber to stand thus to waste.

"The length of this timber is extraordinary. A large-girting tree measures sixty feet to the first bough : with a continuation of upright stem, near ten feet more !

"Though these trees seemed to stand well aboveground, they have, or have had, very strong downward roots ; though the substratum be rock. But the fissures of this were probably their great encouragement.

"Counted the rings of one of these trees, about three feet diameter at the butt, and two at the girting place ; and ran over those of another tree. As nearly as could be distinguished, two hundred rings.

"It is observable that, in several of these trees, a core of about ten years growth has shrunk and separated from the more outward rings.

"In Min. 145, he states that on May 22. "One set of wood-fellers, now in Statfold wood, rope very few trees, throwing them down with wedges alone : which, if the heart-spurn be sand (or rather brittle) will, they say, break it sooner, than almost any number of men pulling at it with a rope.

"Their method is to cut one of the main high growing horizontal roots, or side spurns, just through ; sticking in the wedges between the butt and the end of the root.

"This is less trouble, and consequently gains a quicker dispatch, than roping ; but it is less certain as to the point of falling. Nevertheless, if the toes be left, some of a judicious length to prevent the tree from heeling improperly when it first begins to fall, and others left uncut to pull it to the given point in falling, much may be done by wedges.

"But if the tap root be pliable, yielding to the wedges without cracking, this method of throwing down timber trees becomes in a degree impracticable." See TREE,

OAK, ORCHARD.

TIMOTHY-GRASS, the name of a grass now cultivated in England, of which it is a native, though the seeds of it were carried from Virginia, by one Mr. Timothy Hanson, to North Carolina, where it is now cultivated by the inhabitants ; and from this circumstance it received the name it now bears.

It thrives most in low, damp, marshy grounds : for in such soil and situation it will produce a fine turf in three weeks from the time of sowing the seed. It is very luxuriant, grows to a considerable height, and has in some sort the appearance of wheat or rye, having a broad blade or leaf.

All sorts of cattle are very fond of this herb whilst in a green growing state ; and it will not be improper to add, that they are nearly, if not quite, as fond of it, when dried and made into hay : but when it is intended for this use, it should always be mown when it is in full sap, just before it flowers, for if it is left longer before it is cut, being so luxuriant and quick a grower, it becomes harsh and is much dryer and more chirkly food, than when it is cut in its prime.

"Timothy-grass, says an experienced farmer, in a letter to Dr. Templeman, is in appearance a coarse grass, very little promising to be a pasture agreeable to cattle. Indeed its appearance so strongly prejudiced many against it, that it would have been at once condemned to neglect, had it not been rescued by the enterprising disposition of Mr. Roque, which had sown a considerable spot of ground with the seed first sent from America ; yet the fact is, that, whilst in the sap, it is more agreeable to horses and cattle than any other grass has been observed to be. Mr. Roque's horse soon gave him a convincing proof of this ; for having got loose, he left very fine lucern, and the moment he reached the Timothy-grass, instead of ranging about, as usual with horses, he eat clean before him.

"Deer, which are very nice in their food, are so fond of it, that, as I am very well assured by gentlemen from North America, they sow Timothy-grass there on the skirts of their corn land near the woods ; in order to keep the deer from eating their corn ; the Timothy-grass being much more agreeable to them than even corn.

"The dry hay of their Timothy-grass is exceedingly agreeable to cattle, as appears from a remarkable instance mentioned in a conversation in the Society for the Encouragement of Arts, &c. A worthy husbandman, who had himself often experienced how fond his cows and horses were of it, carried a friend into the field, that he might have ocular demonstration of it. The husbandman

took a tuft of dry Timothy-hay in his hand, and as soon as one of the cows saw it, she came instantly to feed on it though there was plenty of good grass under foot. Another cow soon followed the first, and both eat greedily of it : but each of them refused to eat the hay of common grass, which happened to be mixed with it. So fond were the horses and cows of this hay, that they would follow a person having some of it in his hand, as readily as they would one who carried corn for them.

"A very great advantage attending the Timothy-grass is, that it thrives well in such wet marshy land as will scarcely yield any other good grass ; and here, its numerous and matted roots make so strong a sward, that land which was before a loose mire, shall become so firm as to bear cattle and even carriages, without their sinking into it.

"It is almost needless to add, that in order to sow Timothy-grass seed in such marshy land, it must be drained, and then all the inequalities common in such land, as well as the strong matted roots of coarse grass, should be taken up and burnt. The land being then ploughed and laid smooth, the ashes should be spread upon it, and the seed may be sown early in the autumn ; or rather, the plants should be raised in a nursery, and set in it at six or eight inches distance, every way, from each other. This grass will also thrive well on a clay bottom, where water is apt to stagnate in rainy seasons.

"The Timothy-grass will grow to the height of three or four feet. I have been assured by a gentleman that he has seen it between five and six feet high in Virginia. If it is cut down before the seed ripens, it will soon shoot anew, and yield a good second crop. The foul meadows grass grows to the height of about three feet, and will ripen its seed twice in a season : we may therefore infer, that it may be cut for hay thrice in a season. It is not an early grass ; but as soon as it begins to shoot, it makes up for that loss by its speedy growth. During the drought of a summer, the second crop made a surprisingly quick progress. Its not being an early grass is perhaps no loss ; for as it delights in rather moist meadows, the ground might be poached, were cattle tempted to go early to feed on it.

"If from some imperfection in the soil, the plants of either of these grasses do not fill the ground sufficiently, they may be let to run to seed, which falling in the vacant spaces, soon supply the want. So far as we have yet observed in this country, these self-sown plants do not arrive at the size of the parent plants, which were set at due distances : and this affords good reason to think, that if the seed was sown in broad-cast, and the plants came up thick, they would in the same manner be stunted in their growth.

"The success of the Timothy-grass, when sown alone, demonstrates the utility of sowing the seeds of each grass separately, in order to form a just estimate of their comparative values : for though this grass is a native of England, being a species of the fox-tail, it has been hitherto rather neglected than cultivated, even though nature has pointed it out as an useful plant in wet meadows, by its early verdure and growth. I make no doubt but that the practice of raising grasses separately, will bring other no less valuable grasses to light."

"The attention of the public, says Mr. Baker (in his Report for the year 1775) particularly in England, has been very much engaged for some time past with this grass, which is introduced under a new name, perhaps with a view the more conveniently to answer the purpose of the venders of the seed ; for which I have given 14 shillings a gallon ; and I am informed that in London, it has been sold for five shillings a pint, which is 40 shillings a gallon.

"It is named Timothy-grass, instead of its being called by its proper name, for a strange reason, I think : namely, that one Mr. Timothy Hanson carried the seed of it from Virginia to North Carolina, (a great passage truly) where it is now cultivated by the inhabitants : others insist that it was brought by Mr. Timothy to Carolina from New York. We are told, that from this circumstance it received the name of Timothy : and in order to possess it of this name, and to make us believe it is not to be had in these kingdoms, we are told it is a native of America ; a fact of which I have no doubt ; but it is also a native of these kingdoms, and will be found to abound, more or less, in almost every meadow, particularly in moist grounds. I have found it rise spontaneously in many parts of my land, even in the uplands, after I had manured and improved them ; and the true name of

of this grass is, the meadow-fox-tail, so called, I presume, because the head or ear of it resembles a fox's tail in shape.

"Mr. Stillingfleet's observations upon this grass are clear, although short, and therefore I shall beg leave to transcribe what he says.

"This grass is found in great plenty, in our best meadows about London, and I believe, makes very good hay. Linnæus says, that it is a proper grass to sow on grounds that have been drained.

"I am informed, that the best hay that comes to London, is from the meadows where this grass abounds. I saw this spring a meadow, not far from Hampstead, which consists of this grass chiefly. This grass is scarce in many parts of England, particularly in Herefordshire, Berkshire, and Norfolk. [I am not surprised, says Mr. Baker, at its being scarce in Berkshire and Norfolk; because the first is a gravel, and the latter a sand. But wonder it abounds not in Herefordshire, which is a deep wet country.]

"It might be gathered at almost any time of the year, from hay ricks, as it does not shed its seeds without rubbing, which is the case of but few grasses.

Mr. Miller just mentions this grass; and likewise another which he calls the smaller fox-tail, which I have also found upon my land very frequently; it resembles the first named in every respect, except that it is much smaller.

"Mr. Stillingfleet mentions a third grass of this kind, which he calls the water fox-tail. He says, "this is also found in meadows about town, that are found, but lie under water in winter; and perhaps might be proper to sow on such grounds."

"This last I have not met with; and really had many other writers of the present time, mentioned this third sort, I should have concluded it to be the same as that first named; but I have so great a deference to, and reliance upon this writer's judgment, that I have no doubt of there being a third grass of the kind, which I shall use my endeavours to find. Mr. Stillingfleet has furnished us with an engraving of the first, but not of the water fox-tail.

"Several correspondents of the *Museum Rusticum*, have wrote upon the meadow fox-tail grass, under the name of Timothy, some few of them very rationally; but upon the whole, their letters are not so instructive as might be expected, and tend principally to dispute about trifles, and to furnish panegyrics upon individuals; and as few of the letters seem to have arisen from experience, I shall omit the taking further notice of them.

"I have, during the two last summers, collected by hand, of the native seed. I have bought of that which was sold in Dublin, and said to come from America. A noble lord, who is a member of the Society, received a present of this seed from America. He did me the honour to give me some of it. With this, and that which I bought, I have compared that which I collected, and I find them all to be exactly the same.

"Where the grass rises in ground which is in good condition, and in tillage, I observe, that very early in the spring it affords a very luxuriant and fine pasture, of which all sorts of cattle are very fond: but when the grass rises so high, as that the seed is approaching to maturity, it is exceeding coarse, and I think must make very bad hay. But if it be sown on rich ground, and shall not be suffered to stand longer than just for the heads or ears to unheath from the leaves or blades, which they do in the same manner as wheat, I have no doubt but it will make good hay, and that will afford an heavy crop.

"It is urged, as a recommendation of this grass, that it will, some say in three weeks, form a sod, equal to meadow of many years standing; and that it will, on the deepest swamp or bog, in a short time make a sod, which will bear horses or waggons. I have had no experience of this, and do confess, I should not care to venture my cattle and carriages upon such a surface, unless I had before drained the swamp or bog; with that precaution I have no doubt, but the meadow fox-tail grass will make found meadow, as many other grasses will do, under proper care: yet, I must not omit to observe, that this grass appears to be better suited to the improvement of moist low grounds, than the generality of grasses, and would certainly be very useful upon drained and improved bogs."

TINE, a tooth or spike. And hence the common phrase, of giving two or three tinnings, signifies to draw the harrows twice or thrice over the same spot of ground.

TIT, a small horse.

TOR, rowen or winter-grass.

TOVET, or Tofet, half a bushel.

TRAMEL, an instrument or device, made sometimes of leather, but more usually of ropes, fitted to a horse's legs to regulate his motion, and teach him to amble.

Tramel also signifies an iron instrument hanging in the chimneys, whereon to hang pots or kettles over the fire.

TRANSPLANTING, the act of removing trees or plants from the places where they are sowed or raised, and planting them in others. See the article LUCERNE, PLANTING, &c.

TREE, the first and largest of the vegetable kind, consisting of a single trunk, out of which spring forth branches and leaves.

Plantations of useful trees might be made to very great advantage in many places in every country, and the country greatly enriched by it, while the public would be also benefited by it, since it would raise a continual supply of timber used in ship-building, and on other public as well as private occasions.

We have, in many places, heaths and other barren and uncultivated lands, of very great extent; and how great an advantage would it be to the public, to bring these to be truly valuable? Many, if not all of these heaths, would be found on trial capable of producing trees; and some of them are truly the remains of destroyed forests; and, though the profits to be reaped from the planting these would come late, yet the expence of doing it would be very trifling, in comparison of that profit, and the means easy.

The authors who have given rules for planting, having employed themselves only about small spots of ground, the established orchards, or parks, are by no means to be supposed proper guides in attempts of this kind; and Monsieur de Buffon, who had a great opinion of the knowledge of our Evelyn and Miller, who seem to speak of every thing from their own experience, found, when he set about large plantations, that their opinions and rules were erroneous; and was obliged to have recourse to experiments only, which he varied a thousand ways: and, though many of them proved unsuccessful, yet they all gave hints towards others, by which the attempt might afterwards be brought to succeed.

This sagacious enquirer into the operations of nature in the growth of vegetables, having set apart a considerable quantity of land for the trial, and procured a number of young trees, first divided the whole quantity into a number of small squares, and having made a plan of it, examined the nature, depth, and other circumstances of the soil in each, and minuted the whole down on a proper part of the plan; that himself, or whoever succeeded him, might judge from the different growths of a number of trees planted in the same state in the different soils, the different advantages and disadvantages of every circumstance in the depth and nature of the ground, in regard to the growth of useful trees. Different numbers of labourers were employed about different spots of this ground, and the acorns for the young growth planted at different seasons; but the result in general was, that what should seem the best methods succeeding the worst; and those pieces where many labourers were employed, and the acorns planted before winter, were much thinner of young oaks, than those where the least labour had been bestowed upon the ground, and where the acorns had been planted in the spring; but those places which succeeded best from the sowing, were those which had the acorns planted in holes made by a pickaxe, without any preceding culture of the ground. And those where the acorns had only been laid upon the earth, under the grass, afforded a great number of vigorous young trees, though the greater part had been carried away by birds, and other devouring animals. Those spots of ground where the acorns were set six inches deep, were much worse furnished with young shoots, than those where they had been buried but at an inch deep, and in some places where they were buried at a foot deep, not one shoot appeared, though in others where they had been buried at nine inches there were many.

Those acorns which had been steeped for eight or nine days in wine lees, and in the water of the common sewers, appeared out of the ground much earlier than those which were put in without this previous management.

But the most successful of all the trials was that of planting in the spring such acorns as had been sown together in another

another place, and had time to shoot there; of these scarce any failed, and the plantation was perfectly flourishing, though the growth of these young shoots was not so quick and vigorous as those of the acorns which had remained, where first sown; which was probably owing to the injury the tender radicles received in transplanting.

Thus succeeded the experiments by sowing, while, of those made by planting young trees, such as had been brought out of woods, and places under covert, succeeded much worse than those which had grown in more exposed places.

The young trees of the several parts of the plantation kept on their growth in the manner they had begun to shoot, those of the more laboured parts continuing more weak, and lower than those of the less laboured.

Thus were a number of necessary experiments carefully tried; and the result of the whole was, that to make a plantation of oaks, on a soil of the common clayey or loamy kind, the most successful method is this: the acorns must be preserved during the winter in the earth in this manner: let there be made a bed of earth six inches deep, on this place a layer of acorns two inches deep, over these lay a bed of another half foot of earth, over that another layer of acorns, and so on successively, till as many are employed as there will be occasion for; the whole is then to be covered with a foot depth of earth, to preserve all from the frost. In the beginning of March, these beds are to be opened, and the acorns which will by that time have shot out, and are then in reality so many young oaks, are to be planted out at a foot distance each, and the success of a plantation of this kind need not be feared. This is a manner of planting that is done at a small expence, and even that might be in a great measure spared, were it not for the birds and other devouring animals; since, could the acorns be defended from these, they might be only laid on the surface of the ground under the grass in autumn, and they would infallibly shew themselves in so many young oaks the succeeding spring.

It is easy to continue the carrying the acorns, when taken out of their winter's bed, to the place where they are to be planted, without doing them much injury; and the small stop the transplanting puts to their growth, is in reality rather an advantage than an injury; since it only retards the young shoots for about three weeks, or less than that: and by that means secures them from the few cold mornings that may be expected about the time of their natural appearance.

As it appears from these experiments, that the acorns succeeded best where the least labour and preparation of the land was bestowed upon them; and that transplanting the young oaks, or even removing the acorns, from whence they were laid to sprout, retard the growth of the plants: also that the plants rose in the spring, and prospered, that were only laid on the ground, under the grass in autumn, and is the natural way by which oaks are propagated; this appears therefore to be the best method of propagating these trees; to which the only objection is, that the acorns sown in this manner are liable to be devoured by birds, and other animals, because exposed to their view. This may in great measure be prevented by paring the surface of the ground with a breast plough, laying the acorns upon the pared ground, and covering them with the turf that was pared off; or still more expeditiously, and at a less expence, by paring the surface with a paring plough, such as is sometimes used to pare land for burn-beating; a man immediately following the plough, to sow the acorns pretty thick, and another to throw back the turf upon the seed, will cover it very securely from those devourers, which usually destroy the acorns when exposed to their view. Where neither the breast nor paring plough can be used, the paring axe may be used.

TREFOIL, a genus of plants, the flower of which has a tubulous permanent empalement of one leaf: it is of the butterfly kind, drying in the empalement. The standard is reflexed, the wings are shorter than the standard, and the keel is shorter than the wings: it has ten stamina, nine are joined, and one is separate, terminated by single summits, and an almost oval germen supporting an awl-shaped style, crowned by a single stigma. The germen afterwards becomes a short pod with one valve, containing a few roundish seeds.

Mr. Miller enumerates twelve different species of trefoil, the first of which is well known in England by the name of red clover; and the manner of culti-

vating this plant as been already described under the article **CLOVER**.

The second sort, namely, the white Dutch clover, grows naturally in most of the pastures in England, and is generally known among the country people by the name of white honey suckle.

This is an abiding plant, whose branches trail upon the ground, and send out roots from every joint, so that it thickens and makes the closest sward of any of the sown grasses; and it is the sweetest feed for all sorts of cattle yet known: therefore when land is designed to be laid down for pasture, with intent to continue so, it should be sown with the seeds of this plant. The usual allowance of this seed is eight pounds to one acre of land; but this should never be sown with corn, for if there is a crop of corn, the grass will be so weak under it, as to be scarce worth standing; but such is the covetousness of most farmers, that they will not be prevailed on to alter their old custom of laying down their grounds with a crop of corn, though they lose twice the value of their corn by the poorness of the grass, which will never come to a good sward, and one whole season is also lost; for if this seed is sown in the spring without corn, there will be a crop of hay to mow by the middle, or latter end of July, and a much better after-feed for cattle the following autumn and winter, than the grass which is sown with corn will produce the second year. The seed of this sort may be also sown in autumn, and this autumnal sowing, if the seeds grow kindly, will afford a good early crop of hay the following spring; and if after the hay is taken off the land, the ground be well rolled, it will cause the clover to mat close upon the ground, and become a thick sward.

The seed of this white Dutch clover is annually imported from Flanders, by way of Holland, whence it received the name of Dutch clover; not that it is more a native of that country than of this, for it is very common in moist pastures in every county in England: but the seeds were never collected for sowing in this country till of late years; nor are there many persons here, even now, who save this seed, though it may be done if the same method as is practised for the red clover, be taken with this sort; it should therefore be recommended to every farmer, who his desirous of improving his land, to sow carefully an acre or two of this white clover for seed, which will save him the expence of buying for some years, when the price is great; and there will be a sure market for any quantity he may have to spare.

The third sort, namely hop-clover, called by some yellow meadow trefoil, grows naturally among the grass in the upland pastures of this country; but the seeds are frequently sold in the shops, and are by many mixed with the other sorts of clover and grass-seeds, for laying down ground to pasture. This plant grows with upright branching stalks about a foot high, garnished with trifoliate leaves, whose lobes are oblong and heart-shaped, but reversed, the narrow point joining the foot-stalks. The flowers, which are yellow, grow from the wings of the stalk, upon long foot-stalks, collected into oval imbricated heads, having naked empalements lying over each other like scales, somewhat like the flowers of hops, from whence the plant had the name of hop-clover. But there are two sorts of this clover, which grow naturally in England. The other is a much smaller plant than this, and generally known by the name of none-such, or yellow hop-trefoil.

The hop-clover is strongly recommended by the following circumstances. 1. It not only grows, but flourishes on the most barren sands, and therefore must be a very proper grass to cultivate on such unfertile soils, where any other grass that is worth notice will not grow at all. 2. It is no apt to swell cattle, as the red clover does. 3. In good ground it will continue long, and be a very good seed or crop, as Mr. Tull, though prejudiced against clovers, confesses; and, by its flourishing both on sands and clay, which have not been ploughed for many years, it seems likewise to continue long in any soil.

The fifth sort grows naturally on chalky lands in many parts of England; and in some countries the seed is sown after the same manner of the common red clover, especially on chalky ground, where it will thrive, and produce a better crop than clover. The stalks of this are hairy, and grow erect to the height of two feet or more, garnished with trifoliate leaves, standing upon long foot-stalks, whose lobes are longer than those of the red-clover, and have no marks of white; they are of a yellowish green colour,

colour, and are covered with soft hairs. The flowers grow in oval spikes at the end of the branches; they are of a pale copper colour; their petals are long and tubulous, but the brim is divided into two lips, as the other sorts.

This is known by the title of trefoil, in the places where it is cultivated; but the seedsmen sell the hop clover by that name, so they make no distinction between this, the hop-clover, and none-such; therefore, by which of these three titles the seeds are bought, they prove the same.

This sort of trefoil is much cultivated in that part of Essex which borders upon Cambridgeshire.

The sixth sort grows naturally in Spain and Italy; this has upright stalks near two feet high, which are hairy, garnished with trifoliate leaves, having roundish lobes, which are sawed at their points. The flowers are produced at the top of the stalk in long, obtuse, hairy spikes of a bright red colour, so make a pretty appearance during their continuance. It is an annual plant, so is not proper for sowing as fodder.

The seventh sort is an annual plant, which grows naturally in the South of France and Italy; it rises with a strong smooth stalk near three feet high, garnished with trifoliate leaves, whose lobes are two inches and a half long, and near a quarter broad, standing upon long footstalks, which are embraced by stipulæ or sheaths their whole length. Their flowers are produced at the top of the stalks in very long spikes; they are of a beautiful red colour, so make a fine appearance. It flowers in July, and the seeds ripen in autumn.

The eighth sort grows naturally in Spain and Italy; this rises with a slender stiff stalk near two feet high, garnished with trifoliate leaves, whose lobes are very narrow and hairy. The flowers are produced at the top of the stalks in oblong conical spikes; the indentures of their empalements end in long bristly hairs, which are almost equal in length; the spikes are hairy, and the flowers of a pale red colour.

The ninth sort is the common hare's foot trefoil, which grows naturally upon dry gravelly land in most parts of England, and is a sure indication of the sterility of the soil, for it is rarely seen upon good ground. This plant is seldom eat by cattle, so is unfit for pasture, and is only mentioned here because it is sometimes used in medicine; it is an annual plant, whose root decays soon after it has perfected its seeds.

The tenth sort grows naturally on arable land in many parts of England; this has trailing stalks, which put out roots at their joints. The leaves stand upon large slender foot-stalks; the lobes are roundish, and sawed on their edges; the flowers are collected in roundish heads, standing upon slender foot-stalks, which rise from the wings of the stalks; these have bladdery empalements, which terminate in two teeth. When these lie on the ground, their globular heads, having a little blush of red on their upper side towards the sun, and the other part being white, have a great resemblance of strawberries, and from thence it was called strawberry trefoil.

These sorts are preserved in botanic gardens for variety; they are easily propagated by seeds, which may be sown in an open bed of ground, either in autumn or spring.

The plants, which come up in autumn, will grow much larger, and flower earlier in the summer than those which are sown in the spring, so from those good seeds may be always obtained, whereas the others sometimes miscarry. When the plants come up, they require no other care than to keep them clean from weeds, and thin them where they are too close.

The eleventh sort is the common melilot, which is used in medicine, and has been already described under the article *MELILOT*; which see.

The twelfth sort grows naturally in Bohemia and Austria, but has been long cultivated in England as a medicinal plant, though at present it is rarely used; it is annual. The stalks are large, hollow, and channelled; they rise about a foot high, garnished with trifoliate leaves, whose lobes are oval, and slightly sawed on their edges, standing upon pretty long foot-stalks. The flowers are collected in oblong spikes, which stand upon very long foot-stalks, springing from the wings of the stalk at every joint; they are of a pale blue colour, shaped like those of the common melilot; these appear in June and July, and are succeeded by small yellow seeds of a kidney shape, two or three being included

in each short pod. The whole plant has a very strong scent like that of fenugreek, and perishes soon after the seeds are ripe. *Miller's Gard. Dict.*

TRENCH, a furrow cut in the earth for draining land. See the article *BOG*, and *DRAINING*.

TRENDLE, any thing that turns round.

To TREFALLOW, to plough land the third time before sowing.

TROUGH, a long vessel for holding water, &c.

TRUG, or **TRUGG**, a hod for mortar.

TRUNDLE, a sort of carriage with low wheels, for carrying heavy and cumbersome loads.

TRUNK, the stem or body of a tree; or the part between the ground and the place where it divides into branches.

TRUSS, a bundle of hay, straw, &c.

A truss of hay must contain fifty-six pounds, or half a hundred weight: thirty-six trusses make a load. In June, July, and August, a truss of new hay must weigh sixty pounds.

TUMBREL, a dung-cart.

TUMOUR, a preternatural swelling or eminence rising in any part of a horse, and arises either from external injuries, or internal causes.

Swellings caused by external accidents, as blows and bruises, should at first be treated with restraining; thus, let the part be bathed frequently with hot vinegar or verjuice, and, where it will admit of bandage, let a flannel wetted with the same be rolled on: if by this method the swelling does not subside, apply, especially on the legs, a poultice of red wine lees, strong beer grounds, and oatmeal, or with vinegar, oil, and oatmeal; either of these may be continued twice a day, after bathing, till the swelling abates; when, in order to disperse it entirely, the vinegar should be changed for camphorated spirit of wine, to four ounces of which may be added one spirit of sal ammoniac; or it may be bathed with a mixture of two ounces of crude sal ammoniac boiled in a quart of chamber-lye, twice a day, and rags dipped in the same may be rolled on.

Fomentations made by boiling wormwood, bay-leaves, and rosemary, and adding a proper quantity of spirits, are often of great service to thin the juices, and fit them for transpiration; especially if the injury has affected the joints.

But in bruises, where the extravasated blood will not by these means be dispersed, the shortest way is to open the skin, and let out the grumes.

Critical tumours, or swellings which terminate fevers, should by no means be dispersed; except when they fall on the pasteron or coffin joint, so as to endanger them: in this case the discutient fomentation should be applied three or four times a day, and a cloth or flannel frequently wrung out of the same should be bound on, in order to keep the joint continually breathing.

But if the swelling fixes under the jaws, behind the ears, on the poll, withers, or in the groins and sheath, &c. it should be encouraged and forwarded by ripening poultices, wherever they can be applied; oatmeal boiled soft in milk, to which a proper quantity of oil and lard is added, may answer this purpose; or the poultice recommended in treating of the strangles: these must be applied twice a day, till the matter is perceived to fluctuate under the fingers, when it ought to be let out; for which purpose, let the tumour be opened with a knife or strong lancet, the whole length of the swelling, if it can be done safely, for nothing contributes so much to a kind healing, as the matter's having a free discharge, and the opening being big enough to dress to the bottom.

Pledgets of tow spread with black or yellow basilicon (or the wound ointment) and dipped in the same, melted down with a fifth part of oil of turpentine, should be applied to the bottom of the sore, and filled up lightly with the same, without cramming; it may be thus dressed once or twice a day, if the discharge is great, till a proper digestion is procured, when it should be changed for pledgets spread with the red precipitate ointment, applied in the same manner.

Should the sore not digest kindly, but run a thin water and look pale, foment as often as you dress, with the above fomentation; and apply over your dressing the strong beer poultice, and continue this method till the matter grows thick, and the sore florid.

The following ointments will generally answer your expectations, in all common cases, and may be prepared without, as well as with, the verdigris.

Take Venice turpentine and bees wax, of each a pound; oil of olives one pound and a half; yellow rosin twelve ounces: when melted together, two or three ounces of verdigris finely powdered may be stirred in, and kept so till cold, to prevent its subsiding.

Take of yellow basilicon, or the above ointment without verdigris, four ounces; and red precipitate finely powdered half an ounce: mix them together cold, with a knife or spatula.

This last applied early, will prevent a fungus, or proud flesh, from shooting out; for if you dress too long with the above digestive, the fungus will rise fast, and give some trouble to suppress it; when it will be necessary to wash the sore as often as you dress, with a solution of blue vitriol in water, or to sprinkle it with burnt allum and precipitate. If these should not be powerful enough, touch with a caustic, or wash with the sublimate water, made by dissolving half an ounce of corrosive sublimate in a pint of lime-water.

But this trouble may in a great measure be prevented, if the sore is on a part where bandage can be applied with compresses of linen cloth: for even when these excrescences regerminate, as it were, under the knife, and spring up in spite of the caustics above-mentioned, they are to be subdued by moderate compression made on the sprouting fibres, by these means.

Authors on farriery have in general given very proper receipts to answer every intention of this kind by medicines: but as they have not, I think, laid down sufficient rules for their application in those cases where they are most wanted, I hope the following general directions will not be unacceptable; as the difficulty in healing some kinds of sores arises frequently from the unskilful manner of dressing them.

It may be necessary then to observe here, once for all, that the cures of most sores are effected by the simplest methods, and that it is often of much more consequence to know how to dress a sore, than what to dress it with; and in this consists indeed the chief art of this branch of surgery; for the most eminent in that profession have long since discovered, that variety of ointments and salves are unnecessary in the cure of most wounds and sores, and they have accordingly discarded the greatest part, formerly in repute for that purpose; repeated observations having taught them, that after the digestion, nature is generally disposed to heal up the wound fast enough herself, and that the surgeon's chief care is to prevent a luxuriance, commonly called proud flesh; which all ointments wherein lard or oil enters, are but too prone to encourage, as they keep the fibres too lax and supple; and which dry lint alone, early applied, as easily prevents, by its absorbing quality, and light compression on the sprouting fibres.

Thus if a hollow wound or sore is crammed with tents, or the dressings are applied too hard, the tender shoots of flesh from the bottom are prevented pushing up; and the sides of the sore in time from this distention may grow horny, and turn fistulous; nor has the matter by this method a free discharge.

On the other hand, if sores of any depth are dressed superficially, the external parts being more disposed to heal and come together than the internal, they will fall into contact, or heal too soon; and the sore not filling up properly from the bottom, will break out afresh.

Hence we may justly conceive how little stress is to be laid on famous ointments, or family salves, unskilfully applied; for unless this due medium is observed, or obtained in the dressing, no hollow sore can heal up properly.

I thought it necessary to be a little explicit on this head, as gentlemen so frequently complain of being disappointed in their cures, notwithstanding the excellency of their ointment or balsam; and to convince them that less confidence should be put in these favourite medicines than is generally imagined; for where the habit is sound, and the blood and juices in good condition, there are few simple dressings that will not succeed; and when otherwise, the

most pompous will not avail, till these habits are rectified by proper internal medicines.

As soon then as a good digestion is procured (which is known by the thickness and whiteness of the matter discharged, and the florid red colour at the bottom of the sore) let the dressings be changed for the precipitate medicine; or the sore may be filled up with dry lint alone, or dipped in lime water with a little honey and tincture of myrrh, or brandy; about a fifth part of the latter to one of the former; a pledget of lint dipped in this mixture should also be applied to the bottom of the sore, which should be filled up with others to the surface or edges, but not crammed in too hard, as before observed, nor yet applied too loosely.

By this method, the sore would incarnate, or heal up properly, and soft spongy flesh would be prevented, or suppressed in time; whereas when ointments or salves are too long continued, a fungus or proud flesh is thereby so encouraged in its growth, that it requires some time to destroy and eat it down again: a proper compress of cloth and a linen roller is absolutely necessary both for this purpose, and to secure on the dressings, wherever they can conveniently be applied. *Bartlett's Farriery*, p. 236.

TUPP, a ram.

TUPPING-TIME, ramming time.

TURF, a blackish, sulphureous earth, used in several parts of England, Holland, and Flanders, as fuel.

In Flanders, their turf is dry or pared from off the surface of the earth, and cut in form of bricks. The sedge, or species of grass growing very thick on the turf earth, contributes greatly, when dry, to the maintenance of the fire.

The Dutch take their turf from the bottom of the dykes or canals which run across most of their lands; by which means they not only supply the defect of wood, which is very great in most of the United Provinces, but also keep their dykes clear and navigable: this turf earth is very black. As they take it up from the bottom of the dykes, they spread it about the edges of such a thickness, as that it may be reduced to three inches when moderately dried. In this condition they cut it into pieces of turfs seven or eight inches long, and three broad, and, to complete the drying, lay them up in heaps, and at last in stacks.

In the north of England, Scotland, &c. turf is dug out of soft, moist, rotten earth, called peat-moss. They dig horizontally from the surface, to the depth of about four feet with a spade, which at once fashions and takes them out in parallelipeds nine or ten inches long, and three square; which are spread on the ground to drain as fast as dug; and then set up an end three or four against each other, for the wind to blow through them; and at last they are stacked or housed. The pits or dykes in a few years fill up again, and afford a fresh crop.

The turf or peat, that is cut horizontally, is usually dug out in holes or pits, and cannot conveniently be dug so deep, nor in such a regular manner as when dug perpendicularly, the banks in this last method of cutting being in straight lines; as in some parts of England more southward, particular in Wiltshire, and near Newbery in Berkshire, where great quantities of peat have been dug in that manner.

The surface of these peat grounds is commonly a black, moory and crumbling earth, of about a foot deep, more or less, with sometimes a stratum of whitish earth lying under it mixed with many small shells of the periwinkle kind; having the properties of other shell marle, but in a lower degree than the shell marle found near the sea. The peat below is of different depths, from two or three to five or six feet, sometimes deeper; and below the peat is sand or clay. The peat so is wet, and towards the top it is moist.

When the peat is to be cut, the ground is marked on the surface, in a straight line of a length at pleasure, and between three or four feet broad, which is called the pit: the surface is then dug level with a common spade, and the moory earth carried away, and laid in a heap, in some convenient place to be burnt to ashes. If the water does not rise up to the top of the pit, it is penned up almost to the top, by a dam made up below: for the peat is cut in the water with a narrow spade, shod at the lower end: the spade is about four feet long, besides the handle, and four inches broad, and has an ear, or a sharp iron on one side of it, bent to a right angle, which serves to cut and separate one side of the peat from the pit, as the back of

of the spade does the other. In this manner every peat is formed into an oblong, four inches square, and about four feet deep, if the peat earth runs so deep. The cutter easily breaks the peat at bottom, by leaning the spade forward, which rises in the water upon the spade, and is then laid flat, upon a flat broad bottomed wheel-barrow. The peats being laid close side by side, in three or four layers high, are wheeled away, slipped off the barrow upon the ground, as close as they can lie, where they remain till dry on one side; and then turned to dry on the other. Sometimes in wet summers, they are set up on end, in small heaps, to dry. In very fine weather they will be dry in about a fortnight or three weeks, by turning them on the ground by hand.

The peat, when first cut, is about four inches square, and shrinks in drying to about three inches square, and also something in the length; so upon the whole, they are reduced in drying to about half their first dimensions, but not equally; the hardest black peat, which are the best, shrink less than those that are spongy. The proper time to cut the peat is from March, when the frosts are gone off, to September, or between five and six months.

A quantity of ground is necessary to dry the peat upon, in proportion to their length. The peat of an acre, that run to about a yard deep, will require nine acres to turn and dry the peat upon, if so much was to be dried at once: for the peat being four inches square at the end, the side of the peat upon the ground has nine times that surface: and in that proportion for a larger or smaller quantity of land to be cut out: and some room must be left for paths, at proper distances.

The peat land here is sold at a high price, from sixty or seventy to one hundred and twenty pounds per acre; and when the buyer has cut out the peat, the land reverts to the original proprietor; which, if it lies so low, that it cannot be drained, is of little value; but if the water can be carried off, and it lies near a river or stream of water, the land is levelled, and laid in a proper manner to be floated; and in that case the improvement is very great. For it frequently happens that the surface of the peat land lies so high and dry, before the peat is cut out, that the herbage is of small value, yielding only small crops of coarse grass; but when the surface, by cutting the peat out, is sunk low enough to be watered, and that water can be carried off, such land is then worth above double, or even treble its former value, without any expence to the owner: for the land is laid level by the buyer of the peat,

I saw a tract of land there about one hundred acres, belonging to one farm, which had been examined by boring with an auger; the peat was very deep, and being near a market, was valued at one hundred pounds an acre. And as it lay convenient to water, which could be carried off the land, after the peat was cut out, would be improved, and produce much greater crops of grass than before the peat was cut out of it.

The peat buyer has very little trouble in cutting and selling it; for he employs a cutter, who cuts, dries and delivers the peat, for which he is paid by the load, of forty-two bushels of dry peat per cart load: he cuts and removes the surface that lies above the peat earth, and levels the ground after the peat is all cut out. He is reckoned to earn from two shillings and sixpence to three shillings a day.

An acre of peat ground, of one spade, or four feet deep, produces from one thousand to one thousand four hundred cart loads of dry peat, which was sold formerly at three shillings per cart load on the spot; but it considerably advanced, since the peat land in that country became scarce. One man can cut about six loads of dry peat in a day.

If the weather is so favourable, as that six dryings can be carried off the ground in a season, about two acres and a half of land will be room sufficient to spread and dry the peat upon, produced in one season from an acre of peat of four feet deep.

The peat runs sometimes but two or three feet deep, and is then cut at once; but when it runs deeper than three feet and a half or four feet, it is cut at twice; and the water at each cutting must be kept up near the surface of the ground that is cutting: for then the peat is the easier cut, and easier broke off at bottom, and brought up upon the spade to the surface of the water.

When it is not intended to water the land after the peat is cut out, and therefore of no use to level it, all

the surface is carried away, and reduced to ashes: but if the bottom is to be levelled for watering, the surface of the land, as being the most fertile part of it, is thrown down upon the bottom to level it for watering; and sometimes all the earth above the peat, is thrown down upon the bottom, when necessary to raise it, the turf, and also the moory earth; when this is done, the moory earth should be thrown down first, and the turf for staple laid uppermost.

In wet summers the peat cannot be all dried sufficiently for sale: when that happens, the damaged and broken peat is burnt upon the spot, or carried to the heap of turf and moory earth, where those, together with the white marly earth, are burnt to ashes, with a slow smothering fire, and thrown up in heaps of a round form; or long, like the ridges of a house; where, in a short time, by the changes of weather, a crust is formed upon the surface of the heap, which throws off the rain, and preserves the ashes pretty dry; but as the salts of the ashes are liable to be washed out by much wet, and the value of them are thereby considerably lessened, some are at the expence of erecting sheds, to keep their ashes dry, till they can dispose of them.

The expence of collecting the materials for these ashes, and burning them, is about a penny or three half-pence per bushel; and they are sold to the farmers at about two-pence half-penny or three-pence per bushel upon the spot; but the price was advancing, on account of the demand for them and most of the peat land being cut out. They use baskets for measuring the ashes, of sixteen inches diameter at top, and twenty inches deep, measured diagonally, and heaped measure. The same baskets serve for measuring the dry peat. Forty-two of these bushels of ashes is called a cart load.

The quantity of ashes produced from a cart load of peat, burnt in the chimney, of the best peat, is about five bushels; but in digging peat, the cutter is apt to thrust the spade deeper than the peat, so that the lower ends of the peat, having in them a mixture of clay or sand, produce more ashes than the net peat soil; but the ashes in that case are of an inferior quality: for the genuine peat soil contains much sulphur and produces the strongest ashes, whereof six or eight, to ten or twelve bushels, are commonly sufficient to dress an acre of corn or clover: for the last of these crops, and for grasses in general, whether the natural or cultivated grasses, peat ashes are a great improvement.

The ashes from peat burnt in chimneys, being of the best sort, and kept dry, are the most valuable, and sell at about double the price of the ashes burnt in the field. Formerly these ashes were sold at a shilling per bushel down to ten-pence; this was at first, and before peat was burnt in great quantities within doors. They afterwards sunk in price to about six-pence the bushel; and since that advanced again.

Some have thought that the peat soil has a kind of vegetative quality, and will grow up again in a course of years after it has been cut out; but this is a mistake. In boggy soils or fens, the spongy peat that has been dug out of them, will indeed grow up again; because the peat of such soils is a composition of the roots of aquatic plants, which grow and produce new roots, till the pits are again filled with them, as at first, and then may be cut again, and will produce peat or turf as at first.

But the peat soil we have been treating of, is very different from that of the turf bogs. The peat soil is a composition of rotten wood, most of it entirely rotten, and some but partly so: trees of various kinds and sizes are found in the peat soil, some of oak, of thirty, forty feet, or more in length, the heart hard and sound, and only the sap rotten; abundance of nut-shells also, and other indications, shew that these peat lands were formerly woods. When the soil made up of these is cut out for peat, it is evident that it cannot grow up again into a peat soil: and there have been some instances in that country of peat being cut in pits horizontally, before they came to be expert in the present method of cutting it perpendicularly; and as these pits were cut irregularly, in some parts deep, and others shallow, and much of the ground missed, and not cut at all, the land was all cut over again, in a regular manner, in order to get all the peat out of it. The manner of the first cutting was then observed; and the marks of the spade at the first cutting was in several places plainly visible; which shews that peat soil does not vegetate, and that peat once cut out, will not grow again, and fill up the old pits with the same kind of soil. This is taken

taken notice of here, that the owners of such land may not be misled with the erroneous opinion of a new growth of peat soil, after it has been once cut out.

TURF-ASHES. See the article *ASHES*.

TURF-BOGS. See *Bog, Moor, and Moss*.

TURFING-SPADE, an instrument used to under-cut the turf, after it is marked out with the plough.

TURKEY, the name of a well known fowl, reared in many parts of England.

"Most of our housewives, says a Swedish author on husbandry, have long despaired of success in rearing turkeys, and complained that the profit rarely indemnifies them for their trouble and loss of time: whereas, continues he, little more is to be done than to plunge the chick into a vessel of cold water, the very hour, or if that cannot be, the day it is hatched, forcing it to swallow one whole pepper-corn, and then restoring it to its mother. From that time it will become hardy, and fear the cold no more than a hen's chick. After which it must be remembered that these useful creatures are subject to one particular malady whilst they are young, which carries them off in a few days. When they begin to droop, examine carefully the feathers on their rump, and you will find two or three, whose quill part is filled with blood. Upon drawing these the chick recovers, and after that requires no other care than what is commonly bestowed on poultry that range the court yard.

"These articles are too true to be denied; and in proof of the success, three parishes in Sweden have, for many years, gained several hundred pounds by rearing and selling turkeys." *Rural Oeconomy*, p. 739. See *POULTRY*.

TURNIP, or **TURNIP**, an esculent plant, of which there are three species enumerated by Miller. The first is the turnip which is commonly cultivated in the fields, of which there are the following varieties, viz. the round, red or purple topped turnip, the green topped turnip, the yellow turnip, the black rooted turnip, and the early Dutch turnip. The last sort is commonly sown early in the spring, to supply the markets in May and June, but is never cultivated for a general crop. The red rooted turnip was formerly more cultivated in England than at present; for since the large green topped turnip has been introduced, all the skilful farmers prefer it to the other sorts; the roots of the green will grow to a large size, and continue good much longer than the other sorts. The next to this is the red or purple topped turnip, which will also grow large, and is extremely good for some time; but the roots of this will become stringy much sooner than those of the green topped. The long rooted turnip, the yellow turnip, and the blackish rooted turnip, are now rarely cultivated in England, neither of them being so good for the table or for feed, as the red and green topped turnip, though there are some few persons who sow them for the sake of variety.

The French turnip is not much cultivated in England, but in France and Holland they are in great esteem, especially for soups; their roots being small, are boiled whole in the soup, and so served up to the table; these must be used while they are young, otherwise they will become rank and stringy.

These are supposed to be only varieties, which have accidentally been obtained from seeds, therefore I have not enumerated them as distinct species; but yet I am certain they are constant, where care is taken in the saving of their seeds not to suffer any mixture to stand for seeds: I have sown of three or four sorts several years, and have always found them retain their differences; however, it is not easy to determine if some of these were not by culture first obtained from seeds of the common white turnip. The yellow turnip seems most unlikely to have been an accidental variety, for I have never known this alter, and the roots are yellow within, whereas all the others have white flesh, notwithstanding their outsides are of very different colours.

The long rooted turnip is, I think, a distinct species, the form of the root, and its manner of growth being totally different from the other sorts. I have seen these roots as long as those of the parsnip, and nearly of the same shape; these run deep into the ground, so are unfit for feeding of cattle; and unless they are very young, become strong, so not proper for the table, which has occasioned their being rejected of late years.

The green topped turnip grows above ground more

than any of the other, which renders it preferable for feeding of cattle; and being the softest and sweetest root when grown large of any of the kinds, is most esteemed for the table; but in very severe winters they are in greater danger of suffering by frost, than those whose roots lie more in the ground, especially if they are not covered by snow; for when they are frequently hard frozen and thawed, it causes them to rot sooner than those whose flesh is less tender and sweet. I have seen the roots of this sort, which were more than a foot diameter, boiled and were as sweet and tender as any of the smallest roots.

Turnips delight in a light sandy, loamy soil, which must not be rich; for in a rich soil they grow rank and are sticky, but if it be moist they will thrive the better in summer, especially in fresh land, where they are always sweeter than upon an old worn-out or a rich soil.

The common season for sowing of turnips, is any time from the beginning of June to the middle of August, or a little later; though it is not advisable to sow them much after, because, if the autumn should not prove very mild, they will not have time to apple before winter, nor will the roots of those which are sown after the middle of July, grow very large, unless the frost keeps off long in autumn. But, notwithstanding this is the general season in which the greatest part of turnips are sown in the country, yet, about London, they are sown successively from March to August, by those who propagate them to supply the markets with their roots; but there is a great hazard of losing those which are sown early in the year, if the season should prove dry, by the fly, which will devour whole fields of this plant while young; so that where a small quantity for the supply of a family is wanted, it will be absolutely necessary to water them in dry weather; and where a person sows those seeds in April and May, it should always be upon a moist soil, otherwise they seldom come to good, the heat of the weather at that season being too great for them upon a dry soil; but those which are sown towards the middle or latter end of June, commonly receive some refreshing showers to bring them forward; without which, it is very common to have them all destroyed.

These seeds should always be sown upon an open spot of ground; for if they are near hedges, walls, buildings, or trees, they will draw up, and be very long topped, but their roots will not grow to any size.

They are sown in great plenty in the fields near London, not only for the use of the kitchen, but for food for cattle in winter, when there is a scarcity of other food; and this way is become a great improvement to barren sandy lands, particularly in Norfolk, where, by the culture of turnips, many persons have doubled the yearly value of their ground.

The land upon which this seed is sown, should be ploughed in April, and twy-fallowed in May, that is, once more ploughed and twice well harrowed, and made very fine; then the seed should be sown pretty thin; for it being small, a little will sow a large piece of ground; one pound is the common allowance for an acre of land. The seed must be harrowed in as soon as it is sown, with a short-tined harrow, and the ground rolled with a wooden roll, to break the clods and make the surface even. In ten days or a fortnight after sowing, the plants will come up; at which time, if the season should prove dry, they will be in great danger of being destroyed by the fly; but if it so happen, the ground must be sowed again, for the seed being cheap, the chief expence is the labour; but the ground should be first harrowed to loosen it, especially if it is stiff land.

When the plants have got four or five leaves, they should be hoed to destroy the weeds, and to cut up the plants where they are too thick, leaving the remaining ones about six or eight inches asunder each way, which will be room enough for the plants to stand for the first hoeing; the sooner this is performed, when the plants have four leaves, the better they will thrive; but in the second hoeing, which must be performed about a month after the first, they should be cut up, so as that the remaining plants may stand fourteen or sixteen inches distance, or more, especially if they are designed for feeding of cattle; for where the plants are allowed a good distance, the roots will be over-gained by their bulk, which is what I have often observed. But in such places where they are sown for the use of the kitchen, they need not be left at a greater distance

distance than ten inches or a foot, because large roots are not so generally esteemed for the table.

It is not many years since the practice of sowing turneps for feeding of cattle, has been of general use; how it happened that this improvement should have been so long neglected in every part of Europe, is not easily to determine, since it is very plain, that this piece of husbandry was known to the ancients. For Columella, in treating of the several kinds of vegetables which are proper for the fields, recommends the cultivating rape in plenty; because, says he, those roots which are not wanted for the table, will be eaten by the cattle: yet this plant was not much cultivated in the fields till within the last sixty or seventy years; nor is the true method of cultivating turneps yet known, or at least not practised, in some of the distant counties of England, at this time. For in many places the seed is sown with barley in the spring, and those plants which come up, and live till the barley is cut, produce a little green for the sheep to pick up, but never have any roots. In other places, where the turnep-seed is sown by itself, the method of hoeing them is not understood; so that weeds and turneps are permitted to grow together; and where the turneps come up thick in patches, they are never thinned, so that they draw up to have long leaves, but never can have good roots, which is the principal part of the plant, therefore should be chiefly attended to.

The general method now practised in England, for cultivating this plant in the fields, is the same as is practised by the farming gardeners, who supply the London markets with these roots, and is the same as before directed. But it is only within the compass of a few years, that the country people have been acquainted with the method of hoeing them; so that the farmers formerly employed gardeners who had been bred up in the kitchen gardens, to perform this work; but it is now performed by many country labourers, by which means that practice is lost to the kitchen gardeners; the labourers doing it much cheaper.

There has also been another method practised very lately, by some very curious farmers, in cultivating of turneps, which is by sowing the seed in rows, with the drill-plough. In some places the rows are sown three feet asunder, in others four, in some five, and some six. The latter has been recommended by some, as the most proper distance; and although the intervals are so large, yet the crop produced on an acre has been much greater than upon the same quantity of land, where the rows have been but half this distance; and upon the fields which have been tilled, the crops have greatly exceeded those which have been hand-hoed. The late lord viscount Townshend was at the expence of making the trial of these two different methods of husbandry, with the greatest care, by equally dividing the same fields into different lands, which were alternately sown in drills, and the intermediate lands in broad-cast. The latter were hoed by hand, in the common method, and the other cultivated by the hoeing plough; and when the roots were fully grown, his lordship had an equal quantity of land, which had been sowed in different methods, measured, and the roots drawn up and weighed; those roots which had been cultivated by the plough, where so much larger than the other, that the crop of one acre weighed a ton and a half more than that of an acre in the other husbandry.

But when the turneps are sown in drills, they will require to be hoed by hand, to separate and cut out the plants, where they are too near together in the rows; as also to cut up the weeds between the plants, where the plough cannot reach them. If this is carefully performed, the ploughing of the intervals will encourage the growth of the roots, by thus stirring of the ground, and make it much better prepared for the crop of barley, or whatever else is sown, the following spring. This method of culture may be supposed to be more expensive than that commonly practised, by those unacquainted with it; but those who have made trial of both, find the horse-hoeing to be much the cheapest, and by far the best. For the country people, who are employed in hand-hoeing of turneps, are very apt to hurry over their work, so that half the weeds are left growing, and the plants are seldom singled out so well as they should be; nor are they curious enough to distinguish the charlock, which is one of the most common weeds in arable land, from the turneps;

so that about the middle of September, it is very common to see the fields of turneps full of the yellow flowers of the charlock. Now, in the horse-hoeing, all the weeds in the intervals will be entirely destroyed: so that if a few plants in the rows of turneps should be over-looked, they may be easily drawn when they appear visible, and by this method the land will be sooner and better cleaned from weeds.

The greatest evil which attends a crop of turneps, is that of their being destroyed by the fly, which usually happens soon after the plants come above-ground, or while they are in the seed-leaf; for, after they have put out their rough leaves pretty strong, they will be past this danger. This always happens in dry weather; so that, if there should be rain when the turneps come up, they will grow so fast, as to be in a few days out of danger from the fly; and it hath been found, that those, which have been sown in drills, have escaped the fly much better than those sown in broad-cast; but, if foot is sown along the surface of each drill, it will be of great service to keep off the fly, and a small quantity of it will be sufficient for a large field, where the drills only are to be covered.

Another danger of the crops being destroyed is from the caterpillars, which very often attack them, when they are grown so large as to have six or eight leaves on a plant. The surest method of destroying these insects, is to turn a large parcel of poultry into the field, which should be kept hungry, and turned early in the morning into the field; these fowls will soon devour the insects, and clear the turneps. To this evil the turneps, which are sown in drills, are not so much exposed; for as the ground between the rows will be kept stirred, the plants will be kept growing, so will not be in danger of suffering from these insects, for the parent insects never deposit their eggs upon any plants which are in health; but as soon as they are stunted, they are immediately covered with the eggs of these insects; and this holds in general with vegetables as with animals; who are seldom attacked by vermin when they are in perfect health; whereas, when they become unhealthy, they are soon overspread with them; so that it is the disease which occasions the vermin, and not the vermin the disease, as is commonly imagined.

When the turneps are sown in drills, it will be the best way to plough between every other row at first, and some time after to plough the alternate intervals, by which method the plants will receive more benefit from the often stirring the ground than they would do, if all the intervals were hoed at one time; and the plants will be in less danger of suffering from the earth being thrown up too high on some rows, while others may be left too bare of earth; but, when the earth has been thrown up on one side of the drill, it may be turned down again soon after the next interval is ploughed. This alternate moving of the earth will prepare the ground very well for the succeeding crop, and greatly improve the turneps; but, as the plough cannot well be drawn nearer to the drills than two or three inches, the remaining ground should be forked to loosen the parts, and make way for the fibres of the roots to strike out into the intervals; otherwise, if the land is strong, it will become so hard in those places which are not stirred, as to stint the growth of the turneps. This may be done at a small expence; a good hand will perform a great deal of this work in a day, and, whoever will make the trial, will find their account in practising it, especially on all strong land, where the turneps are much more liable to suffer from the binding of the ground, than they will be on a loose soil; but yet, in all sorts of ground, it will be of great service to practise this.

When the ground is thus stirred in every part, one ploughing will be sufficient, after the turneps are eaten, for the sowing of barley, or any other crop; so that there will be an advantage in this, when the turneps are kept late on the ground, as will often be the case, especially when they are cultivated for feeding of ewes, because it is often the middle of April before the ground will be cleared; for the late seed in the spring, before the natural grass comes up, is the most wanted, where numbers of sheep or ewes are maintained, and one acre of turneps will afford more feed than fifty acres of the best pasture at that season.

In Norfolk and some other counties they cultivate great quantities of turneps for feeding of black cattle, which turn to great advantage to their farms, for hereby they

procure a good dressing for their land; so that they have extraordinary good crops of barley upon those lands which would not have been worth the ploughing, if it had not been thus husbanded.

When the turneps are fed off the ground, the cattle should not be suffered to run over too much of the ground; for if they are not confined by hurdles to as much as is sufficient for them one day, the cattle will spoil three times the quantity of turneps as they can eat, so that it is very bad husbandry to give them too much room: therefore the hurdles should be every day removed forward, and if the turneps are drawn out of the ground before the cattle or sheep are turned into the new inclosure, there will be less waste made, for they will then eat up the whole roots; whereas, if they are turned upon the turneps growing, they will scoop the roots, and leave the rinds, which being hollow, the urine of the sheep will lodge in them; so that, when they are forked out of the ground, the sheep will not eat any of those roots which are thus tainted.

I cannot omit taking notice of a common mistake, which has generally prevailed with persons who have not been well informed to the contrary, which is in relation to the mutton which is fatted with turneps, most people believing it to be rank and ill tasted; whereas it is a known fact, that the best mutton this country affords is all fatted on turneps, and that rank mutton, whose fat is yellow, is what the low marshy lands of Lincolnshire, and other rank pastures produce.

In order to save good turnep-seeds, you should transplant some of the fairest roots in February, placing them at least two feet asunder each way, observing to keep the ground clear from weeds, until the turneps have spread so as to cover the ground, when they will prevent the weeds from growing. When the pods are formed, you should carefully guard them against the birds; otherwise they will devour it, especially when it is near ripe; at which time you should either shoot the birds as they alight upon the seed, or lay some bird-limed twigs upon it, whereby some of them will be caught; and, if they are permitted to remain some time, and afterwards turned loose, they will prevent the birds from coming thither again for some time, as I have experienced. When the seed is ripe it should be cut up, and spread to dry in the sun; after which it may be threshed out, and preserved for use.

There have been many receipts for preventing the fly taking turneps, but few of them deserve notice; therefore I shall only mention two or three which I have seen tried with success. The first was steeping the seeds in water with flour of brimstone mixed, so as to make it strong of the brimstone: another was steeping it in water with a quantity of the juice of horse aloes mixed, both which have been found of use. The sowing of foot or tobacco-dust over the young plants, as soon as they appear above ground, has also been found very serviceable: in short, whatever will add vigour to the young plants, will prevent their being destroyed by the fly, for they never attack them, till they are stunted in the growth.

Miller's Gard. Dict.

Mr. Lisle is inclined to think, that the best way to manage turneps, the seed of which, says he, is impatient of growth, and apt to burst in too much wet, as also to corrupt, if the ground be so dry as only to give it a damp, but not wet enough to set it on growing, is, first to harrow the ground fine, after it has been brought to a perfect tilth by ploughing, then to roll it with a roller big enough to break the little clods, if any such remain, and so let it lie till the next rain; then, the ground being mellow to sow the seed, and harrow it in with short-tined harrows, which may not open the ground too deep, nor bury the seed; then roll it again with a one-horse roller, in order to keep the moisture in the ground as deep as the seed may be: for the surface of the earth must not be dried before the seed can strike root, which may be in twice twenty-four hours; and yet that surface must be so fine, and so lightly compressed, that the seed may spear through it. He takes the mystery, as he calls it, of the success or miscarriage of a crop of turneps to consist in these four things, viz. first, in the seeds not lying too deep; secondly, in its not lying too wet, which it cannot easily do if harrowed in shallow, for the surface of the earth is soon dry; thirdly, in its not lying too dry; and fourthly, in its lying in a fine bed. In another place, he tells us,

that his gardener affirmed to him, that he had found turnep-seeds, which had been dropped by accident and covered over with earth in digging, fresh and good a year after, when the earth was turned back again, and that it has then grown and produced good turneps. The reason is, that every seed which is buried so deep as not to be affected by the changes in the air, may remain in a sound state, and in a fit condition to vegetate, for many years, as hath been evinced by numbers of instances.

Mr. Duhamel advises after the two first hoeings, a slight ploughing all over the field, with a plough that has no fins to the share, as a speedier and cheaper way to thin the plants; the turneps will not require any farther care. They will have attained their full size in October, before the frosts come, and should then be taken up, stripped of their leaves, which may be given to cattle, and laid upon hurdles in a dry place, with a layer of dry sand between each layer of turneps, which may be thus piled up, and which will keep very well in this condition, for the food of cattle during the winter. In Norfolk, they stow them in their barns, when intended for fattening of bullocks.

A dry season is the best for hoeing turneps, because neither the weeds nor the turneps hoed up then will be so apt to grow again: and Mr. Lisle supposes that care should be taken to hoe up those that are deepest rooted in the earth, and to leave those that grow upon, and almost out of it, without much regarding their size; because those which lie on the ground, and have room to grow, will soon become the largest.

Some sow turneps on their flax and hemp grounds, at the same time as they pluck up those plants, and the seed is pretty well buried by the stirring thereby given to the earth. Others give their corn stubble only a slight ploughing after harvest, then sow the turneps very thin, and harrow in the seed. These methods do very well when the ground is in good tilth. Others again, sow late turneps, merely for the sake of their leaves, which they use as green feed, when they are about a foot high; and in this case they sow the seed very thick.

An easy way to have two growths of turneps in the same field, is to sow seed of the last gathering, and seed that is two years old; for this last is longer before it rises, than the new: and an advantage attending this method, is, that the turneps, by rising at different times, will have the better chance to escape the fly, or grub, which sometimes destroy them entirely: for it has been observed, that these flies often come suddenly in great swarms, and eat up the turneps as fast as they rise; and that they sometimes disappear as suddenly; so that the turneps which rise a few days after, in a neighbouring field, are not at all injured by them: consequently, when the turneps of the same field rise at different times, one or other may escape the ravage of these insects; for they destroy them only while in their seed leaf.

The worm to which turneps are very liable may be guarded against, or at least in a great measure, as Mr Lisle informs us, by liming the ground. This will also render them much sweeter than they would otherwise be; and we are of opinion that fresh slaked lime strewed over the ground when the turnep-seed is sown, will contribute greatly to preserve the young plants from the fly. It is to the worm lodged in the root of the turnep, perhaps engendered from the egg of the fly, that Mr. Lisle imputes the distemper or disease in turneps, which the Norfolk farmers call the hanbery; so named from a like distemper in a horse's heel. It is a watery excrescence, formed probably by this insect, in the same manner as galls are formed upon the leaves of the oak. In some years it takes off whole crops, and the turneps never thrive after it has begun to grow in them.

A gentleman, remarkable among many other good qualities, for several excellent improvements which he has made in agriculture, tried with success the following experiment, to preserve turneps from the fly, and the better to secure their growth. He sowed the seed in a nursery, where there was least danger of slugs or the fly, and where they might easily be watered in case of great drought, to make them grow the quicker. They remained in this nursery, till they were large enough to be transplanted. By this means he gained some weeks longer, to perfect his fallow, or give a thorough ploughing to ground which had borne a crop that season. He transplanted his turneps into the field, and by planting them regularly at due distances, greatly

greatly lessened the expence of hoeing; their regularity making it very easy to destroy the weeds from time to time, as they appeared.

In the second part of the Memoirs of the Society of Berne for the year 1762, the reverend Mr. Bertrand, not satisfied with even a scrupulous discharge of the duties of his clerical function, has instructed his parishioners, his country, and mankind, in the important subject of agriculture. The improving of light soils by the culture of turneps, is one of his objects: upon which he very judiciously observes, that though it be right to plough stiff lands before the winter, in order to their being mellowed by the frost; yet, as the finest and best parts of the soil will be in danger of being washed off, or carried down into the loose earth underneath, when this is done in a light ground, or in mould which has a sandy or gravelly bottom; it will be most adviseable here, to turn the stubble down immediately after the corn has been taken off, and then to sow turneps; because their spreading leaves will shelter and secure the fine mould upon the surface, and keep the land in good heart, whilst the earth will be loosened and divided by their roots, so that it will be rather fitter for a spring crop, than if it had lain uncultivated.

The chief use of turneps is, to feed cattle in the winter and spring, when there is a want of grass for their pasture. Cows, oxen, and hogs, are very fond of this food, which fattens them, and increases the milk of the former. Sheep too eat it readily, and thrive upon it, when they have been used to it early, but they do not relish it when it has not been offered them till they are grown old: however, if they are kept fasting two or three days, most of them take to it, and when they have once tasted it, they become very fond of, and feed kindly upon it. In some places, they feed their lambs with turneps till the middle of April, though they then begin to run up to feed. Farmers choose rather to do this, than to let them hurt their clover, saint-foin, lucern, &c. Some parboil them a little, at first, till their cattle, and particularly their sheep, are accustomed to them: but a lamb only three weeks old, will, after it has once eaten of this food, scoop out a raw turnep with great glee.

Turneps, if not clean eaten, and well cleared off the ground, may take root again, run to seed, and do great damage to the ensuing crop. Mr. Lisle instances it in a gentleman of Berkshire, who ploughed up a turnep field in the spring, and sowed it with peas: but the little dwarf turneps that were left behind, uneaten, notwithstanding his ploughing them up, took root again, run to seed in great quantities, and did much damage to his crop of peas.

The practice of turning a flock of sheep, at random, into a large field of turneps, is very bad: for they will then spoil more in a fortnight, than would keep them a whole winter. The best way, therefore, of feeding them with these roots, is, as Mr. Tull advises, and after him M. Duhamel, one or other of the three following methods, which are equally applicable to the drill, and to the common husbandry.

The first is, to portion out the turnep ground, by inclosing with hurdles so much only as the sheep can clear in one day; and so to advance the folds farther into the field every morning, until all be spent. But it is to be observed, that the sheep never eat them clean this way, but take only the leaves and the heart of the turnep: so that great part of them remains in the earth. It is true that these fragments, if left there, rot, and become a manure: but when they are wanted for the food of the flock, and are to that end pulled up with iron crooks or forks made for this purpose, the sheep do not relish, and consequently eat but little of these then dirty withered remains, tainted with their urine, dung, &c. nor can they nourish them so well as roots which are fresh and cleanly.

The second method differs from the former only in pulling up the turneps so far as they are hurdled off, before the sheep are turned in. They then eat them better, because the food is fresh and in good condition. Besides, as the whole turneps are pulled up more easily than their pieces can be, there is not such waste as in the other way. The turneps which grow next to the hurdles should be thrown towards the middle of the space hurdled off; because they will be less liable to be trampled upon and spoiled there, than nearer to the hurdle, where the sheep run about most, in search of means of escaping into the open field.

The third way is to pull up the turneps, and carry them into some other ground, and there spread them every day on a new place, where the sheep will eat them up clean. This is done when there is land not far off, which has more need of dung than that where the turneps grow. The expence of carrying the turneps is compensated by saving the price, or at least the carriage, and removing of the hurdles: only when the turneps are laid on a spot of grass, as is frequently done in wet weather, the benefit of the dung and urine of the sheep is lost.

This method is requisite when the field on which the turneps grow is wet; because, 1. The sheep would trample upon, and bury, part of the turneps, which would be lost. 2. In treading that wet earth, they would poach it, and render it unfit for corn. 3. By this means a field may be dunged, as we have just observed, which wants it more than that where the turneps grew. 4. This must necessarily be done, if wheat has been sown in the alleys between the rows of turneps, according to the principles of the new husbandry.

Turneps are always carried off the field, when they are intended to fatten the larger sorts of cattle: and they should be cut in pieces for them, lest they choke themselves with the whole ones. They are given morning and evening to stall-fed cattle, which in the intervals, eat likewise common fodder; but the turneps increase their appetite to such a degree, that a middle sized bullock, stalled for fattening, will consume near two hundred pounds weight of these roots in twenty-four hours, besides hay: whereas, if nothing but hay were given him, he would hardly eat half the quantity that he will with the turneps. A healthy bullock, in only good plight at the time of his beginning to be fed with turneps, will be very well fattened in three months.

Mr. Tull says he found by experience, that the best way of sowing turneps is in single rows, six feet asunder. He sowed them in double rows also at that distance, but they did not do well: and he likewise sowed them in single rows with intervals of only three feet. These last yielded a greater crop than a neighbouring field, which was sown and managed in the common way: but neither the single rows three feet asunder, nor the double rows with intermediate distances of six feet, yielded, says he, half so much, as the single rows six feet asunder: from whence he concludes, that it is best to leave a space of six feet between the rows; for that, if the alleys are well ploughed, these turneps will thrive wonderfully, even though no other moisture falls but the dew, which will sink into the earth to their roots.

However, notwithstanding Mr. Tull's experiment, M. Duhamel is for sowing turneps in double rows, if the intervals are of six feet; or if they are sown in single rows, he would have these rows be but four feet asunder, which is the space left between the rows of vines in Languedoc, and which is there ploughed with oxen.

Mr. Tull did for some time drill his turnep-seed upon six feet ridges, a single row upon the middle of each, and found in this way his crops were better, than on three feet ridges: but upon further experience, he found four feet ridges were more proper than six; and at the end of his table of the contents of the horse-hoeing husbandry, he writes as follows, viz.

“Those who have the engine (for drilling turnep-seed) are advised to sow turneps in single rows, on high four feet ridges; but when they are designed for seed, in six feet ridges.”

Turneps at their first coming up, are often destroyed by the fly, which eat off the young leaves, the two first or seed leaves in particular; which destroys the turneps. These flies come in such numbers, that large fields of turneps are frequently destroyed by them in a day or two; they come suddenly and go off in the same manner; for which reason Mr. Tull contrived to put a brass spout, or tube, to his turnep drill, which carries part of the seed so far behind the share, that it falls into the furrow after it is in part filled by the mould; so that the seed that drops first into the furrow lies as deep as the bottom, and what drops from the spout lies shallower. This may be improved, by making holes in the bottom of the spout, or by making the bottom of it with wire, like a screen; and then the seed will drop, and be covered, by the mould, at such different depths, that it will come up at more different times, than if the lower side of the spout is made solid, and discharges the seed

seed only at the end of it. By this means, and sowing mixed seed, half new, and half old, there will be many chances of its escaping the fly.

There is another advantage in drilling the seed in this manner, the plants may be thinned by hand, the person employed to thin them, taking hold of the strongest plants, with the fore finger and thumb of his left hand, may draw up the others with the other hand, without displacing, or much disturbing, the strong plants that are to remain; which is a safer way of thinning those plants than with a hand hoe, as Mr. Baker has experienced in thinning his turneps. In this way some more seed may be drilled upon an acre, than the common allowance of four ounces; for the more gradually the plants come up, they will rise the more distinctly, and at the greater distances in the row; and may be the more easily set out at the distances they are to remain for a crop.

If the land is in good heart, a proper soil for turneps, and drilled early, a foot asunder in the rows, is a proper distance for large turneps; but in different circumstances, ten inches distance is sufficient, and four feet intervals between the rows.

Some farmers draw up their turneps late in autumn, and lay them up in store against winter. In this way, the turneps are always ready; while those that remain in the field, are sometimes so much frozen, or covered with snow, that it is difficult to get them out of the ground when they are wanted.

There is a certain period in the growth of turneps, as in other plants, when they are in the greatest perfection, and most nourishing to cattle. Some who have occasion to buy turneps know this, and reckon that an acre of turneps before Christmas, will fatten as many sheep, as an acre and a half, of the same turneps, after Christmas. The principal reason why the farmers do not use them till winter and spring, has been the scarcity of food for their cattle at that time; but now they are not so much at a loss in that respect as formerly; as several plants lately introduced, do fully supply cattle in the room of turneps, as carrots, parsneps, cabbages of various kinds, and rape or cole seed.

An ounce of seed will sow as much land when drilled, as a pound will in the common way: and if care be taken to distribute only the necessary quantity, a great deal of trouble will be saved in the hoeing of the plants, afterwards, to thin them. But it is essential to observe, and we must again repeat it, that all roots, whether turneps, carrots, parsneps, parslly, or any other, always thrive best where there is a great depth of fine, light, well loosened mould. M. Duhamel trenched the whole of his kitchen-garden three feet deep: all his pot-herbs grew very fine, and his roots in particular were of a surprising size.

Mr. Tull, by drilling his turnep seeds alternately at different depths in the earth, was sure to succeed in one part or other, whether the season was wet or dry. If wet, the seed slightly covered sprouted first; and in dry seasons, that which lay deepest was the first that rose. By this means, and by mixing the seed, half new and half old, for the new always comes up soonest, he had four comings up, which, as he observes, gives the plants so many chances to escape the fly.

If one was sure of having rain immediately after the turneps are sown it would undoubtedly be right to sow them very shallow; but if no rain happens, they are best deeper in the earth, because they there meet with moisture sufficient to make them grow.

When the season has been so kindly that all the seeds have grown, and the plants have not suffered by the fly or other insects, they must be thinned early, that the ground may not be exhausted by such as are not intended to remain; for those that are left should be about a foot asunder.

When the turneps sown in drills thrive well, only each alternate alley need be hoed at one time, and the others a few days after; it being better to feed the plants gradually, by dividing the hoeings in this manner, than to give them a great deal of food at once, by hoeing all the alleys together, and afterwards leave them double the time without any culture at all. Another advantage attending this method is, that the plants will be the less liable to be killed by hot dry weather, and the less apt to be damaged by heavy rains. But it will not, indeed, so effectually destroy weeds, which ought always to be a principal object of the husbandman's care, and which ever is one of the chief in-

tentions of the New Husbandry. However, as all weeds are very apparent in the alleys, it is easy to extirpate them there; and as to those which may chance to be in the rows, the persons who thin the turneps may cut them up at the same time. He will there most easily distinguish the charlock from the turneps, especially when the leaves of these last are come to be about the breadth of a half crown.

All plants sown in single rows are greatly benefited by the alternate hoeing of the alleys between them: for, as M. Duhamel observes, 1. Four of these hoeings, which cost no more than two entire ones, are almost as beneficial to the plants as four complete hoeings. 2. A plant which finds a great deal of nourishment on one side, is the better able to thrive without receiving so much on the other. 3. If, in hoeing very near the plant, some of its roots are broken; those on the other side, not hoed, supply the wants of the plant, till the broken ones have made fresh shoots. 4. The horse-hoe may therefore be brought very near to the turneps, without fear of hurting them; provided it do not force them out of the earth. 5. When a farmer has a great quantity of turneps to hoe, they are sooner supplied by this culture, than they possibly could be if all the alleys were to be hoed.

A furrow should not be left open near the turneps, while they are young; because the earth about them would in that case become too dry: but there is no danger of this in the autumn, when they are grown strong, and the earth is moist. Neither is it advisable to leave a furrow open near them during the winter; because they would be in danger of being hurt by the frost.

When these plants are grown large, and their roots are consequently pretty well extended, the hoe-plough need not come quite so near them as at first: nor is it necessary to hoe them at all, till they are about the bigness of one's finger's end.

One alternate hoeing, or which is the same thing, two half hoeings, will be sufficient when the turneps are sown late. But when they are sown early, and many weeds grow, one hoeing will not be enough.

By following this culture, M. Duhamel has seen turneps which weighed from sixteen to nineteen pounds; and we may depend on their weighing one with another twelve pounds a-piece in a good soil, which is a vast produce from an acre of land. Mr. Miller says, that one acre of turneps, thus properly cultivated, will afford more feed for sheep or ewes in the winter, than fifty acres of the best pasture at that season.

Another vast advantage which attends the sowing of turneps in rows, is, that instead of occupying the whole ground when it should be sown with wheat, and sometimes even when it should be sown with spring-corn, as is frequently the case in the old way; they are no hindrance to either in the New Husbandry: for as alleys are in good tilth, three rows of corn may be sown, seven inches asunder, between the rows of turneps; and when these roots are pulled up, the ground where they grew is hoed, and becomes the alleys between the beds of corn.

The best turnep-seeds are obtained from the largest roots, which may be either transplanted for that purpose, or marked out in the field where they were sown. Those which are commonly sold in the shops, seldom produce the finest plants.

Experiments on Turneps cultivated according to the New Husbandry.

In 1754, M. de Chateaufieux sowed turneps on beds, in two rows. They suffered greatly for want of rain, and none of them grew to the size they would have done in a more favourable season. Some of them weighed eight pounds; but their general weight was from three to four.

In 1755, M. de Chateaufieux sowed some beds with one row, some with two, and others with three rows. They were afterwards thinned, so that the plants stood a foot asunder in the rows. Those sown in one row were the largest, and, in general, the most equal. Some of them weighed fourteen pounds, and the most of them from seven to eight. In the other rows, they did not weigh so much; but they were more numerous.

In consequence of these experiments, M. Duhamel, to whom they were communicated, makes the following striking calculation relative to the quantity of food which turneps will afford for cattle.

"Let a square whose side is 216 feet be formed into beds four feet wide, which is sufficient for one row of turneps. These will be 216 feet long, and consequently will contain that number of turneps, planted a foot asunder. These 216 multiplied by 54, the number of beds, will give 11664 turneps for the product of the square; and these multiplied by six, the supposed weight, of each turnep, will give 69,984 pounds for the weight of all the turneps, on this spot."

This may be looked upon as a very considerable crop; for it will be sufficient to stall-feed four bullocks during the three winter months, at the daily allowance of 200 pounds each: and yet there is reason to believe that the quantity will be doubled in a good year, as will be pretty evident to those who consider at how low a rate the medium weight of the turneps is here estimated.

In 1755, M. Duhamel sowed turneps in a field, on beds cultivated with the horse-hoe. They grew extremely fine; many of them being twenty-nine inches in circumference.

The following account of the advantages of the Drill Husbandry in the culture of Turneps, was sent by Mr. Willy, of South-Petherton, to the Society for the Encouragement of Arts, &c.

The generous method you have taken to promote useful knowledge must give every lover of his country the greatest pleasure, and incline him to do all in his power to increase it; it is with this view, and by the persuasion of many friends, I presume to lay before you the following lines, hoping they may give you some satisfaction in respect to the difference betwixt the Old and New Husbandry.

I began husbandry in the year 1742, had always an inclination to drilling, and was at much trouble and expence in getting one instrument after another made for the purpose; but was often disappointed, and for some years was forced to lay by the thoughts of it. About eight years since a gentleman lent me Mr. Tull's treatise; I then got some new instruments made, which sowed very regularly, and since that time have sowed all my corn in rows. Several closes I ploughed in six furrow ridges, and sowed with three rows of wheat, ploughing the intervals with a small-fall, drawn by one horse, and made it fit for wheat the next year; it generally took one third of the common quantity of seed, and in two years it yielded more than half as much again as the best crops in the common way did in one year; which, considering the small expence of seed and labour, was some advantage, though not very great; but then it left the ground in very good order for the next crop of spring corn. I kept one close, about two acres, four years to wheat in the same method: but the two last years did not answer to the two first, which makes me think Mr. Tull wrong, when he says, that plants of a different nature are nourished by the same sort of food. I could give an account of the exact quantity produced in each year, but it would be tedious: upon the whole, I believe this method of sowing wheat will be of no advantage except in poor strong clays, where I apprehend it must exceed all others. But there are a few inconveniences attending it; frequent ploughing the intervals is apt to make the wheat shoot fresh ears, which do not ripen with the others; and if any of the full ears when near ripe do but touch the fresh ploughed earth, ever so little wet will make them sprout, and these will injure the whole crop; and I find it impossible to keep all up, as the rows are at so great a distance. But my method of drilling in the open fields, and which I intend to follow, is to put five rows about eight inches apart, on a ridge about five feet in breadth. This takes but two-thirds of the seed sowed in the common way, and has always produced a better crop than the lands on each side of mine; this my neighbours are now convinced of, and several of them have drilled their wheat this season: our soil, for the most part, is a deep heavy sand.

I apprehend the principal advantage in drilling wheat is placing it at a proper depth, which I think is within two inches or thereabouts. I have observed, that the first motion of the wheat is by some roots, which in a little time run very deep; then it shoots up its blade; next it begins to form a head, about an inch under ground, from which come (very soon in a mild season) the second and third blades; and after that it begins to shoot fresh roots and branches from this same head, till in time it grows very large, especially in a fruitful soil and a good season; and it keeps on shooting fresh roots all the growing season: now if the corn is too deep, and a severe frost happens while

this head is forming, the plant is quite destroyed: but if it lies shallow, it shoots a new blade from the corn, and goes on in its operations as before; this was the case in 1763; a severe frost happened in the night of the thirteenth of February, which destroyed a good deal of wheat; so that some which lay deepest was ploughed up, and sown with other seed in the spring. Last year multitudes of the plants were killed in the same manner, and brought the crop very thin. In short, I am very certain, that whoever will make their observations will find that what I have said is the truth, That the shallowest corn will flourish sooner and better, and from thence will be led to see the advantage of drilling wheat.

But although I intend leaving off Mr. Tull's method of sowing wheat, yet I hope always to follow it in beans and turneps.

My beans I have sown these four years in double rows, about ten inches apart, and about two feet intervals. These I plough from and to the beans, when about six inches high; this is done with a little fall drawn by one horse, and will plough three acres in a day. This method hath succeeded so well, that many are come into it; although the farmers have always an aversion to new methods of managing; we sow but one-third of the seed, and have a much better crop, as is allowed by all.

As for turneps, all my neighbours will allow the drill to beat every thing. I sow a double row about eight inches wide, on a ridge about five feet, and though I did not sow this year till August, I have turneps two feet round, after wheat. I have given them but one ploughing as yet, besides hoeing them out at proper distances. I believe all will acknowledge I have double the crop in weight with any sown in the old way. I left four intervals unploughed in one close, to see the difference, and it is very surprising. One of my neighbours was prevailed on to sow a few rows in a piece he was sowing, and let my man plough them. The difference is so great that he is become an advocate for the drill husbandry; indeed I do believe that it will soon make its way through all the prejudices of the old farmers to the contrary; especially as we have a drill invented by an ingenious carpenter, with which several farmers have sown beans, pease, turneps, and wheat, and it answers exceedingly.

For these seventeen or eighteen years past, I have been striving to improve a crop of turneps. Before this, nothing was known or aimed at hereabouts, but sowing in the common way, one pound of seed in an acre; and then come thick, come thin, weeds and all grew together, till the sheep were turned into eat the crop as it was, and generally it was very poor.

The first improvement I made was by Ellis's direction, to drag them well with heavy harrows till they were got pretty thin, by which method I soon got better crops than any about me. But then I sowed double the quantity of seed, that I might have sufficient stock of plants for my after husbandry. My neighbours were soon convinced of the advantage of this, and followed my example, which is now the common practice. After this, finding the thinnest was best, I got some hoed; this I found still better, but very expensive, our people being not used to it. I tried Mr. Ellis's receipt to prevent the fly from destroying the young plants, but my ploughmen refused to sow the seed when mixed with sulphur. I then invented a long box, made full of holes, for the seed to fall through, and fastened it to two wheels so as to keep it above ground; this went so light that a boy could draw it, and sowed the seed very regularly. I shewed this to a friend of mine, (Mr. Joseph Pittfield, of Sidland in Dorset) who had one made immediately, and soon made an improvement on it, by having the holes made in rows about a foot asunder. Finding that the plants could be thinned and cleared at a much less expence, I followed this method of sowing for myself, as did some of my neighbours, for some years, and with a deal of satisfaction. A few years since, I was willing to try what stirring the ground deeper would do; and being resolved to try the drill husbandry in corn likewise, I had a small fall made, with which one horse will plough more than two acres in a day, first turning four or five inches deep from the plants, and then back to them again: we generally sow turneps after wheat, peas, and flax, and my method is to plough the ground into six furrow ridges, which with the open furrow makes about five feet in breadth. On such a ridge I sow (out of a short box) two rows of seed, though sometimes but one, and harrow it

in with a very light harrow. When they have four or five leaves I get them thinned, and give them a ploughing; and some time after, when they begin to kern, I have them thinned and cleaned again: and this is all the husbandry I have hitherto bestowed, and all I think is necessary, as we do not sow till late; the cost of which is about three shillings *per acre*.

I have sown some betwixt rows of beans, and have answered very well: when the beans were pulled I had the plants thinned and cleaned, and the earth ploughed between the rows.

The first I sowed last year was a small piece about half an acre, where hemp failed; I had the ground ridged up, and sowed with two rows of seed, and managed, as I said before: indeed the ground was dunged for the hemp. This was sown the latter end of July, but did not come up till the middle of August, for the want of rain. I pulled them before Christmas, and had fifteen putt loads, which every one will acknowledge to be a good crop; I believe double a common one; and though the rows were four feet apart, the leaves touched each other. The next I sowed was after wheat, about the middle of August: when the wheat was carried off, I had the ground ploughed into ridges where the old furrows were, and sowed one row of seed on each ridge: these cost but little in thinning and cleaning, and once ploughing, and were a very good crop: the largest of them was more than two feet round, and weighed above six pounds; indeed towards the hedges they were much smaller; I had fifteen putt loads per acre, though the ground had bore three crops since it was dunged. Another piece of two acres I sowed after peas, in double rows; but not till the latter end of August: I had the ground ridged up, and when the plants were fit, I had them thinned and cleaned as usual, but left four ridges for ploughing to see the difference; and truly it was surprising: those that were ploughed were more than three times as large, though they had all the same husbandry, except ploughing. They are as good a crop as the wheat stubble, though sown later, which makes me think double rows are best: our soil is mostly heavy good sand.

We have reserved for this article the following account of several very important experiments made by Mr. John Wynn Baker, under the direction of the Dublin Society, and published at their request, on the culture of cabbages, the turnep-cabbage, borecole, and turneps, by various methods, with an accurate state of the produce; and of the absolute and comparative advantages of each in feeding sheep and horned cattle. See the articles BORECOLE-CABBAGE, POTATOES, and TURNIP-CABBAGE.

In the month of March, 1763, two acres of ground, very highly manured with dung, were planted with potatoes, in the manner usually practised in this kingdom, with spade and shovel; in the beginning of November following the potatoes were dug. The land being low, and the winter very wet, it could not be ploughed until the beginning of March, 1764; when, it should be observed, the under stratum, upon which the dung and potatoes lay, rose at the ploughing as stubborn and strong as if no part of the ground had been tilled before: which proves the potatoe tillage, in the manner in which it is usually practised, not to be so beneficial to land as is generally imagined: the fact being, that only about thirty inches in every nine feet of the ground is tilled at all.

In the night of the 10th, and on the 11th and 12th, of May following, there was very fine rain; this rain enabled me, on the 12th, to reduce this stubborn ground pretty fine by the harrow.

In the month of March, 1763, the other part of this field was broke for fallow (an improper time to break fallows; but, my entrance upon the farm in that month was the cause); in June following it was cross ploughed, which brought it into very large lumps: from the position this ploughing threw them into, they were exposed, in a greater number of points, to the influence of the weather, than the ground would have been, had the second ploughing been in the same direction as the first.

In this situation I left this fallow till the March following; when it was ploughed for the third time, with the potatoe ground, in the same direction as the first; by this third ploughing this land was brought into an exceeding fine tilth.

This benefit arose from the ground not having been harrowed at all. This is something contrary to the common mode of culture; but was adapted to the species of

ground I had to work upon, which I shall describe hereafter.

What the harrow would have done in part towards reducing it after the second ploughing, was completely effected by the influence of the summer and winter; the first destroyed all the weeds and couch-grass (with the latter of which the ground abounded); and the lumps exfoliating by the operation of the winter, by degrees fell into fine mould; whereas, had it been harrowed before the winter, the rains would have run the smaller particles together, so as to have given a great adhesion to the ground before the spring, abstracted from the like mischief, which the cattle would have done by drawing the harrow. In the beginning of June, I ploughed this part of the field a fourth time, and the potatoe ground a second; by which ploughing I laid the whole field into ridges of five feet width, except about half an acre, which I reserved for other purposes, as will appear hereafter.

In this field I had two parcels of manure ready prepared for it. One consisted of earth raised from the headland; mixed with lime, which lay about twelve months, having been in that time twice turned.

The other parcel consisted of the like earth, and lime, mixed in the same manner, after which I mixed dung with it, *stratum super stratum*, which lay about two months, when I turned it: after which it lay about two months longer: by this stirring, the ingredients, of which this parcel was composed, were perfectly incorporated with each other; and a new putrefactive fermentation was excited in it, which perfectly prepared it for the land; and all the earth was so fully impregnated with the juices of the dung, that it was very little, if any thing, inferior to the dung: whereas, when dung lies by itself, great part of the volatile saline particles are lost, as soon as the fermentation begins: some fly off in vapours, and others run off with the juices of the dung and rain which fall upon it.

When I have mixed dung and earth, in the manner already described, I always once or twice, when the season affords it, cover the compost with a large quantity of snow, or ice; which, upon dissolving in its passage through the whole, causeth the earth to be finely impregnated by the dung. Snow, by being gathered with shovels or rolled together in balls, is longer dissolving than ice, and therefore I prefer it, unless it be ice of water which happens to be the soakage of a dung-yard, such ice being always replete with food for vegetables.

The land being now, in June, in five feet ridges, in the manner already described, I began to draw out my compost, which I disposed in the following manner: I drove the cars up every alternate ridge, and upon each of them dropped the compost, till I had manured about three acres of the fallow ground; then, with shovels, I divided this manure, as equally as could be, in every furrow, which was readily done, from the convenient manner in which it was deposited.

In the same manner I put out the other parcel of manure (which, it may be remembered, I before said consisted of lime and earth) upon an acre and a half of the potatoe ground; and on a part of the fallow ground, where no compost or other manure had been put, and spread in the same manner as the former.

The whole field being thus manured, I ploughed it again, which was the fifth ploughing of the fallow, and third of the potatoe ground; by this ploughing I altered the position of every ridge, by laying the middle of each exactly over the manure; consequently the furrows were made, where the middle of the ridges was before.

The half-acre before-mentioned I manured with at least double the proportion of compost, which was allowed to the other part of the fallow; and as it was flat, it was necessary to manure every part of it, being intended for turneps, to be sown in the promiscuous way.

To this piece of ground I gave a sixth ploughing, as it could not have the benefit of the horse-hoe, when cropped; and therefore I thought it necessary to reduce it as fine as possible, in order to give the broad cast crop of turneps every advantage I could.

The field being prepared in the manner already described, I proceeded to crop the land in the following order.

July the sixth and seventh, I planted one row of cabbage plants upon the middle of every ridge, of about an acre of the fallow ground, the plants in the rows two feet from each other. In like manner I planted about half an acre with turnep-cabbage plants.

Hence

Hence it may be observed, that the plants were in rows five feet asunder, and two feet asunder in the rows.

This business ought to have been done, at least, a month sooner; but I could not get the ground ready in due time; however, the success of these crops may encourage others not to give up their expectations, although they may happen to be as late as I was, which must frequently occur in the course of business; though this is always to be avoided as much as possible.

I never begin to put my plants out till about six o'clock in an evening, unless I can be ready for planting in a rainy day, which is always to be preferred; in the other case I always keep the men at this work as long as they can see. If it can be done in, or immediately after rain, that will save the expence of watering the plants, which is an object worthy of attention in a large work of this kind; besides the circumstances of the plants succeeding much better.

On Friday the 6th of July we had fine rain, and on the seventh I finished. On the eleventh we had some light showers, and on the twelfth fine rain, which secured life to my plants; but they began to look sickly before the twelfth; three of the intervening days having been hot and dry.

On the seventh I also planted three of the five-foot ridges, the plants in the rows two feet asunder.

Be it observed, that, for the obtaining large cabbages of the spring sowing, the seed ought to be sown early in March; and, if once planted out before the final planting them, it will be an advantage to the crop; the case is the same with respect to turnep-cabbage; but it is more essentially necessary in the common way of raising cabbages; for, otherwise, they will run into long shanks, and will not cabbage well; most gardeners allow their plants too little room: this is not the case here; my cabbage and turnep-cabbage seeds were not sown till the twenty-sixth of March, and I was so much hurried, that I never had time to get them planted out before the final planting, save about three thousand plants; and yet they are all very short in their shanks. This may justly be attributed to the manner of disposing them, and the culture they receive in this husbandry.

Here I cannot omit to remark one circumstance, for the observation of gentlemen and farmers who may adopt this husbandry, viz. That I have not one cabbage this year of the sort I intended to have; what I have being chiefly sugar-loaf, the seedman having deceived me; and, if I had not happened to have about an ounce of turnep-cabbage seed by me four years old, I should not have had one plant of that kind this year; the seed, which I bought in Dublin for it, turning out a poor, small, wretched cabbage.

I shall now proceed to make my report of the farther treatment and success of these crops, before I proceed to the turneps, &c.

Upon the 17th of August, I horse-hoed my cabbage, turnep-cabbage, and borecole, for the first time, by taking off, at one furrow of the plough, only one side of each ridge, close to the plants: thus they remained till the 25th, when I ran the plough in the same furrow; by which, with the first furrow, I ploughed about twenty-one inches deep. This being finished, I immediately returned the earth back to the plants; this afforded them fresh nourishment; and in order to give their roots time to penetrate this fresh earth, which, by the horse-hoeing, was become very fine mould, I let them remain in this state till the twelfth of September; when I horse-hoed them again, by taking off the other side of every ridge; and, on the twentieth, deepened the furrow in the same manner as the former, and immediately returned the mould back to the plants; and, on the eighteenth of October, threw up a small furrow on each side of every ridge, which finished the culture of these crops, and restored the ridges to the form in which they were when the plants were put out upon them.

The plants all grew very luxuriantly; and, in the hottest weather were infinitely more brittle in their leaves, than any I could see in the gardens of my acquaintance: which is a certain indication of health in this kind of plants.

The horse-hoeing was so essentially destructive to weeds, that it cost me but four-pence to weed these crops, which occupied about an acre and three quarters of ground.

The repeated horse-hoeings cost me two shillings and

four-pence an acre, for workmen's wages, exclusive of horses, of which I used two, and sometimes three.

December the 8th, I cut one row of the cabbages; they beginning to decay, which is indicated by their bursting. The number was two hundred and fifty-eight, and they weighed sixteen hundred-weight; three quarters, and twenty-one pounds; i. e. one thousand eight hundred and ninety-seven pounds: which, at an average, is seven pounds and near six ounces for each cabbage.

The produce upon an acre, on weighing this row, which was five hundred and sixteen feet long, amounted to twenty-three tons, four hundred, two quarters and fourteen pounds; i. e. fifty-two thousand and thirty-eight pounds: which is, at least, from ten to seventeen tons less, as I compute, than the produce would have been upon an acre, had I obtained the sort I intended to have; which was the large, late, Dutch cabbage. However, such a produce as was here obtained, will be an ample reward for the labour any one may bestow in this husbandry, as will appear when I shall come presently to shew how many cattle twenty-three tons will maintain.

December the 17th, I took up one row of the turnep-cabbages, which were in number two hundred and forty-nine, they weighed eighteen hundred weight, and fifteen pounds; i. e. two thousand and thirty-one pounds, after chopping off the roots and stalks below the turnep, which ought not to be weighed, as being no part of the food for sheep or cattle: the weight of these plants, one with another, was something more than eight pounds and two ounces; some few weighed fourteen or fifteen pounds. The produce upon an acre, on weighing this row, which was four hundred and ninety-eight feet long, amounted, at the same proportion, to twenty-five tons, fifteen hundred, three quarters and seven pounds; i. e. fifty-seven thousand seven hundred and sixty-one pounds.

This crop was much greater than ever I had before; and, from some observations I have made this year, I am inclined to believe, their culture may be improved to a produce of ten tons more upon an acre: but, abstracted from that, the produce already obtained is more valuable than any crop I know of, for they are invincible by the winter, either in or out of the ground. The great distress of even the careful farmer is in the months of March and April, for his ewes and lambs, when turneps are gone, or are but very indifferent food, and all other green winter-food is exhausted.

Feeding ewes upon dry hay affords but little milk to their lambs; add to that, hay is not made without great expence and anxiety, over and above the rent of the land; for really, where the farmer is so unfortunate as to have his hay upon hand in wet weather, it is a business which will exercise his patience, no less than it will consume his money.

One superior excellence in these plants is, that sheep will prefer them to turneps: another is, that they are a firmer and more substantial food; and, to ascertain their firmness in texture, and quality in keeping after being drawn, I have kept them near twelve months exposed to the open air, to the extremes of heat and cold, and, after that, they were found, save some few.

If any person who may cultivate this plant for sheep, should keep a large flock, he may let the plants remain in the ground till he wants them; in that case he may turn the sheep into the field, where they will eat them quite down to the stems; and, as the plants stand naturally above the ground, and by my manner of cultivating them, they are still higher, by being placed on the tops of the ridges, the sheep cannot dirty them, as they do turneps when turned into the crops; add to this, that when the sheep have eaten all the leaves, and begin to eat the butts or turneps of this plant, they will not rot as turneps do, when wounded; but will certainly keep sound, even after that, for six weeks or two months: nay, yesterday, the fifteenth of February, upon dressing some of them for seed, I found some, which had been accidentally wounded by cows, upwards of three months ago, perfectly sound, notwithstanding the great quantity of rain which had fallen upon them.

When the leaves are wanted early in the winter for sheep, or black cattle, or, the land is wanting for any other crop; in either case the plants may be taken up, the leaves taken off, and the turneps thrown any where upon a piece of sound dry grass ground, where they will keep, and

and be ready for sheep in the spring : but this work is attended with some trouble and expence, the roots being very firm in the ground.

The latter end of December, and in January, the plants began to throw out fresh shoots, which are to produce the seed : and, when they began to do so, all the leaves of the preceding year fall off, being first greatly decayed ; and as the leaves, in October and November, are really very numerous, and afford a large quantity of food for cattle, is well worth the trouble to take them off before they begin to decay ; and when this is judiciously done, the trouble is very little.

The method which I would recommend is, that two men be sent into the field, each taking one row before him, and, as he pulls off the leaves, laying them upon the ridge between the turneps ; when these two ridges are finished, or as many as may be thought necessary, let one horse, or more, be brought with a pair of cleaves upon his back ; let him be placed in the furrow, between the two rows ; and as he passes along, the two men fill the cleaves, which may be most conveniently done, from such a disposition of the business, without any injury to the turneps in the rows.

Where extensive crops of these plants are raised, it will be very useful to collect all the roots, whether left in the field by sheep, or otherwise separated, and mix them with heaps of earth, where a putrefactive fermentation will shortly commence, by which the earth will be strongly impregnated with volatile and fixed salts, and will then be an excellent manure ; and, indeed, all succulent vegetables will contribute to the same end, under the like treatment.

I must beg leave in this place just to mention, for the consideration of the society, and which I earnestly recommend to be tried by mariners, another use, to which, I think, this plant may be converted, which is still of more importance than any which I have yet named.

We lose more men in the beginning of a war in the navy, as I have been informed by the navy-surgeons, by the scurvy, than by the enemy, which is attributed to their sudden change of food. From fresh provisions and vegetables on shore, the men are at once brought to salt provisions.

The turnep of this plant, I am inclined to believe, would keep three or four months on ship-board, perhaps longer ; but the navy-surgeons have told me, that if it would keep six weeks, it would save the lives of many men. Something has been said on this subject before, in a pamphlet intitled, *Hints on Husbandry*, in a letter to the Dublin society, printed by Flinn, in Castle-street.

I cannot dismiss this subject, without earnestly recommending the culture of this plant to the attention of the farmer, particularly to such as keep any stock ; and, although the plant is very little known, except in the gardens of the curious, yet, whoever will cultivate it in the way I have here set forth, will find himself amply repaid for his labour ; for how comfortable is it for a man's mind to be at ease about his stock, in the months of scarcity ? Whereas I have every year observed, that the farmer's stock, particularly ewes and lambs, are turned into his meadows to live upon the springing grafs, to the irrecoverable injury of the hay harvest ; as frequently have I seen them upon young clover, to the manifest injury of that crop.

I could enlarge greatly upon these injudicious practices ; but in brief I shall only say, that if I shall live to see the culture of this plant generally established, I shall have the comfortable reward of knowing that I have been useful to mankind ; a circumstance which will be more grateful to me, than if I had conquered a nabob, or extirpated an Indian nation.

December the eighteenth, I cut two perches in length of one of the rows of borecole, which contained twenty-one plants ; they weighed one hundred and eighteen pounds, which is very near five pounds ten ounces for each plant : but I am inclined to believe, that these plants will succeed as well, if they are planted only eighteen inches asunder in the rows. However, at the above proportion, there would be seventeen tons and fourteen hundred upon an acre. But, if the produce would be the same, were the plants only eighteen inches asunder, in that case an acre would produce, by this culture, above twenty-three tons and twelve hundred.

This plant is well worthy the farmers or graziers attention, for, as fast as it is cut, it will again, in about a

month or six weeks, afford another crop : I have been cutting these plants for my family-use ever since the middle of August last ; I believe some of them have been cut three times ; and they are excellent for the table. For feeding cattle and sheep they are highly valuable, as no frost will injure them ; and, although the first crop amounts not to as many pounds upon any given quantity of ground as the others, yet the succeeding crops will, I believe, make their produce nearly, or quite, of equal weight with any other of the cabbage kind. But I must not omit to observe, that as these plants afford only open leaves, and many of them very small, there will be a little more trouble in collecting and carrying them to the sheep and cattle, than there will be with the other kinds.

It may not be improper to observe, likewise, that upon the approach of the spring, when they begin to throw out their spring-shoots for seed, if the large leaves have not been taken off for winter use, they will decay and fall off in the same manner as the turnep-cabbage leaves have already been described to do.

I have not yet tried it, but I believe that the best way of using this plant, would be to allot one whole field to the culture of it, proportioned in size to the stock intended to consume the produce ; and in September or October, to turn the ewes into the field for a few hours, morning and evening, and then lodge them on any piece of grafs or fallow, which may want improvement, to which they will greatly contribute by emptying themselves upon it ; and thus continue turning them into the borecole field, till they have eat all the luxuriant leaves ; then let the plants rest a month, and there will be another crop. By having two small fields under this crop, a flock of store-sheep might be maintained a whole winter at a very small expence ; for whilst the produce of one field would be consuming, the other would be coming on.

This method occurred to me from an accident, which attended my borecole this year. My cows got into the field, and presently devoured some of the leaves of the plants ; these plants have engaged my attention ever since, and I have the pleasure to see them again in a very luxuriant state.

If any person should be able to put this scheme in practice before I can accomplish it, I recommend it to them, not to let the sheep pasture so long upon the crop, as to wound the stalks for want of leaves ; as too great an injury to the stalks may check the succeeding growth ; which injury, I am inclined to believe, will not happen to the plants, at least not in so great a degree, whilst they have a sufficient quantity of leaves.

It doubtless will be observed, that I confine this scheme to ewes or store-sheep : my reason for that is, that fat sheep should always have as much food before them, as they may choose to eat ; add to this, that sheep, when they are fat, are more subject to be lame, than store-sheep, to which ploughed ground will greatly contribute.

We shall now return to the state of the field, in which it was after being manured, and ploughed into small ridges of five feet breadth, with the compost under them in the fallow part, and part of the fallow with the lime and earth, and the potatoe ground aided with the lime.

Upon the fourteenth of July, I sowed with my drill plough what remained of the ridges of the fallow manured with the compost. That part of the fallow which was manured with the lime and earth, and that part of the potatoe ground which was before described to be in ridges, with turneps, and that part of the fallow before described to be flat, and manured with a double proportion of the compost, I sowed in the promiscuous way with turneps also.

The drilled turneps filled only one row along the middle of each ridge.

When the drilled turneps were about three inches high, I thinned them by hand, as being much preferable, and more expeditious than any instrument, intending to have them singled out to about one foot asunder in the rows : but, it being so new a work, the women could not be brought to do it effectually at once, they apprehending, that the whole crop would be lost, and urging, that they were sure there was already too much ground allowed to one row : under these circumstances, I could not get this work done quite to my mind this year, as I had, besides this field, two other sown in the same way, amounting in all to about twelve acres.

My turneps should have been sown at least three weeks earlier ; but the immoderate and continual rains of the preceding

preceding winter, involved me so much with my spring sowing, that I could not accomplish my turnep-sowing earlier.

The turneps, after being thinned, received the horse-hoeings much about the same time and distances as the cabbages; with this difference only, that I deepened the furrows of but a few ridges in another field by a second ploughing in the same furrow, which I did not find to benefit the turneps much: for, if the ground be well prepared before the sowing, the depth of one furrow will be enough for turneps, provided that be deep and bold.

Thinning the turneps in drills by hand cost me eight-pence an acre; weeding of them cost me four-pence; and the repeated horse-hoeings about fourteen-pence an acre for workmen's wages, exclusive of the horses, of which I generally used two, except in very hot days, and then I found three were necessary.

The broad-cast turneps were carefully thinned by hand, when they were about two inches high; which the women did with more courage than they did the drills; and sometime afterwards, I hand-hoed them once, and weeded them twice.

Thinning them by hand cost me four shillings. Hoeing them afterwards cost eight shillings, and weeding them cost me two shillings and four-pence. They were scarcely half an acre; this expence being therefore doubled, they cost me at the rate of twenty-eight shillings and eight-pence an acre, over and above the extraordinary ploughing, and double proportion of manure.

In truth, this crop greatly exceeded my expectations, being by far the best I ever had in the broad-cast way; but I attribute their success wholly to the thinning them by hand; for two, three, four, and often more, turneps will be so united and interwoven, that it would be impossible for the most dexterous hoer to separate them; whereas the fingers and thumb will preserve the master plant, whilst the others are most conveniently drawn from it by the other hand of the person employed: add to this, that there is no labour in which we are more liable to be deceived, than turnep-hoeing.

In one of my other turnep fields I manured about an acre of ground with shell-marle, which I sowed in drills with turneps in the same manner as the former, on the sixteenth of July.

In the same field, I manured about half an acre with the native earth, which had been exposed to the weather for upwards of two years, which I sowed likewise in drills with turneps on the sixteenth of July.

Both these crops were thinned by hand, and horse-hoed, in the same manner as the former.

Thus we have five experiments in the drill way upon turneps, with different manure. One with the compost already described, one with lime, one on potatoe ground, aided with lime, one with shell-marle, and one with native earth; and also one in the broad-cast way, with a double proportion of the compost, and an extraordinary ploughing.

The principal point to be determined by these experiments is, whether sowing turneps in drills, or the broad-cast way, will afford the heaviest crop: but the trials with the different manures will, I hope, be also useful.

The produce of drilled and broad-cast Turneps compared.

December the seventeenth, I measured out three square perches of the best of the broad-cast turneps, and also three square perches of the drilled; and the produce was as follows:

The three perches of the broad-cast turneps weighed sixteen hundred weight and one quarter, *i. e.* one thousand eight hundred and twenty pounds; which, at the same proportion, amounts, upon an acre to forty-three tons, five hundred weight, three quarters and six pounds; *i. e.* ninety-six thousand nine hundred and seventy pounds.

The three perches of drilled turneps weighed seventeen hundred weight, two quarters, and twenty-one pounds, *i. e.* one thousand nine hundred and eighty-one pounds; which, at the same proportion, amounts upon an acre to forty-seven tons, two hundred, three quarters, and two pounds, *i. e.* one hundred and five thousand five hundred and ninety pounds.

	T.	C.	Q.	lb.	Pounds
An acre of drilled turneps	47	2	3	2	or 105520
An acre of broad-cast ditto	43	5	3	6	or 96970
In favour of the drilled	3	16	3	14	9650

Thus, we see, that, notwithstanding the extraordinary proportion of manure, and the extraordinary ploughing, which was afforded to the broad-cast turneps, the drilled crop, with intervals of five feet, produced the greatest quantity upon an acre, by three tons, sixteen hundred, three quarters and fourteen pounds weight.

The drilled turneps in my other fields were very large, regular, and even crops, as many gentlemen saw during their growth.

Those sown on the acre manured with the shell-marle were very near as good as the rest—those sown on the potatoe ground were not near so large, but were regular—those sown in that part of the fallow-ground which was limed, were very poor crops—and those sown on the ground manured with the native earth were miserable.

The crops in my other fields were all treated in the same manner as that already described; except, that the fallows were broke in September, 1763, instead of March, 1763.

It now remains to describe the nature and quality of the land, and then to draw conclusions from the various experiments.

The land lies upon a lime-stone quarry, which is very near the surface; and is, naturally, a very strong and stubborn soil, with an infinite number of loose lime-stones in it. With dry winds, or a parching sun, the ground unites, and is as hard as bricks; moderately wet, it is reducible by instruments; but, when thorough wet, it runs together, and is like brick-clay when tempered. This, I repeat it, is the natural quality of the land, and is what the writers would call a barren, grey, stiff earth, but is not quite a clay.

I have found repeated tillage, when the land is in a proper state of moisture, will reduce it, and divest it of its natural adhesion. Tillage and manure together render it capable of producing any thing; as, I believe, such agents will do upon any land, provided it can be kept moderately dry. The fields, which I had under turneps and cabbages, have been in appearance all the summer a fine loam, and really bore the complexion of very fine land, abstracted from the rich appearance of the crops.

I recommend to the practice of all persons, who may have such land as this to work upon, never to harrow the fallows before winter, but as early as may be in the spring, and during the working the fallow in the summer, but not to leave more than one day's ploughing unharrowed, but rather harrow in the evening what has been ploughed in the morning, and then the harrow will reduce it; but if the ploughing is continued for two days, without any harrowing, the harrow will have no more effect upon the land, than it would have upon bricks, unless it be moistened with rain; in which case it will be reducible, as, it may be remembered, I described the potatoe ground to have been reduced, after rain which fell on the twelfth of May.

Conclusions to be drawn from the preceding Experiments.

These experiments prove gardens to be no more than farms in miniature, under an extravagant expence of culture; since we can with the plough raise more tons of the larger kinds of garden vegetables for twenty shillings, than by the spade for as many pounds: and, indeed, I do not see why most of the small ones may not be raised in the same way.

They also prove, that it is profitable for the farmer to raise different species of cabbage for his cattle in winter; and I have it in contemplation to try them for summer use also. However, for the winter, it is an object of great importance, not only to the well feeding of cattle, but to the saving an infinite consumption of hay, which by this husbandry may, at least, be pastured in summer.

The experiments on the turneps prove, first, that it is more profitable to raise them in drills than in broad-cast: secondly, that the culture is a great deal cheaper: thirdly, that less manure will produce a larger crop, than in broad-cast, provided it be disposed the same way as mine was; fourthly, practice shews the expence of drawing the drilled turnips for sheep or black cattle, to be at least two-thirds less, than drawing the broad-cast: fifthly, in the drill way not a turnep need be left upon the ground; whereas, in the broad-cast way, the leaving many is unavoidable, to the great annoyance of the succeeding crop, particularly if that shall be barley: and sixthly, that the land is left after drilled turneps, in a much higher state of preparation for a succeeding crop, than it can possibly be in the broad-cast way.

To these advantages another may be added, which I find very material, viz. that of slicing them for black cattle, which is highly necessary, even when they are small, nay more so, for cattle are sometimes choaked with a small turnep. A man will be near as long slicing a small turnep as a large one, and will make no dispatch; whereas, my men and boys now slice for me every evening about nine hundred weight in an hour; which is a task upon them after night-fall, except on Saturday nights; then they slice double the quantity.

As it seems to be a paradox to say a man will slice a large turnep as soon as a small one, it may be proper to explain it to the reader. The man is in danger of cutting his hand when he is slicing a small turnep; but in no such danger with a large one: and, besides that, one slice of a large one, contains more food, than two or three whole small ones.

The experiments prove, that the potatoe tillage, in the manner it is now generally practised, is not so beneficial an improvement of land, at least not of strong ground, as is generally imagined: although there is a greater consumption of dung than in any other husbandry.

The experiment with the lime upon the fallow ground, proves lime to be an insufficient manure, for the high improvement of lime-stone ground. There are so many advocates for lime as a manure that it is adventurous to say any thing against it; but, I hope, the reader will observe, that I pronounce upon it, as being insufficient, "for the high improvement of lime-stone ground." I have tried lime in another field of my farm, in which I sowed wheat, and my success was no better in that than in my turneps; and I earnestly recommend it to every improver, who may have favourable opportunities of getting lime, that he try it upon a small patch, before he launches into a large expence for it; such caution may perhaps save him money. This advice arises from practice; for I imprudently burnt a large quantity of lime at an expence of near an hundred pounds, and, I can truly say, I have not received in benefit as many shillings.

The experiment of the shell-marle, proves that to be a very high and excellent manure; for, as it will produce turneps upon poor ground, it may be safely relied upon for any other crop.

The native earth proves to be perfectly insufficient for turneps; though it certainly mends the ground a little, besides that it adds to a shallow soil.

Accidents and Distempers.

Turneps are subject to be destroyed by the fly. In an orchard I sowed two acres with turnep-seed in drills in July last. They were invaded by the fly; I had a contest with them for a fortnight, and at last conquered them, with a loss of only four or five perches of my turneps, which happened where there were most trees. Every morning before the dew was off, I had the rows dashed with lime, which was flaked every day on purpose. This lime adhered so closely to the leaves, when they were wet with the dew, that it defended the upper sides from injury: then I found the flies began on the under side of the leaves, which I had never seen them do before; however, upon this, I was obliged to have the dust thrown very low; and, whilst the plants were wet, a great deal adhered to them, even on the under sides:—thus I saved my turneps, which were as fine a crop as any I had, save the four or five perches before-mentioned.

The upper side of the turnep leaf, in its infant state, is very smooth, and on that part the flies always lodge, unless they are interrupted; in that case they will destroy the plants by wounding the under side, which is not so inviting to the insect as the upper, it being a little rough, though not enough to protect it from them.

The greatest inconvenience I found in this work was, that every little shower of rain washed off all the lime, and then the work was to begin again; sometimes I repeated it three times a day: however, it will be found to answer well, but it requires to be done with care.

I have, by the same method, saved lucern, which is also subject to be destroyed by the fly, upon its first coming up.

I discovered last season three distinct species of the turnep fly (if I may so call it); one of them is black; it seems to hop like a flea, and resembles it exactly. The second is a small degree larger, and very distinguishably has wings,

upon which are two small white specks; and the insect is of an oval form. The third is like a domestic fly, but not by a fourth part so large.

The turnep-cabbage is subject to the rust, or mildew. In my orchard I had some plants put out, at different distances for experiments; they grew very well for a time, but they were all infected with the rust, and those nearest the trees suffered most. In my field I could find but three, which were injured by this distemper. This seems to prove that they require an open exposure; and therefore they better suit the purpose for which I have recommended them.

Turneps, cabbages, turnep-cabbages, and boorcole, are food for black cattle and sheep.

A sheep, I find, will consume about twenty pounds of turneps in twenty-four hours, provided they are allowed as many as they can eat, which should always be allowed to fat sheep; but as sheep vary in size, so I presume will they consume more or less food.

An acre of turneps, of forty-seven tons to an acre, will maintain one hundred sheep fifty-two days, allowing each sheep twenty pounds a day. My sheep weigh about twenty pounds a quarter.

In the month of November last, I gave my sheep access to some pea-ricks, which I had erected on purpose for them, of which they eat with great eagerness; but I find they affect them in the same manner as they do horses, when given to them new; for the sheep, I apprehend, from violent colics, which I conceive the peas gave them, were seized with strong convulsions; and in this way I lost six of them, in a few days before I considered what could be the cause: but having examined the intestines of every one of them, and finding no symptoms of any other disease, I was led to draw the following conclusion; and what seems to confirm my opinion is, that I have not lost one since I took them from the peas. If other persons have not met with the like accident, who have fed their sheep with new peas, it should seem that turneps and peas together do not agree with sheep. However, that is a fact which I shall soon be able to determine, for I shall admit the sheep to the peas again to-morrow, which will be the twentieth of February; a season in which it is imagined we may safely give peas of the preceding year to horses, and therefore, I conceive there can be no danger in giving them to the sheep: but, if they should be affected as they were before, I think there cannot remain a doubt, that the peas and turneps disagree in their stomachs. And here I shall leave a space to add to my report afterwards.

Now, the fifteenth of March, the sheep have been ever since at the peas, and I have not lost one.

Of cabbage, and turnep-cabbage, a sheep, of about twenty pounds a quarter, will consume about fifteen pounds a day. An acre, at that rate, will maintain one hundred sheep about thirty-four days. The cabbage, and turnep-cabbage, are a firmer and more substantial food than turneps.

I have fed a cow this winter upon turneps, and I have now two bullocks which are stall-feeding upon turneps also. It is computed that they weigh between four and five hundred weight each; and I find by experiment, that each of them eat about two hundred and sixteen pounds in twenty-four hours; which is, therefore, about half their own beef-weight; from hence we may, with reason, imagine a beast will eat every day of turneps, at stall-feeding, about fifty-six pounds for every hundred weight of beef he may contain.

One of the bullocks was put up miserably poor from the plough, for an experiment, on the fourteenth of December; he took kindly to the turneps; and on the sixteenth I began to give him with his turneps, pea-flower, to the amount of eight pounds every day; and I find he is greatly improved, but he will not be beef; though I am very inclinable to think, that if he had been put up six weeks sooner, in April, he would have been good beef. This experiment I shall repeat next year. What induced me to mention it here is, that some other persons may perhaps try it next winter, and, if they should, I shall be much obliged by their report of the effect. I am led to believe, that bullocks may be profitably fed with peas, because horses and pigs thrive very fast upon them.

When the cattle are first put to turneps they dung but little, the turneps going off chiefly by urine, the quantity of which is really incredible; but, after some time, they dung more; and, from a whitish colour, the dung resumes the natural colour, and is of the common firmness. I al-

low each of the cattle seven pounds of hay every day, and I do not find that they eat fewer turneps on that account; the reason, I believe, is, that the hay makes them more eager for the turneps. They refuse water.

To each of my cows, and store cattle, I allow seventy-two pounds of turneps a day, and a little straw, thirty-six pounds being what I find a moderate sized beast will eat at a meal. To my plough bullocks I allow the same quantity of turneps, with as much straw as they can eat; but I forbid them having the turneps till they have been unyoked about an hour, and after they have eat some straw; as I conceive the turneps are too cold for them immediately after their labour.

I have lately confined a milch cow four days, and fed her with turneps, and could find no disagreeable flavour in her milk from that food, though I have often heard turneps complained of as giving a bad taste to the milk when cows are fed with them. Query, whether it might not arise from the leaves of trees falling upon the turneps? Leaves of trees always spoil the milk when cows eat them. Here follow

Calculations upon the feeding Black-Cattle with Turneps and Cabbages.

Suppose four cows or bullocks, of four hundred weight each to be stall-fed upon turneps, allowing each beast two hundred and sixteen pounds a day, an acre of forty-seven tons would maintain them one hundred and twenty-one days. Indeed a larger stock should be put up for heavier cattle, as the turneps will not keep so long.

Suppose ten dairy cows to be maintained upon turneps, allowing each cow seventy-two pounds of turneps a day; at this rate, an acre of forty-seven tons will keep them one hundred and forty-seven days. All cattle, fed in this manner, should have about seven pounds of hay a day allowed to each.

The fat cattle eat about one hundred and a half of cabbages a day; therefore an acre of twenty-three tons will, at that rate, maintain four bullocks, of four hundred weight each, seventy-six days.

When fed with cabbages, they dung more, and make less urine, than when they are fed with turneps, and will drink a little water.

Hence I am induced to believe, that cabbages are a better food for cattle than turneps. I am fully persuaded near as many tons may be raised upon an acre, with proper seed and good management; but they will cost five or six shillings an acre more.

There remains one general observation to be made, and which I imagined contributed greatly to the success of the abovementioned crops, viz. that we had for these species of crops, very seasonable and fine rains. From the sixth of July, on which day I began to put down my cabbage-plants, to the first of December, both inclusive, we had seventy days, in which there was, more or less, rain; and the latter end of August, and beginning of September, the heaviest dews that I have seen. From the sixth of July to December the first, both inclusive, were one hundred and seventy-seven days; so that we had but one hundred and seven dry days, many of which, I see by my calendar, were cloudy and inclinable to rain.

"Land, says an Essex farmer, cannot be brought into too good tilth for sowing turneps: they require a deep, loose, well-wrought mould; and to effect this, discreet ploughing and harrowing is the best way. I say discreet, because one ploughing, properly timed, is worth three that are out of time. It is a maxim in husbandry, that some land cannot be ploughed too much; but we should add, at proper seasons and intervals, or an ignorant farmer might ruin himself, and yet think, he had followed the directions that were given him.

"A light land requires less ploughing, as well as less nicety in the times of ploughing, than a stiff heavy soil: and it is also sooner brought into good tilth: two well-timed ploughings will often do it; whereas a clayey soil will require three or four, before it is brought into order.

"An early ploughing will greatly forward the getting a stiff soil into order: the month of April should be the latest, that such, when intended for turneps, should be turned up. It may then lie till the beginning of June, when it should be harrowed down with loaded harrows to break the clods, and immediately cross-ploughed: about a fortnight after this it should be ploughed for the last time, and imme-

diately cross-harrowed and sown out of hand with turnep-seed pretty thick, and scratched with a light harrow to cover the seed.

"Light lands, as I said before, may do very well with two ploughings, one in the spring, and the other just before sowing at Midsummer.

"I look upon it that turnep-seed cannot well be sown too thick, for it seldom all comes up, and of what does get above ground, much is often destroyed by the fly and slug; so that the plants sometimes, though the seed was sown thick, require but little thinning by the hoe. In fact, I think it better at first to bestow an additional quantity of seed, than to have to sow three or four times over, as I have been often obliged to do, till I practised this method of sowing thick, which generally succeeds very well with me.

"The beginning of July is the time in which I for the most part, sow my turnep-seed; in this matter the grand affair is to hit it off, so that the turneps do not grow sticky or spongy before the winter, and yet are forward enough in their growth to resist the frosts, &c. and be fit food for the cattle in the winter, or in the spring.

"To have a good and profitable crop of turneps, it is absolutely necessary they should at proper times, be hoed, not only to kill the weeds, but also to thin the plants, and set them out at a proper distance.

"The proper time for the first hoeing is when they have put forth their fourth leaf, and the second hoeing should be in about three weeks afterwards: twice is, in general, enough, unless a very following rainy season should come on, when it will be proper to take the advantage of the first sun-shine weather, to give them a third hoeing; this, indeed, is often neglected, but I always found it pay well, by the thriving condition it put my crop in.

"As to the distance at which the plants should stand one from the other, that must be regulated by the size of the turnep; but it should never be less than one foot, nor is there occasion for its being more than two; about sixteen or eighteen inches is a proper distance for the common turnep we generally sow about us.

"If the soil on which the turneps grow, is light and dry, the most profitable way is to feed your sheep on them in the spot where they grew; but if the soil is heavy and stiff, it is best to have them pulled and carried in tumbrils on to some dry pasture, or on any dry field you want to mend; for was you to feed them on the land, one half of them, at least, would be rolled in the dirt, trodded under foot and spoiled.

"Land cannot be too rich, or too well dunged, for bearing turneps; and this will bring them forward, and make them escape the fly better; for when once the leaves become rough, the fly does not chuse to touch them: it is therefore certainly best to encourage them in their growth, and bring them as soon as possible out of danger.

"When my young crop of turneps have come up, and I have been fearful of the fly, I have frequently sown over them wood ashes, and sometimes foot: these have been of great service, especially if gentle rains followed, as neither the flies nor slugs chose afterward to touch them. But I must observe, that this is no safe remedy, if the weather is dry and hot, for ashes being of a hot nature, will then be apt to burn up the crop.

"As to the slugs, the best way of destroying them in dry weather is with a light roller: this crushes and kills them, and does the crop service, especially if it is light land; for it presses the particles closer, so that the moisture in the earth is not so soon exhaled by the heat of the sun; consequently the young turneps do not so soon suffer by a continued drought.

"It is scarcely necessary to observe, that dry weather is best for hoeing turneps in, as then neither the weeds nor the turneps that are cut are apt to grow again.

"In light gravelly or sandy soils, the seeds of turneps may be deeper covered than in stiff clayey land: in the first it may be pretty well harrowed in; in the latter, it should only be slightly scratched with a very light short-tined harrow, or even only bush-harrowed; as by that means they will sooner appear above ground, be sooner out of danger and thrive better afterwards, the apple of the root growing almost entirely out of the ground, the whole nourishment being collected by the tap-root, and by the horizontal roots, which issue from it on all sides.

"The quantity of seed to be sown on an acre, should be from two to three pounds, according to its goodness; and many use equal quantities of old and new seed, think-

ing this method best; for the new seed comes up first, and if the fly takes it, the old seed in a day or two succeeds, and generally fares better.

"If a crop of turneps fails, either through any defect in the seed, or by the ravages of the fly or slug, it is usual for the farmer to sow the same land again; and this, if there is occasion, he repeats two or three times, till at last he secures himself a crop. For the reason above-mentioned it is esteemed best to sow early, as by that means there will be time, if the first crop fails, to sow another.

"Turnep-seed is very apt to take damage from wet, if it is not covered as soon as sown: without this precaution it will sprout prematurely, malt or mould: by too early a germination the seed is apt to burst.

"When pease are sown on a rich mellow earth, they are apt to grow rank: in this manner they cover the ground, keep the moisture in it, raise a kind of fermentation in the soil, and make it hollow and porous; inasmuch that when the crop has been off, turneps have been harrowed in without ploughing, and have thriven amain; but there is danger in pursuing this practice without great caution." *Museum Rusticum*, vol. I. p. 205.

"I have in my time, says a Norfolk farmer, sown a great deal of land in turneps, and have applied them with great advantage to various uses; but our chief reason for cultivating them in this county is for feeding and fattening sheep.

"It is almost needless to say, that they answer this purpose extremely well, their use is too well known to all the eastern farmers, to be in these days controverted.

"We have various methods of spending them: some fold their sheep on the land where the turneps grew; I have done this, but it is not a method I approve of: however, for the benefit of such farmers as chuse to practise it, I shall give one caution; which is, that they use wicker hurdles for folding their sheep, which will otherwise be apt to thrust their heads through the bars, and entangling themselves, are by that means often killed in the night, to the great loss of the owner.

"If, however, it should not be convenient to the farmer to get these wicker hurdles, but he should be obliged to take up with those made of rest stuff in form of a gate, let him then be careful, when he has set his hurdles, and staked and bound them right, to pull up all the turneps that grow within two or three feet of the outside of the fold, and throw them over the hurdles for the sheep to eat within-side.

"This will take away any temptation the sheep may have to put their heads through the bars, and they will by that means escape the danger of being strangled.

"Every animal is fond of liberty; and though the sheep will bear confinement, perhaps, better than any other creature, yet whoever has seen them when first driven into the fold, must have observed that they naturally go round the hurdles to try to find an opening to get out at; by this means the turneps which grow near the hurdles are trampled on, dirtied, and spoiled. For this there is a very easy remedy; let the shepherd only pull up all the turneps that grow near the inside of the hurdles, and all will be well.

"I observed before, that I am not fond of giving my sheep turneps as they grow: I think it much the better way to have them pulled; by this means they have an opportunity of eating the whole root, and my stock of winter fodder goes much further; whereas, when they feed on the turneps as they grow, they generally scoop them out, and leave a hollow shell in the ground, which, though it may afterwards be forked up, the sheep will scarcely ever by hunger be induced to touch, as it cannot but be soaked by the dung, urine, and dirt from the feet of the sheep.

"I find it then the best way to have my turneps pulled before they are given to my sheep; they go much farther, and do them more good.

"But in this method there is one seeming inconvenience, which is; that in frosty weather when the ground is hard, I cannot have them pulled, yet this difficulty is very easily removed, by laying up, at the beginning of the winter, a sufficient store of turneps, secured from the wet, and not much exposed to frost.

"I think it worth while to have a building particularly dedicated to this use, and find it answer well: it is built in form of a small barn, and boarded round.

"In the beginning of the winter, before the frost sets in, I have a large quantity of turneps pulled, and the dirt is carefully scraped off them; and, after cutting off the heads

and tap-roots; I cause them to be regularly laid in my store, with this caution, however, that all round the sides next the boarding, my men lay straw to keep out the frost. The heads, or tops, I give to all my cattle in general, as they are cut off; by which means I in fact suffer no loss.

"I find these stored turneps a happy resource when hard weather comes on; then I open my repository, and deal them out to my sheep in such a manner that there may be no waste; and as soon as the weather breaks, and the earth becomes less hard, I resort again to the fields, and have them pulled as usual.

"For some years I had another manner of storing my turneps, which was by digging a deep pit in a sandy, dry field, which being filled with turneps, they kept there very well; yet, as this method was subject to many inconveniences, I left it off.

"I have discovered another use for the turnep, besides feeding my sheep, oxen, and cows with it, which I must mention before I conclude this letter. I find it agrees remarkably well with hogs, which will eat of it greedily, and thrive on it apace.

"I have several times tried this, and have often killed fine young porkers that had for many weeks eat nothing but turneps boiled in swill, or wash, till they were tender.

"I have at other times given turneps to large hogs, that have been put up to fatten, in order to their being killed and salted for family use; and here I was not disappointed in my hopes; they always came on well: but I made it a custom to give them, for a week or two before they were killed, a few bushels of boiled peas, in order to harden their fat, that it might not boil away in the pot.

"I gave them boiled pease rather than raw, because, having been long used to eating the soft turnep, I found they did not afterwards take kindly to the hard, raw pea.

"Hogs may easily be brought to eat raw, unboiled turneps; but it is much better to boil them when the hogs are to be fattened; for though they will eat enough of them raw to keep them in tolerable good plight, yet they will not eat enough to fatten them apace." *Museum Rusticum*, vol. I. p. 335.

"I had last winter, says an ingenious clergyman of Northampton, a piece of turneps intended for feeding sheep; but my method of consuming them at first astonished my neighbours.

"I fed them off by the fold; but I first turned in some ewes, which greedily devoured all the tops and leaves; when they had finished them, I immediately folded my ewes on a fresh spot.

"After the leaves were eat off the first spot enclosed by the hurdles, by the ewes, I turned in some wethers, which eat with a very good appetite the apples of the roots, leaving, however, the lower part scooped out in the ground: these I had forked up, and they were eat by my store-sheep.

"My neighbours were convinced my method was right, because I evidently kept and fattened more sheep on the same quantity of land than they did; yet they begged I would give them my reasons for this my practice.

"I told them I would readily comply with their request, and the more so as it might be a means of tempting them to imitate what they saw practised with success.

"Continuing my discourse, I informed them that many years experience, and constant observation, had convinced me, that if you turn a parcel of sheep promiscuously into a field of turneps, the ewes and lambs would immediately attack the leaves; the fattening wethers would, for the most part, prefer the apple of the root; and the store-sheep not being nice, would indiscriminately devour both leaf and apple, and even eat the leavings of either of the others.

"I farther informed them, that I had frequently observed that when a parcel of wethers have been turned into a piece of turneps, the farmer, thinking to have no waste, generally kept them in till they have eat the roots up. But this is very bad husbandry; for after the wethers have eat the most delicious and sweet part of the root, they loathe the rest, which is generally gritty, dirty, and sodden, inasmuch, that nothing but absolute hunger will tempt them to taste it. In this period they pine and loose flesh; and by the time they are turned into a fresh bite of turneps, they are but little better than they were at first.

"The appetite of a beast that is fattening should be tempted, not palled; and undoubtedly, such of the sheep

as are most forward will be most delicate; and this delicacy, if the farmer is wise, he will indulge, as it will eventually turn out to his advantage.

"Thus, in my manner of feeding turneps, the ewes come first, because they prefer the leaves; the wethers that are to be fattened follow, and make the most pure and sweet repast; and the store-sheep, which are the least nice of any, come last, and clear off the remains; at least, as much of them as they ought to be permitted to eat; for I do not hold it good to oblige them to eat what are in a half putrefied condition, and fodden with dung and stale.

"My neighbours were so well pleased with my reasons, and so well convinced by what they saw, that they are determined to adopt my practice; and if any of your readers should be of the same mind, it would give me great pleasure, as I cannot feel a truer joy than what results from my endeavours to be of service to my fellow creatures." *Museum Rusticum*, vol. II. p. 231.

"I last year sowed some turneps, says a farmer near Chelmsford, on near ten acres of good light land. Some other business interfering, prevented my getting them hoed in due time, inasmuch that, by the latter end of August, they seemed to be almost covered with weeds.

"Being willing to endeavour at recovering my crop, I caused the field to be harrowed and cross-harrowed, which set them out pretty well, and cleared away a great number of the weeds, inasmuch that the turneps got a-head, and grew to be a tolerable crop.

"I send you this for the information of some farmers, who, when they have delayed hoeing their turneps for a few weeks, if the weeds get forward, think they have lost their crop; whereas, would they adopt this method, which has been more than once recommended, they would find it answer any reasonable expectation they could form. I have several times tried it, and it always succeeded with me more or less. The work costs but little, and the benefit resulting from it is considerable. I have known farmers plough up a crop of turneps which, by harrowing, would have yielded them a good return." *Museum Rusticum*, vol. V. p. 239.

"I have known many, says farmer White, of Suffolk, who intend feeding off their turneps with sheep, keep the turneps till they are too old to be applied with advantage to that use. Your readers may give me credit, for I speak from experience; and I can assure them, that one acre of young turneps is of more value for fattening sheep than two acres of old ones, as the wethers you turn in will get flesh and fat at least as fast again on the first as the last.

"Let this maxim be treasured up in the farmer's memory; and let him not at any rate be tempted, for the sake of spending a few weeds and grass on his fallows, to keep his turneps till they are of little worth.

"If any of your readers should be incredulous, let them try the experiment; it will be but little expence, and still less trouble. I did so myself before I adopted the practice, and was in a very short time convinced: this happened some years ago, and I have continued this method ever since." *Museum Rusticum*, vol. II. p. 279.

We shall conclude this article with the following letter we were favoured with from Mr. Mathew Cox of Wallhampton, near Limington, in Hampshire:

"I have, says he, inclosed you a draught of a hoe-plough, which I have found to answer very well for hoeing carrots and turneps, which may probably be improved by some of your society: the following is the particulars of its success this year 1766. I took possession of the farm I live on in April, and going soon after to London, ordered my servant to sow two acres of carrots with four pounds of seed; on my return, I found he had sown all the seed I had left him, being twenty-eight pounds. In May the carrots came up as thick as sand on the shore. The people here being entirely unacquainted with the method of hoeing, made my work very tedious, as I was obliged constantly to attend them. It cost me sixteen and six-pence per acre, and the work not half done; I then harrowed them, &c. according to Mr. Billing's directions, and in June found ten times too many to come to any size; but could not get the second hoeing performed under one guinea per acre: I then gave directions for this hoe, which I fixed to the common horse-hoe plough, and hoed my two acres in five hours with ease; next day I harrowed them with common harrows. About ten days after, I harrowed them again, and have kept nine horses on

them ever since August; except a quarter of oats in seed time.

Whoever uses this plough will find it answer the first hoeing extremely well, as it will leave whatever it hoes at two inches and a half distant; consequently the second hoeing, which must be by hand, will be very trifling; and often there will be no occasion for it. I first hoe the long way of the land and then cross it. The hoe I have is bare two inches; but I find it is too narrow.

a a, Plate XXVI. fig. 5. are the two out-sides of the hoe, which are flat, and so go on the outside of the block on the common horse-hoe at *A A*, fig. 4.

b, Goes on a mortice at the bottom of the block, at *b*. *c*, the pin goes through the holes on the flat side of the hoe at *a a* and the block *A A*.

d, d, d, The cutting parts two inches and a half wide; and leaves a space of two inches and a half.

E, A chain that hooks to a staple on the beam, and keeps all steady. I have ploughed ten inches deep with this hoe.

F, F, Two bars of iron worked in to the three uprights.

I always use the harrow belonging to the common horse-hoe with the above. I sometimes fix M. De Villier's cultivator to the above carriage: I have a field of twenty-two acres of wheat, in which is sixteen different ways of sowing, preparing the seed, and manuring the land."

Mr. Marshall, in his *Rural Economy of Norfolk*, vol. ii. says that "An experienced farmer in this neighbourhood has frequently found that steeping old turnep-seed in water and letting it lie a few hours in the sun before sowing, has brought it up much sooner than sowing it dry.

"He adds, that this year, having neglected to steep it, he had turnep-seed lay three weeks in the ground before it came up. He was advised to plough in the few straggling plants which appeared soon after sowing, under an idea that the fly had eaten off the remainder: but he judged from experience that the principal part of the seed was still in the ground; he accordingly waited until rain fell, and has now, I see, a very fine crop of turneps.

"This is a valuable incident; for it is highly probable, that in the beginning of the season, when old seed is obliged to be sown, many crops of turneps have been prevented by ploughing the ground prematurely."

In another part of the same volume he says, "What a variety of enemies have turneps in this country! The fly, the canker, the maggot at the root, and the anbury, have this year already destroyed myriads.

"The fly took them in their infant state; the grub and caterpillar, whilst their tops were yet small; and, now when their tops have almost got their full size, they are hourly dwindling with the anbury.

"The grub in itself would not perhaps be fatal; but the rooks, in order to come at it, pull up not only the plants which are attacked, but those also which are free from it; and by this means clear them as they go.

"The anbury is a large excrescence, which forms itself below the apple. It grows, it seems, to the size of both the hands; and, as soon as the hard weather sets in, or it is, by its own nature, brought to maturity, it becomes putrid, and smells very offensively.

"At present, the state of three specimens which I have taken up, and examined attentively, is this. The apples of the turneps are just forming about the size of walnuts in the husk while the anburies are already as big as the egg of a goose. They are irregular and uncooth in their form, with inferior excrescences (resembling the races of ginger) hanging to them. On cutting them, their general appearance is that of a hard turnep; but on examining them through a magnifier, there are veins, or string-like vessels dispersed among the pulp. The smell and taste somewhat resemble those of turneps; but without their mildness; having an austere and somewhat disagreeable flavour, resembling that of an old stringy turnep. The tops of those which are much affected turn yellow, and flag with the heat of the sun; so that, in the day time, they are obviously distinguishable from those which are healthy.

"It seems to be an idea among farmers, that the cause of the anbury is the soil's being tired of turneps; owing to their having been too often sown on the same land. This, however, is positively erroneous; for the piece from which I drew these specimens was an old orchard, and never before bore turneps in the memory of man.

"Quere—Is it not caused by the above-mentioned or some other grub, that, wounding the vessels of the tap-root, diverts the course of the sap; which, instead of forming the apple, forms this excrescence."

Mr. Marshall further states, in Minute 61 of the same volume: that, "A neighbouring farmer having one side of a close of turneps which he could not get off fast enough to be sown with wheat, he cut off their tops with a spade, gave the tops to his cows, carted the bottoms into a new-made adjoining ditch, (backing the cart and tipping them in) and covered them over with a little straw; and, over this, with bramble-kids, to keep the stock from them."

"Here they lay until wanted, in a frost, when the cart was again backed to the ditch, and the turneps loaded with a fork."

"He says, that his beasts eat them as well or better than fresh-drawn turneps; and that in general they came out as sound as when they went in. Had the tops been deposited with the roots, they would probably have brought on a fermentation, and have spoiled the whole deposit."

"Might not this practice be extended to the preservation of turneps in the spring?"

"Turneps, this year, began to run the beginning of January: they have now, in general, got spring shoots five or six inches long; and, if the present open weather continue, the roots must be considerably exhausted, and the land very much drawn, long before bullocks in general are finished, or grass begins to grow. But if they were now (when labour is cheap and plentiful) topped and carted into dry ditches, or formed into stacks with straw, their goodness might be preserved, and the land be got into forwardness for barley."

"If they were stacked in or near the yard, there would not, for shed or straw-yard bullocks, be any labour lost."

"Whether, after this remarkably mild winter, the spring prove very mild, or very severe, they would, by this means, be removed out of harm's way."

Mr. Young, in his *Annals of Agriculture*, vol. VII. inserts the following account of turneps by the Rev. Orbell Ray, of Postock:

"Your address to your correspondents, in Number 40, requesting them to inform you of the measures which they pursued for preserving their turneps, and relieving their land from the exhausting effects of their very rapid vegetation, during the late spring, determined me to send you the following account of my treatment of this root, the advantages of which I have experienced for many years, and which, with a few variations, is, I believe, the general practice of the Suffolk farmers. About the middle of February, I began to draw my turneps, cutting off the tap-root at the same time, and carried them to a pasture field, adjoining to my farm yard, where they were unloaded, and labourers employed to take the roots, one by one, and set them upon the grass, in as upright and close a manner as possible. I pursued this method through the month of March, until I had collected above an hundred loads; always availing myself of dry windy weather, when the tops are less brittle, and the roots in the cleanest state. The expence varies with the distance of carriage; the setting up, about three half-pence per load of 40 bushels. The growth of the top is not much interrupted by the loss of the tap-root, and is an ample compensation for the waste of the bulb. I carried about two loads per day to nine bullocks, which were confined in a farm yard, with suitable bins; and do not recollect that I ever experienced so profitable an expenditure of my turneps. The cattle did not leave the yard till the second week in May; when they were turned into a field of fresh luxuriant ray-grass; I observed that the succulent quality of the turnep-top was more acceptable to their palates than the grass; and I am moreover convinced of this very important circumstance, that the quantity of nutritious food is increased by this method."

Mr. Marshall, in his *Rural Economy of Norfolk*, gives the following remedy of destroying caterpillars; by which he says many hundred acres of turneps have been saved.

"Mr. Samuel Barber had, at one time, upon his farms, at Staninghall and Woodbastwick, near four hundred ducks at work: and, through their industry, has saved a principal part of his crop: had he begun to employ them sooner, he believes he should have saved the whole."

"The different detachments (some of them near one hundred strong) were kept by a boy or girl. They were regularly driven to water, and rested three or four times a

day: but had no corn nor any other food given them. After having drank, they would disgorge the caterpillars in great abundance; so that they soon fell to again with fresh appetites."

"Half or three-quarter-grown ducks are preferable to old ones, which are lazy, and will sooner eat the turnep-tops than run after the caterpillars."

"It is very amusing to see the young ones dart at their prey: these, however, when the caterpillars grow scarce, take to the turnep-tops, and after they have reduced the vermin to a certain ebb, do the turneps more harm than the caterpillars themselves do."

"This has been used as an argument against employing ducks; and, in respect to old ducks, it may have its weight: but if the caterpillars are so few as to tire the young ducks in looking for them, the plants cannot sustain any material injury from them."

"The fact seems clearly to be, that where one acre of turneps has been saved by any other means whatever (hand-picking excepted) an hundred have been saved by ducks."

"In the same Volume he says, 'Young Swann, of Suffield, had, the winter before this, some of the best turneps in the country. Seeing him, last summer, sowing some in what appeared to me a slovenly manner, the surface being covered with chick-weed, groundsel, charlock, and other rubbish pulled up by the harrows, I asked him why he did not give his land another earth before he sowed it. He answered, that the land was not foul; and that he, purposely, let the seed-weeds get to a head: having found, from the experience of two or three years back, that his turneps succeeded best when the seed was sown in that manner: saying, that he believed the wreck shaded the young plants, and kept the fly from them. I asked him if the rubbish was not in the way of the hoe: he said, not much; for being young, and tender, it withers away to little or nothing, before the plants be fit for the hoe.'

"Two or three days ago, I examined this close of turneps; the plants are thinner than one would wish, (perhaps owing to their being badly hoed) but there is not a squally patch in the whole piece."

"There may be two advantages arising from letting the soil lie some time before the last ploughing: it requires a degree of texture, and moistness, favourable to the infant plants; and is prevented, by the dead weeds, from being, afterwards, run together by heavy rains."

In the *St. James's Chronicle*, January 7, 1792, there appeared the following account of the Swedish turnep, or Ruta Baga, which promises to be a valuable article to the farmer. "It is a species of turnep that was discovered in Sweden by Linnæus; but the seeds of it only reached this country of late. It has been sold here by its Swedish name of ruta бага; and sometimes is called the Swedish turnep. Its appearance is not the most promising. It does not on ordinary loamy or light soils, grow to such a size as the common kinds of field turneps; scarcely, perhaps, does it equal in size the yellow turnep; but it seems to be better adapted to strong clay land, and thrives better in damp soils than any other kind of turnep. Its skin too is very thick, which is rather an unpromising appearance. Its flesh, however, when used at table, is excellent, very much resembling that of the yellow turnep; and all kinds of cattle are singularly fond of it. The leaves too, which exactly resemble those of the cole-seed plant, are an excellent green for the table, but are not nearly so abundant as those of other turneps, though more hardy with respect to frost; nor have we had any opportunity of yet perceiving that the bulbs are in any case affected by frost, or the young plant consumed by the fly."

"Its excellence, however, consists in two peculiar qualities, which it possesses: one of those is that of admitting of being transplanted with the same facility as a common colewort. It may therefore be either cultivated in the usual way, as turneps, or transplanted into the field from a seed-bed, as greens, according to circumstances. Experiments sufficiently numerous have been made fully to ascertain this fact beyond a doubt."

"But as the most singular quality of this plant (says the writer of this article) is one that I should not mention, because it is so contrary to the invariable experience of men in all cases of similar nature, were it not upon such authority as I consider to be indisputable. It is well known that turneps in general, and all other plants of this genus, when suffered to run to seed, become dry and sticky; and

as the seeds ripen, the heart of the bulb becomes withered and shrivels up, so as to leave a dry hollow ball, when the seeds are perfected. By the information I have received from a gentleman in Norfolk, whose name is well known, and highly respected in the literary world, I am assured that after this plant has fully perfected its seed, the bulb still continues fresh and succulent, and fit for use by cattle.

"On mentioning this fact to another gentleman, who had cultivated the Swedish turnep on a large scale, he confirmed this observation by the following fact, which accidentally came to his knowledge.

"He had saved some seeds of it in his garden; and his gardener, as usual on reaping the seeds of turneps, pulled up the bulbs, and threw them into a waste corner without the garden walls. There they were allowed to remain neglected above ground for several weeks. In passing that way, he accidentally struck one of them with his foot, and finding it firm, he took it up. The weight surprised him.

"On cutting it up, he found it fresh and fit for use. He carried it as a curiosity into the kitchen, where it was dressed, and served up to table; and my informant eat of it, and found it very good.

"On expressing my surprise at this singular quality to my Norfolk correspondent, he writes me, of date as late as the 6th of December, in these words:

"I have nothing to mention to you on the subject of experimental agriculture at present, except that I have had an eye-witness to the soundness of the bulbs of the rutabaga, after they had perfected their seeds, in a gentleman who is so near you, that I wish to refer you to him for an account of their appearance, on the first of September last. Doctor Andrew Coventry, the new Agricultural Professor at Edinburgh, having done me the honour to pay me a visit, I carried him to a place where they grew, and there finding some of the roots remaining in the ground, we pulled up one or two, and found them in the state I mentioned, not a little to his surprise as well as satisfaction; as they thereby promise to be a most valuable acquisition to the husbandmen. Every farmer will know how to estimate the value of such a plant. It promises to supply a desideratum in husbandry that has been sought for in vain, ever since the introduction of turneps."

TURNIP-CABBAGE, the name of a species of cabbage, so called because the stalk, at some distance from the ground, after rising of the usual thickness, and in the manner of those of other cabbages, enlarges suddenly to such a degree, that it forms a knob of a very large turnip: of which likewise it has sometimes the figure, though it is, in general, more oblong.

By this peculiar formation of the stalk, or production of the turnip-like knob, together with its being perennial, this species of cabbage is distinguished from all others. From the top of this turnip rise a number of leaves, of a greenish-red, or sometimes greenish-purple colour; which answer to the radical leaves in other plants. They do not, though this plant is truly of the cabbage kind, ever close together, and form a compact globular or oblong mass, as in the common species; but keep their erect growth, or turn outwards.

From among these leaves spring a number of other stalks, of which those that are nearer the extremity, branch, and send out flower stalks, spreading horizontally; and those that are more in the center, grow erect, and without branches. On these stalks are leaves, springing out alternately, and of the same colour with the others. The flowers are small and yellow, and succeeded by long pods, full of seed, of the size of that of mustard, and a light-brown colour. We have given a figure of this plant on Plate XXVI. fig. 6.

It may be justly doubted, whether or no this plant be originally a native of our country: though it is at present found growing wild in some places near Dover. But, from its general character, which does not agree with the indigenous plants of the same kind; from its being unknown to the earlier botanic writers, or, at most, known only in the view of an exotic; and from its being now to be met with wild, only in the one place mentioned, it is most probable, that what is there found was the produce of seed conveyed originally thither by some accident; and which has since propagated itself, and spread spontaneously, as it easily might, from its perennial nature and extreme hardiness. It is frequently cultivated in gardens, where there are collections of vegetables: but, for the most part, rather as a curious than an esculent plant. Though cer-

tainly, the turnip, or knob, is at least as wholesome as either any turnep or cabbage, and is much liked by some; and the leaves are also thought good by others; but, in general, both are said to be strong, and seldom admitted to the table with us. This plant, however, affords sprouts, which, after they have undergone the action of a strong frost, are exceeding good; and may consequently be had at that time when all others fail. The lying in very small room, proportionably to the quantity of solid substance, and the keeping good much longer than any other sort of vegetable of a similar nature, are qualities, moreover, which fit this plant in a most peculiar manner for the use of seamen, as is ingeniously remarked by Mr. Baker, in his report to the Dublin Society. See the article TURNIP.

It appears from Gerard, that there were, in his time, two kinds of this plant; one which he calls *caulorapum rotundum*, or round rape-cole; and the other *caulorapum longum*, or long rape-cole. The difference of these two kinds consisted only in the form of the knob or turnip, as is expressed by the names themselves; and in the long kind's shooting forth smooth indented leaves from the turnip part, which leaves the round kind wanted. I have here sent you a sketch of these two kinds, according to the prints Gerard has exhibited of them; and they may serve also to give some idea of the general figure of the plant, to those who have never met with it.

I have not however seen in any garden, nor find any traces in the late writers, of more than one kind of this plant: so that if the round and long kinds, mentioned in this manner by Gerard, were really different species, the long is now lost. But it seems more probable, that this was only a degeneracy of the plant, by means of the farina of the common kinds of cabbage; as the deviation from the round knob towards the plain stalk, and the breaking out of the leaves from it seem to indicate.

If there really were two original kinds, or this difference arose from a permanent seminal variation, it would merit attention under the present circumstances to recover them; since it frequently happens in correspondent cases, that where there are two allied species, the one has qualities which fit it to a particular purpose in a very superior degree to the other. This plant was rare in Gerard's time in our country; as he mentions his having the seed from Spain: and indeed it was so little known, that he says it is to be sown and set as cucumbers and melons; and that it was then accounted a dainty meat. It did not however make its way to the table in common, or even as a curiosity in gardens, much more at that time than since. For Parkinson, who wrote after Gerard, and enumerates many more species of cabbage than his predecessor, does not take the least notice of it. Tournefort, and most of the later writers, mention this plant under various names; but they do little more with regard to it, than give the name and description. Miller, in his Gardener's Dictionary, says, this kind of cabbage "never varies, for I have cultivated it many years, and have not found it to alter. It grows naturally on the sea-side, near Dover. It hath a perennial branching stalk, in which it differs from all other species. I have cultivated it these three or four years, and have eaten the young shoots, after they have been much frozen, when they were very sweet and good; but at other times they are very strong and stringy. In very severe winters, where the other sorts are destroyed, this is a very necessary plant, for the most severe frosts do not injure it."

'Till lately we see, therefore, this plant was only considered, either as a kind of curiosity in botanic or other gardens, where there were collections of different kinds of plants, or as an esculent herb: but in this latter view, it seems not to have acquired any great reputation, as it is so seldom, even notwithstanding Miller's recommendation, met with on the table here; though I am well informed, that in some of the factories in the East-Indies, it has been cultivated from European seed, and is much liked.

The first public notice I find taken of this plant, in the present view of cultivating it for feeding cattle, is in a pamphlet published by the late Mr. North, gardener, near Lambeth, who speaks of it under the article of cabbage; of which he says, "There are four species that may be cultivated to great advantage for cattle; to wit, the white cabbage, the lardy-curbed Savoy cabbage, the turnip-cabbage, and the green curled cabbage." When he comes to treat particularly of the turnip-cabbage, he thus expresses himself: "The turnip-cabbage is one of the hardestiest

diest roots that grow ; and I dare affirm, might be propagated to great advantage for feeding sheep, &c. For in the most severe winter that I can remember, when cabbages, favoys, turneps, &c. have all been demolished by the extremity of the weather, the turnep-cabbages have not been hurt. The turnep part grows all above ground, which is crowned with many large smooth leaves, like those of the red cabbage, but which grow open like the tops of turneps. They are a very solid juicy root, and do not grow spongy when they are old as turneps do. The tops may be cut off, and given to sheep, &c. in the spring, and the roots laid by in an out-house to feed them in April and May, when no other roots can be had. Sheep are so fond of these roots, that they will leave the best turneps for them. When they are given to sheep, they should be cut to pieces ; but they will eat them fast enough, tops and bottoms, as they are growing in the fields. After Michaelmas, when turnep-cabbages have their full growth, they will weigh from four to eight pounds a piece."

It may be proper here to caution against a misconception, from the inaccuracy of an expression of Mr. North, in calling the turnep-like part of this plant, a root ; for it is no more than an enlargement of the stalk in that part ; being, when the plants are large, several inches above the ground. It is proper to observe likewise, that Mr. North has under-rated the weight of these plants ; it appearing, by Mr. Baker's account, that some weigh fourteen or fifteen pounds. This is the first notice I find in any published work, of this plant's being considered as proper for feeding cattle : but it appears in the minutes of the Society's books, that some little time before the publication of this pamphlet, on the enquiry set on foot by the late Mr. Wych, concerning a proper food for cattle in hard winters, this plant, together with the Chinese or white vetch, and the Siberian medicago, were proposed to the Committee of Agriculture for their consideration, by a gentleman well known to that Society ; and this plant was particularly recommended for its hardiness in the ground, its quality of not rotting, though long kept, its nutritive property, and the fondness which cattle shew for it when offered to them as food.

Mr. Baker, nevertheless, whose report on this subject of the Dublin Society the reader will find under the article TURNEP, must have the honour of being the first who really introduced this plant into use, as an article of husbandry. For it was on the authority of his judicious experiments, related in that report, the same gentleman, who formerly recommended the turnep-cabbage, as abovemented, to the London Society, induced them last year to offer a premium for its culture : and there is no one object of a similar nature, hitherto taken into consideration, either by this Society, or that of Dublin, which bids fairer for being of great public utility : as this plant seems to answer all the ends of what was sought for, with so much pains and attention, in the research set on foot by Mr. Wych, after a proper winter pabulum (as it was called by him for cattle in scarce winters.

The turnep-cabbage may be cultivated in the manner of other cabbages ; of which the particulars may be seen under the article CABBAGE. But the success Mr. Baker had with his method, particularly in relation to the magnitude of the turnep, which seems to go far beyond Mr. North's notion, recommends strongly the trial of that manner ; except that, as he properly remarks, where the plants are raised in the spring, the seed should be sown in the very beginning of March ; the plantings, transplanted to a proper close bed, as soon as they are sufficiently strong to bear it ; and the final transplantation of them out into the field at the distances in which they are to grow, should not be deferred later than the beginning of June. This would both give more time for the plants to become large before winter, and a better chance to avoid a total want of rain, after transplanting ; the only accident, except the destruction by caterpillars, or other insects, to which this kind of crop is subject ; as the plants bid defiance, after they have firmly taken root, to all inclemencies of weather, either with respect to cold, wet, or drought.

It may be inferred from the above particulars, which, as we see, stand on unquestionable authority, that, considered as an article of husbandry, this plant must be a very valuable acquisition ; as it is of easy culture, and as little

subject to fail by accidents, as any crop whatever : as the produce with respect to quantity, is likely to prove, under favourable circumstances, thirty-five or thirty-six tons per acre, as appears from Mr. Baker's account : as its produce is greatly preferable either to turneps or other cabbages ; being much more nutritious, and less watery and cold ; a fault in the common turneps : as it may be depended on in the most rigorous and severe season, when every thing else but dry fodder fails, and may be taken from the place of growth, in case of exigence, whenever the ground is not covered with a very deep snow : and as it is much liked by neat cattle, sheep, deer, and hogs ; agrees perfectly well with all of them ; and fattens them in the most profitable manner. This is certainly very sufficient ground of recommendation, as an object of premium, to the London Society ; and it is hoped will be so, as a subject of experiment and trial to those gentlemen, or more liberal kind of farmers, who attempt improvements in husbandry.

I have thus endeavoured to give all the light I can into the nature of this plant, considered as an article of husbandry : but before I conclude, I must beg leave to subjoin a few words respecting it in another view, of such importance to a particular set of men, whose health and safety manifold reasons recommend to the care of the public, as makes it merit a very serious consideration. What I allude to is, the intimation given by Mr. Baker, of the probability that this plant might be rendered extremely serviceable to seamen in long voyages. As there can be no doubt of the just foundation of this opinion, it ought to be kept in sight as much as possible, till the matter be realized in practice. The putrid scurvy, arising from the eating salt provisions, is the great bane of a sea-faring life. The numbers disabled or carried off by it, particularly in time of war, are almost incredible ; and, if we considered the public value of lives so lost, both with respect to the natural power and expence, policy, as well as humanity, bids us listen to every feasible proposal for mitigating this evil. The use of vegetables in the diet along with the salt-beef or pork, is well known to be one of the most effectual means of prevention of this disease : and indeed, it has been so well understood, the great quantities of cabbages, &c. have been sent off to the fleets cruising in the bay, or elsewhere within reach, to the great relief and refreshment of the men. But this species of cabbage, abounding more in the saccharine juice than the other kinds, would be a more efficacious preventative or palliative of the scurvy ; and the solid compact texture of these turneps, which makes a considerable weight, lye in a small compass, together with their repugnance to that putrefaction, to which other turneps, cabbages, &c. are quickly disposed, renders it practicable to keep them on shipboard, in any climate, for many months ; provided they be preserved from the access of any extraordinary degree of moisture.

If this plant should be, therefore, generally cultivated the field-way, and consequently produced at a very cheap rate, as Mr. Baker has shewn, that betwixt thirty and forty tons may be obtained by an easy method of culture in one year, from one acre of ground, they might be purchased at a much cheaper rate than any other article of provision at present in use for the victualling of ships.

This seems to be an object very well worth the consideration of the India company ; as it might be a means of preventing that delay and ill success of some voyages, which arise from the sickness of the men ; and it is attended with no difficulty, but what regard the stowage. For the plant being already cultivated in some of the factories in the East-Indies, where it succeeds as well as here, and consequently might in all the others, as no climate or season appears injurious to its growth, it might be procured at a proportionably cheap rate, as well for the supply of the homeward or outward bound ships : and indeed, considering the nature and state of the provisions on board ships returning from India, it would undoubtedly be peculiarly beneficial in that case. *Museum Rusticum*, vol. VI. p. 46.

TUPETH, a species of the convolvulus or bindweed. See the article BINDWEED.

TWIFALLOWING, or TWYFALLOWING, ploughing the ground a second time, which is generally done in June.

V.

VALÉ, low ground ; a valley.

VAN, an instrument to winnow corn. *See the article* THRESHING.

VASCULIFEROUS PLANTS, such whose seeds are contained in vessels divided in the cells.

VAT, or FAT, a vessel for holding wine, ale, beer, cyder, &c. in the time of their preparation.

UDDER, that part of a cow, mare, ewe, &c. where the milk is prepared, answering to the breasts in women.

VEGETABLE, a term applied to all plants, considered as capable of growth, *i. e.* all natural bodies which have parts organically formed for generation and accretion, but not sensation.

Vegetables, according to the analyses made of them by chemistry, are distinguishable into two grand tribes, the acid and the alkaline ; the first affording a volatile acid, and the second a volatile alkali, upon a dry distillation : thus guaiacum, cedar, box, cinnamon, cloves, sorrel, mint, balm, &c. afford an acid ; but garlic, onions, horseradish, scurvy-grass, mustard, &c. afford an alkali, which, rectified, is hardly distinguishable from that of animal substances, so as nearly to resemble the spirit and salt of hartshorn.

VEGETATION, the act whereby plants receive their nourishment and growths ; of which, three principal functions are understood, *viz.* nutrition, increase, and generation.

From Scripture we learn, that the earth has been endued, from the beginning, with a certain seminal virtue to produce plants ; which virtue, proceeding from God, was not confined to the first production of things, but extends likewise to all future consequences of times ; and this faculty which the earth has of producing plants, is from this commandment of the Almighty : " Let the earth bring forth grass, the herb yielding seed, and the fruit-tree yielding fruit after his kind, whose seed is in itself upon the earth ; and it was so." Gen. i. 11.

Philosophers ask, what can be that virtue the earth is said to be endued with, if it be only the inherent quality whereby it produces, naturally, all sorts of plants, without the concurrence of seed ? or if a seminal virtue (or seed) must be administered to it ? Some follow the first opinion, for this reason, that earth dug up from a great depth and put into pots, after a set time or season, produces several sorts of plants of itself without seed ; but though this opinion be approved of by many, it has not, however, the least appearance of probability on its side ; for who (considering with attention the progress of nature, sees the marvellous mechanism of the organs of plants, the whole texture of their internal as well as external parts) could be persuaded to attribute it to a heavy and indigested mass of clay or earth : therefore, it is more rational to say, that plants have their origin from seeds, which being taken from the first plants, have propagated their species by the Creator's will, as far as our times, and will continue to do so (particularly where they are natives) to the end of the world.

The sun, rain, the exhalations of the earth, and the rest of the exterior causes, are capable to excite a certain motion or fermentation in the bosom of the earth ; but unless there be a seed which contains already the conformation of the plant, whose parts are unfolded by that fermentation, never such fermentation or motion can give origin to the plants ; therefore, we have great reason to think, that all plants have their origin from seeds, actually or potentially, since the first rudiments of a plant can be discovered no where else, nor by the naked eye, nor even by the help of a microscope ; so that the seed contains not only the coarser matter of the plant, with its organical parts, which have the ratio of a body, but likewise a certain spirit, that is, an active and vegetative substance, which may

be called the soul of the plant. Although, in some manner, it may be said to sleep in the grain or seed, yet when excited to motion by the heat of the sun, the warmth of the earth, and with rain impregnated with particles of volatile salts, it then unfolds its parts, and pushes the embryo plant forward.

A sprig or cutting must contain in it this seminal property, for being set at a proper season, it produces a tree with all its generative parts ; which it would not do were it not endued with some seminal virtues.

This generative or seminal faculty, is a power of the vegetative soul of a plant, by which it lives, and produces its likeness for the preservation of the species : but this faculty is not discernable from the seed itself, nor from the spirit contained therein, for as the seed is said to be a part of some substance, designed for the production of another substance of the same species, it is not absolutely necessary to distinguish that prolific virtue from the seed itself, nor from the spirit contained in it ; for after the seed is sown and softened by the warmth and humidity of the earth, its germ (wherein the plant is contained, as in an epitome) is unfolded by a gentle fermentation, and arises into a plant.

That the heat of the sun, and the temperate warmth and humidity of the earth, are the first principles of vegetation, appears from the sterility or fertility of the soil in those climates where these two principal agents act, or do not act in concert ; since, in the most northern countries, where the humidity of the soil is excessive, and its natural warmth is too much concentrated, the fermentation of the seed being made with too much precipitation, and without that gradation necessary for the easy and most perfect expansion of the different parts of the plant, thereby they are frustrated of that strength they should have before they come out of the matrix it has been formed in, to resist the injuries of the air and the inconstancies of the seasons, it perishes almost as soon as it appears on the surface of the earth ; for although the earth has in some measure, though very imperfectly, acted its part (as it cannot alone, and without the assistance of the sun, carry the plant to its last perfection) that tender parent of nature, by the obliquity of its situation, being reduced to the incapacity of darting its rays as favourably and abundantly in those climates as he does in others more happily situated, cannot either help the mother earth in her pregnancy, nor rectify what she has left imperfect in her productions, which therefore die almost as soon as nature itself is apprised of their existence.

Likewise in those other climates situated quite different from these, where the sun by being too profuse of its influences, penetrates the inmost parts of the womb of the earth, and by its too violent and too often repeated acts, and exhaling its salts, and evaporating its radical humidity, causes an excessive dilation of its pores, a disunion, and but too often an entire laceration of its generative parts, so as to render them quite sterile or barren, and therefore incapable to contribute to that fermentation absolutely necessary for the production of plants.

On the contrary, in those happy climates where the parts of the earth are so situated in respect to the sun as to be under his most favourable aspect, and exposed to none but his most benign influences, it almost always continues in its natural flourishing state, being seldom visited by the most powerful and penetrating beams of the sun, but at those regular and periodical times appointed by nature for its pregnancy, when they are necessary to excite her fecundity, or to nourish and cherish her productions when once brought forth.

Suppose our seed to have been sown in this last soil, and situation, the first things which present themselves to the imagination are the sun and earth concerting together, the

one by its heat, and the other by her moisture, how to rid the embryo of that hard tough substance it is enwrapped in, and which is the greatest obstacle to the bursting forth of its parts; therefore the earth, which is the first agent in this case, and which is to do the office of incubation, makes use first of its natural moisture to soften the outer rind or husk, by having it percolated through the pores or pipes of the said husk, whereby they are so opened and dilated as to facilitate the introduction of the different salts appointed to operate on the whole substance of the seed, by unfolding the different parts it contains, and disposing them severally towards assuming their respective forms.

It cannot be imagined that the earth acts alone in this first operation, that it could direct itself to action without the concurrence of the sun, which on this occasion excites, by a gentle warmth, the different salts the moisture of the earth is impregnated with, that they may be capable to conquer the stubbornness of the husk, by forcing themselves into its almost imperceptible pores, conquering all the obstacles and erasing all the obstructions which the several substances may meet with; by this means a free passage being opened for such a quantity of the moisture as is necessary to make a due separation of the husk from the more essential part of the seed, and salts employed in that operation being volatilized or already fixed on that essential part, leave the husk filled with nothing else but the lymph, which groweth turgid, and being deprived of the nourishment it received when united to the substance of the seed, begins to tend towards its destruction.

The following procedure in the vegetation of plants is exemplified by Malpighi in a grain of wheat; the first day the grain is sown, it grows a little turgid, and the secundine or husk, gapes a little in several places, and the body of the plant being continued by the umbilical vessel to a conglobated leaf (which is called the pulp or flesh of the seed, and is what constitutes the flour) swells, by which means not only the germ or sprout (which is to be the future stem) opens and increases, but the roots begin to bunch out, whence the placenta, or seed-leaf, becoming loose, gapes. The second day the secundine or husk being broken through, the stem or top of the future straw appears on the outside thereof, and grows upwards by degrees; in the mean time, the seed-leaf guarding the roots becomes turgid with its vesiculæ, and puts forth a white down, and the leaf being pulled away, you may see the roots of the plant bare, the future bud, leaves, and the rest of the stalk lying still hid. Between the roots and ascending stem, the trunk of the plant is knit by the navel-knot to the flower-leaf, which is very moist, though it still retains its white colour and its natural taste. The third day the pulp of the conglobated or round leaf becomes turgid with the juice it has received from the earth fermenting with its own; thus the plant increases in bigness, and in its bud or stem becomes taller, and from whitish becomes greenish, the lateral roots also break forth greenish and pyramidal from the gaping sheaf which adheres closely to the plant, and the lower roots grow longer and hairy, with many fibres growing out of the same; indeed there are hairy fibres hanging on all the roots, except on the tops, and these fibres are seen to wind about the saline particles of the soil, little lumps of earth, &c. like ivy, whence they grow curled about the latent roots, and then break out into two other little ones. The fourth day the stem mounting upwards, makes a right angle with the seminal leaf, the last roots put forth more, and the other three growing larger are clothed with more hairs, which straightly embrace the lumps of earth, and where they meet with any vacuity, unite into a kind of net-work; the conglobate or flower-leaf is now softer, and when bruised yields a white sweetish juice, like barley cream; by stripping it off, the root and stem of the plant are plainly seen, with the intermediate navel-knot, whose outer part is solid like a bark, and in the inner more soft and medullary. The fifth day the stalk still rising puts forth a permanent or stable leaf, which is green and folded, the roots grow longer, and there appears a new tumour of a future root, the outer sheath is loosened, and the seed-leaf begins to fade. The sixth day the stable leaf being loosened, the plant mounts upwards, the sheaf still cleaving round it like a bark; the seed-leaf is now seen sinuous or wrinkled and faded, and this being freed or cut from the secundine, the flesh, or pericarpium is found of a different texture, the outer part, whereby the outside of the seed or grain is heaped up, being more solid, but the inside vascular and full of humour, especially that part next

the navel-knot. All the leaves being pulled off, the roots torn, and the flower-leaf removed, the trunk appears; wherein, not far from the roots, the navel-knot bunches out, which is solid and hard to cut; above there is a mark of the sheath-leaf, which was pulled, and underneath, as in an armpit, the germ is often hid; the hind part of the plant shews the breaking forth of the roots likewise, with the faded placenta, &c. After the eleventh day, the seed-leaf as yet sticking to the plant, is crumpled and almost corrupted; within it is hollow, and about the secundine the mucus and white substance of the seed being continued to the navel-knot, forms a cavity, all the roots becoming longer, put forth new branches out of their sides, the second leaf withers, and its vesicles are emptied; the internodes, or spaces between the knots, grow longer; new germs appear, and the middle root grows several inches longer. After a month, the roots and stalk being grown much longer, new buds break out at the first knot, and little turnours bunch out, which at length break out into roots.

Thus, according to Malpighi, in this short space of time, the plant passes through all these various changes and mutations, which, though his observations may be real as here represented, yet it does not happen with such celerity in all sorts of plants, though in some kinds all these variations may come to pass in a shorter time.

The plant carried thus far, it still wants food for the future preservation of its vegetative life, which being deprived of such nutriment, it cannot exist; of which naturalists are so sensible, that their common opinion is, that water is the great vegetable food, which they endeavour to confirm by repeated experiments, especially by that made on a sprig of baum, mint, &c. which being set in a phial of pure water, without any mixture of earth, grow and put forth roots, leaves, and branches; without considering, that those sorts of plants being of a short duration, the juices which they have received from their mother earth in their first formation circulating through their vessels, being continually recruited by the salts the water they are set in is impregnated with, together with those they receive continually from the ambient atmosphere, are more than sufficient for the support of their short life in the water, which subsists no longer than that the water continues to supply them with salts, of which when once exhausted, it grows viscous, obstructs the pores of the vessels, and hinders thereby the admission of salts even from the atmosphere, imbecillitate by degrees the functions of the vegetative soul, which being forced for some time to feed on its own substance, becomes at last enervated and impotent, whereby the plant withers and dies for want of food, unless the water is changed before it comes to the last period, which appears at its growing offensive to the smell; even that precaution becomes useless at last for the greatest part.

Those salts, the water is impregnated with, being heterogeneous to those which enter into the composition of the juices, which circulate through the vessels of the plant, have soon, by disordering the whole frame of that mechanism, procured the extinction of the plant.

The great quantity of oleaginous particles those sorts of plants are composed of, which keep their pores extremely dilated for the admission of salts and other nutritive particles, contribute much towards the production of this phenomenon; but in plants of a closer texture, whose pores are so exiguous as not to be forced, but by the impetuosity of salts exalted and volatilized, best by the warmth of the earth and the heat of the sun, this experiment is of no effect; therefore, water cannot be simply considered as the great vegetable food, although it has a very considerable share in the nutriment of plants: but were it water alone, to which vegetables owe their increase, there would be no need of manures nor changing the kinds. The rain falls in all places upon the most barren land, as well as on the most fertile; nor could there be any reason why the same field should yield a large crop of wheat one year and not the next, since rain showers down nearly alike on the earth.

VILLING, ploughing, or cutting up the turf, or upper surface of the ground in order to its being burnt. See the article **BURN-BAKING**.

VENTILATOR, a machine by which the noxious air of any close place (as an hospital, jail, ship, chamber, granary, &c.) may be changed for fresh air.

The noxious qualities of bad air have been long known, though not sufficiently attended to in practice; but it is to be hoped, that the indefatigable pains taken by Dr. Hales, to see

set the mischiefs arising from foul air in a just light, and the remedy he has proposed by the use of his ventilators, will at length prevail over that unaccountable sloth or obstinacy, which, where particular interests are not concerned, seems to possess the generality of mankind, and which rarely allows them to give due attention to any new discovery.

The ventilators invented by that ingenious gentleman consist of a square box, A B C D (plate XXVI. fig. 7.) about ten feet long, five wide, and two deep; in the middle of which is placed a broad partition, or midriff, made to move up and down, from A to C, on hinges at the end E, by means of an iron rod Z R, fixed to the midriff at Z.

Another box, of the same size with the former, having a like midriff, bar, &c. is placed near the former (fig. 8.) with its rod, R Z. Both these rods are fixed to a lever F G movable on the center O; so that by the alternate rising and depressing of the lever F G, the midriffs are also raised and depressed alternately, by which means these double bellows are at the same time both drawing and pouring out the air.

That the midriffs may be rendered lighter, they may be made of four bars, lengthwise, and as many places across them, each about three inches broad, and an inch thick, the vacant spaces being filled up with thin pannels of fir board.

In order to make the midriffs move with greater ease, and without touching the sides of the boxes, there is an iron regulator N L (fig. 7.) fixed upright to the end A C of the box. As very little air will escape if the edges of the midriff be within one twentieth part of an inch from the sides of the box, there is no necessity for leathern sides as in common bellows. The end A C of the box must be somewhat circular, that it may be the better adapted to the rising and falling of the midriff; and at the other end of the midriff a slip of leather may be nailed over the hinges.

To the ventilators above described, eight valves are adapted for the air to pass through; these valves are placed at the hinge end I Q, fig. 8. numbered 1, 2, 3, 4, &c. The valve 1 opens inward to admit the air to enter, when the midriff is depressed at the other end, by means of the lever F G; and at the same time the valve 3, in the lower ventilator, is shut by the compressed air, which passes out at the valve 4: but when that midriff is raised, the valve 1 shuts, and the air passes out at the valve 2. The same is to be observed of the valves 5, 6, 7, 8, of the other box; so that when, by the motion of the lever F G, the midriffs are alternately rising and falling, then two of the ventilators are constantly drawing in the air, and two of them at the same time are blowing it out at their proper valves, the air entering at the valves 1, 3, 6, 8, and passing at the valves, 2, 4, 5, 7. To the ventilators, before the valves, is fixed a hook Q Q M M (fig. 9.) as a common receptacle for all the air that comes out of these valves, which air is conveyed away through the trunk P, passing through the wall of a building, &c.

It would be foreign to the intention of this work to point out the various uses of these machines in extracting foul air out of ships, hospitals, &c. but we must not omit the following

Experiments on the preservation of corn by ventilation.

M. Duhamel caused a case, or little granary of preservation, to be made of oak planks two inches thick, forming a cube of five feet every way. At six inches from the bottom was a flooring, or second bottom, of lattice work, placed upon joists five inches thick, and covered with a strong canvas. This small granary was filled quite full of good wheat, of which it contained 94 cubic feet, weighing 5040 pounds. It was covered with good oak planks, so closely joined, that neither rats, mice, or even the smallest insects could get in; leaving only some ventholes, with trap doors, or covers, fitted very exactly to them, as mentioned before.

This corn laid up without having been dried at all by fire, was not ventilated more than six days in a year, which was sufficient to keep it so well that the best judges allow it to be as good as could be. Even when the bellows had not been worked for several months, the corn was still allowed, by good judges, to look and smell perfectly well: but they objected that it did not handle well, that is, that there was some little dampness in it. The bellows were worked for half a day, and this objection was entirely removed.

This wheat was old, and had been as well dried as any

corn generally is in a common granary: therefore it being still damp, at the end of a considerable time, shews the necessity of taking away the superfluous moisture, and of reducing our corn to the same degree of dryness, as that of the hottest countries, in order to preserve it in great bodies.

Experiments on ninety-four cubic feet of wheat.

In May, 1743, ninety-four cubic feet of wheat were put into one of the little granaries before-mentioned. It was of the harvest of 1742, of an excellent quality, perfectly clean, and so dry, that a small parcel of it which was put, for a trial, into a stove heated to fifty degrees of M. de Reaumur's thermometer (123 of Fahrenheit's) lost but one sixteenth of its weight. This wheat was well cleansed from dust, and deposited in the granary, without being dried by any fire.

During the first three months, it was ventilated for eight hours once a fortnight: during the rest of the year 1743, and all 1744, it was ventilated once a month: all the year 1745, and part of the year 1746 it was ventilated half a day once a month; and after that, but once in two or three months.

In June 1750, the granary was emptied and the wheat looked and smelt very well, but felt a little rough in the hand, because, not having been stirred for six years, the little hairs that are at the extremity of the grain, and the particles of the bran were roughed up: but after passing twice through the wind screen, that objection was entirely removed. See the article THRASHING.

This corn was eight years old, during seven of which it was preserved in one of M. Duhamel's small granaries, without any sensible diminution, and without any damage from vermin or insects: we cannot say absolutely without any expence, because a man was employed from time to time to ventilate it. But this was a very trifling charge, and may be reduced almost to nothing, by working the bellows with swifts like those of a mill.

Experiments on seventy-five cubic feet of new wheat, extremely moist, ground, and which had already contracted a bad smell.

The harvest of 1745 was very rainy: almost all the wheat of that year was grown in the ear; the sheaves were extremely wet when they were housed; the grains adhered so closely to their husks, that they were greatly bruised by the flail; and if they were left but a very little while upon the barn-floor, before they were cleansed, they heated, and contracted a smell like that of pigeon's dung: in short, they were so very moist, that they lost an eighth part of their weight when dried in a stove heated to fifty degrees of M. de Reaumur's (one hundred and twenty-three of Fahrenheit's) thermometer; and when laid up in the common granaries, in the usual way, they were always in a state of fermentation, though but a foot thick, and turned every fourth or fifth day.

Seventy-five cubic feet of this grown wheat, which smelt very ill, and was so moist as to wet the floor of the granary where it laid but a few days, were put in this condition, and without being dried by fire, into one of M. Duhamel's little granaries, with small hopes of success.

As this corn was very hot when put into the granary, it was ventilated three or four times the first week, and once a week during December and January: and as it had then lost great part of its bad smell, it was ventilated but once a fortnight from that time till June. Then perceiving, by thrusting his hand into the top of the heap, that it heated, and concluding that it was going to be entirely corrupted, M. Duhamel ordered the granary to be emptied: but after the depth of about a foot had been taken from the top, he was greatly surprised to find the rest cool, with very little bad smell, and drier than that which was preserved in the common granaries.

The reason why the top of this corn was the worst, was, undoubtedly, that the moist vapours were always forced upwards in ventilation. It therefore might, perhaps, have kept very well, if, instead of emptying the granary, it had been ventilated oftener: for this would, probably, have dried away the remaining moisture, even at the top, as the following experiment will shew. But however that might have been, this teaches us one important thing, which is, that the top of the heap is most subject to heat in this sort of granary: so that if the grain taken out of the vent-holes

is in good condition, it may be concluded that the rest is still better.

Experiment on five hundred and fifty-five cubic feet of wheat very damp, mixed with smut, and which had contracted a bad smell.

The wheat of the year 1750 grew in almost continual wet; the harvest was very rainy; and the same weather continuing all the year 1751, no pains that could be taken to turn the corn laid up in the common way, could dry it, or prevent its heating and contracting a bad smell. The wheat of this crop was likewise mixed with a considerable quantity of blighted and smutty grains, which always contain a great deal of moisture, doubly difficult to be exhaled from them, and which soon makes them contract a bad smell, which they speedily communicate to the sound corn.

Five hundred and fifty-five cubic feet of this wheat were deposited in one of M. Duhamel's granaries of preservation, after being cleansed with such perfect care, that scarce any mark remained either of blight or smut among it; though these faulty grains amounted to near a sixth part of the crop. But there still remained a fine dust, or powder, occasioned by the moisture, so closely adherent to the corn, that it could not be taken off by any means.

This wheat was laid four and a half or five feet thick in one of these granaries, the bellows of which were worked by a wind-mill; and as there was no want of wind during all the year 1751, and till the spring of 1752, the corn was often ventilated, without trouble or expence; by which means it was not only well dried, but also cleared of great part of its bad smell. It was indeed, when taken out of the granary, very full of dust, which had fallen off the grains as their moisture was exhaled: but this was then easily separated by proper screening; and the wheat proved so good, that the bakers bought it at the highest market price.

This experiment proves, that even very moist corn which has a great disposition to ferment, may be preserved by ventilation only: and as to the smutty grains with which this was mixed, the reverend Dr. Hales, after rightly observing that kiln-drying is apt to make wheat grind unkindly, proposes the following method of drying smutty corn, after it has been washed; cold air not hurting it, as kiln-drying is found to do. "That I might be well assured, says that friend to all mankind, of the good effect of thus drying smutty corn, having procured a quantity of very smutty wheat, which weighed seven pounds and fifteen ounces, on the 26th of May, at five in the morning, it was washed clean in four several waters, which was done in a few minutes, and was then laid to drain in an oat-sieve, till half an hour after five; when it had increased in weight, by wetting, ten ounces, besides the moisture that was equal to the weight of the smutt-balls and smut that was washed from the wheat. It wasted but two ounces and an half, by the first two hours ventilating; two ounces and five drachms in the second two hours, viz. from eight to ten; in the next six hours, viz. from ten to four in the afternoon, it wasted at the rate of four ounces every two hours; from four to six, two ounces and an half, and from six to eight, one ounce and an half: in all, about twenty ounces; some allowance being made for what corn was wasted by handling and biting some of it from time to time. It was ventilated in these fourteen hours with about forty thousand gallons of air, which passed upwards through it, and made it sufficiently hard and dry, so as to be fit for grinding: it was well coloured, and handled well; and, from flinking, as smutty wheat does, it became much sweeter. The visible dewy moisture was blown off in three hours; but it continued damp and cold to the feeling till two o'clock, when some little dust began to fly off it.

"And whereas it wasted off much less moisture during the first four hours ventilation, when it ought to have wasted the most, on account of its being then wettest, this was owing to the foggy haziness of the morning: which as it went off, and broke out into fine warm sunshine, towards ten o'clock, so the air being thereby become dry, it imbibed moisture more strongly from the corn; and that this was the true cause of the difference, is farther confirmed by a like experiment which I had before made on a gallon of wheat, April the first, there being then a very dry north-east wind.

"It will be advisable to begin to ventilate corn as soon as

possible after washing, that the moisture may have the less time to soak in: for the less moisture soaks in, so much the sooner the corn will dry.

"If the moisture is so easily carried off from wet wheat, by ventilation, this method will doubtless much improve what is called cold wheat, viz. such as is grown, and has been housed in a cold wet season; and will therefore soon carry off the moist vapours which arise from corn, and which cause it to heat and grow musty.

Other experiments on the preservation of corn by ventilation.

The prior of the royal abbey of St. Stephen in Caen, filled a granary of preservation twelve feet wide, thirteen feet long, and six feet deep, which forms a parallelepiped of nine hundred and thirty-six cubic feet, constructed according to M. Duhamel's directions, with wheat that had been kept all the winter in a common granary. It was cooled from time to time by two bellows, which two men worked by means of a lever; and though the place where this granary of preservation stood, was neither so dry nor so airy as might have been wished, the corn kept perfectly well in it.

In the beginning of September, 1754, M. Vaudusfel filled one of M. Duhamel's granaries of preservation, seven feet square and six feet deep, with good wheat, undried. It heated a little at the end of eight days; but two men, with a small double ventilator, cooled it in two hours time. It began to heat again about week after, when he repeated the same operation, which cooled it presently. By the 20th of October it was quite cool, though it had not then been ventilated for fifteen days; and according to a letter of his writing to M. Duhamel, dated the 14th of October, 1756, it still continued in the same good condition. Corn of the year 1754 and 1755, not dried, but only ventilated, had likewise kept with him as well as could be wished.

VERJUICE, a liquor obtained from grapes or apples too acid for wine or cider. It is generally made in England from the juice of the crab, or wild apple.

VERMIN, a collective name including all kinds of small animals, that are troublesome to men, beast, corn, fruits, &c.

Mr. Young in his *Annals of Agriculture*, vol. XIII. says, "My present subject shall be confined to those destructive vermin, rats and mice, which I have often considered as of greater consequence, and much more prejudicial than the generality of farmers are aware of. In proof of this opinion, it will probably be admitted, that a single rat eats, and destroys, a quart of corn per week; I think this much under the real damage; which, notwithstanding it amounts per year to the large quantity of twenty quarters, two bushels, and four gallons, for the maintenance of one hundred rats; and I believe there are very few capital farmers but have many more than that quantity of rats belonging to them.

"The damage sustained by farmers from mice, is probably nearly equal to that of rats. But an experiment may easily be made, and a more just idea of the expences attending those destructive vermin, ascertained, by confining a single rat and mouse, and feeding them with corn. Such an experiment would be of great public utility; as it would certainly induce farmers to be much more vigilant than they are, in the destruction of those vermin, if they formed proper ideas of the losses sustained by them; which, on the most moderate calculation, will be found to amount to the sum of forty pounds per annum to every capital farmer, and half that sum to a small farmer. So that the total value of the corn destroyed, amounts to such a sum of money as to be of great consequence to the nation."

Mr. Marshall, in his *Rural Economy of the Midland Counties* gives the following striking instance of the industry and mischievousness of mice, which occurred in an intended plantation: "This field was in autumn sown with wheat: the nook, an oat stubble, and has not borne wheat for many years: yet, on digging it, a large board of wheat was found, some four or five yards from the fence of the wheat field, and between which and the nook is a very high bank and deep ditch across which every grain must have been carried, and perhaps, one at a journey!

"The workman thinks the board consisted of near half a gallon of wheat; if of one quart, it corroborates, strongly, the idea of mice being more mischievous than moles, to the farmer."

In his *Rural Economy of Yorkshire*, Mr. Marshall observes

serves that, "The different species of vermin which have more particularly excited notice in that district are mice, rats, and dogs.

"The mouse rivals the sparrow in mischievousness toward the farmer. In the field, the barn, and the dairy, mice are equally troublesome and destructive. In the field, the quantity of destruction is not easily to be ascertained; but it is probably much greater than the unobservant are aware of. At seed time and at harvest they not only feed freely upon corn, but fill their granaries with it, as a resource in less plentiful seasons. Much care is bestowed on the destruction of moles; and it might be worth while to endeavour to lessen the number of field-mice, which, I am of opinion, are in their nature more injurious to the farmer than moles are.

"In the rick-yard, the barn, the dwelling-house, the garden, and the nursery-ground, their mischievousness is too obvious to be overlooked; and the utility of lessening their number in these places is too well known to require an enumeration of facts to prove it.

"The method of destroying mice is a subject not unworthy the attention of any man who is interested in rural affairs. If some art or some natural enemies were not employed in lessening their number, the entire supply of human food would not be sufficient to support them. Even in their present state, I have heard it intimated by a man whose observations are frequently just, that it is a disputable point whether the mouse or tithe-man is a greater enemy to the farmer. This idea, however, is more applicable in a grassland country, where corn, being less in quantity, is more liable to be destroyed by mice, than it is in an arable country, where the proportion of corn is greater; where the barn is oftener emptied; and where pillar stack-frames and pillar granaries are generally more in use.

"The barn and the stackyard are usually put under the care of the cat: to let a mouse-trap in a barn full of corn has perhaps been considered as a thing so unlikely to be effective, that it has seldom been tried: I have never met with an instance of it, excepting one in this district, in which its success has been extraordinary. A barn, which for many years had been remarkably infested with mice (notwithstanding a numerous guard of cats), has by a proper use of traps, been kept in a manner wholly free from them.

"It having been observed, during long experience, that these mischievous animals, uncontented with their destruction among the corn, attacked leather, grease, or other animal food, which happened to be left in the barn, traps were set in their runs and natural hiding-places, and baited with these substances. The success was every thing to be desired; for although a total extirpation has not taken place, an annual saving of some quarters of corn has been the consequence.

"Under an idea that it was a change of food which in the barn constituted the bait, the same principle was applied in the cheese-chamber, and with the same success. Here traps baited with corn were taken with avidity.

"In the garden it was observed, that much depended on the season of the year: therefore, here, natural hiding-places were sought for; and if convenient ones could not be found, artificial ones were made, in different parts of the garden, with logs, stones set hollow on-edge, boards, &c. In these hiding-places a variety of food is laid for several days, whenever mice become troublesome; and whatever food is preferred, with that traps are baited.

"By these means the entire premises have been kept in a manner wholly free from mice.

"While the number is great, almost any kind of trap may be used, provided it be properly baited: for taking a remaining artful few, a common shaped round steel trap, adapted to the size of the mouse, has been found to be the most effectual.

"The rat. This animal, equally artful and mischievous, is difficult to be taken by stratagem. In farm-homesteads situated near water, it is become almost impossible to keep down their numbers. In every country they are a growing evil, not only in rural economy, but in manufacture and in domestic life. Should their numbers continue to increase with the same rapidity they have done since the present breed got footing in the island, they will in no great length of time become a serious calamity. They are perhaps at present an object of national attention. A simple and certain method of destroying them would indisputably be a public

good of no small magnitude: and the nation's purse might be worse employed than in giving a reward for so desirable a discovery. Some years ago the French government offered a premium for a speedy and effectual method of destroying ants in one of their West-India Islands, and it had the desired effect.

"It is not through an antipathy to dogs that I class them here among vermin. I am led to it by facts, which, though not extraordinary, ought to be known.

"A few years ago the whole country was alarmed with the apprehension of canine madness. A considerable proportion of the dogs kept in it were actually mad. Much live stock and several persons were bitten. Fortunately, however, thus far none of these have been attacked by that horrid disorder; but they still live under the dreadful apprehension of their being every day liable to be seized by the greatest calamity human nature is liable to. "Since writing the above, no less than seven persons were, in one place, bitten by one dog! much live stock has also lately been bitten. In a neighbouring village, a calf which had been bitten, was seized with madness, and bit the person who had the care of it.

"What aggravates the first-mentioned instance is, that the person to whom the dog belonged knew that he had been bitten a few weeks before, yet suffered him to go loose, though urged to the contrary. Surely, on culprits like this, some severe penalty or some severe punishment ought to be inflictible. A general law against every man whose dog is suffered to stray in a state of madness, might have a good effect.

"If the practice of worming be really effectual in preventing the mischiefs of canine madness, a severe penalty is due from every owner of a dog, which has not undergone so salutary an operation.

"Several instances are related of persons to whom canine madness has proved fatal in a neighbourhood. And the instances of live stock which have suffered by the same means are innumerable.

"In the course of last winter (1786-7) the value of sheep worried by dogs, in one township alone, was calculated at near one hundred pounds. A small farmer, whose entire flock did not amount to more than forty, had thirteen sheep and eleven lambs worried in one night.

"These are not mentioned as singular facts: every district and almost every year afford instances of a similar nature; nor do I mention them to excite a momentary indignation in the breast of the reader; but in hopes that they may be instrumental in rousing the humanity of those who have it in their power to mitigate the danger, and lessen the quantity of evil.

"The quantity of human food which is annually wasted on useless dogs is itself an object of national attention. When the horrors of canine madness, the wanton torture of innocence, and the wanton destruction of one of the first necessities of life are added, the object becomes of the first concern to the nation. Who, even in these days of public economy, would think ten thousand pounds a-year ill bestowed in doing away such an accumulation of public evil? Yet who does not know that in doing it away ten times ten thousand a-year might be drawn into the national treasury! Let not the patriotism of princes, the ability of ministers, nor the wisdom of parliament, be spoken of in this country, until a national absurdity so glaringly obvious be removed.

"There are men whom friendship inclines to the cause of the dog. Far be it from me to damp the flame of friendship. But is not the lamb equally, at least, entitled to our friendship? Who sees the little innocent dragged to the slaughter without regret; and who, without remorse, could see one lie mangled in the field, half alive; half eaten up, by the merciless, yet befriended dog.

"But the operation of a tax upon dogs would probably be different to what is generally conceived. I am of opinion, that were such a tax to be laid on judiciously, the immediate destruction of dogs would be inconsiderable. The tie of affection must be weak which a shilling a year would dissolve: even the poor man's dog would die a natural death under those easy circumstances. But what poor man would think of paying even a shilling a year for a dirty troublesome puppy for which he had not yet conceived any particular affection? Thus the number of dogs would annually and imperceptibly decrease.

"In six or seven years the tax would require an advance:

its productiveness would be lessened, and the rearing of another class of dogs would require prevention. In a few years more it might receive its final advance.

"The productiveness of the tax ought not to be considered as the primary object of a tax upon dogs. The removal of the public evils which have been enumerated should be at least jointly considered. Five shillings a head would reduce the number of dogs; and would, perhaps, be found to be more productive than a lower tax.

Dogs necessary in husbandry, manufactures, &c. and hounds kept in kennel ought, perhaps, to be exempted from the tax.

To kill Rats and Mice.

Rats and Mice may be destroyed by the following methods: to the powder of arsenic, commonly called rats bane, add fresh-butter, made into paste with wheat or barley-meal and honey. Spread pieces of this mixture about those parts of any house they most frequent; they will eagerly eat it, and having done so, will drink to that excess as to kill themselves. It should be cautiously laid to prevent young children's getting at it; and the person who prepares it should take particular care to clean their hands after it, as it is so strong a poison. Unslaked lime and oatmeal mixed together will likewise destroy them. Oatmeal and powdered glass mixed, or you may add to them some fresh-butter and lay it near their haunts. Filings of iron mixed with oatmeal, or with dough, or wheat-flower, will have the same effect.

Fry a piece of rusty bacon, lay it on in the middle of a board three feet square, covering the board pretty thick with bird-lime; only leaving some narrow passes in the board for the mice or rats to get at the bacon; in doing which they will frequently get among the bird-lime and be caught. In Staffordshire it is customary to put bird-lime about their holes, and they running among it, it will stick to them so that they will not leave scratching till they kill themselves. Or take oatmeal-flower and colocintida, make it into a paste, and lay it in the places where they haunt.

The seeds of wild cucumbers, and black hellebore, mixed with such food as they eat, will kill them. Or powdered hellebore mixed with wheat, or barley-meal only, made into a stiff paste with honey, and laid where they come, occasions their present death. But let the person who mixes this preparation, be cautious in the use of it.

When you have caught a rat or mouse, cut or beat him severely, and let him go, and he will make such a crying noise, that his companions will leave the place. Some persons flea off the skin of their heads: but this appears to be too cruel to practise.

Mix honey, metheglin, bitter almonds, and white hellebore, with wheat or barley-flour; make the whole into a strong paste; throw it into their holes, and it kills them. Some persons destroy them by putting hemlock-seed into their holes.

Make a paste of bitter almonds, colocintida, barley, wheat, or oat-flour, with mead or honey, and put it in their holes, or lay it where they frequent, and it will certainly destroy them.

Mix filings of iron or steel with a stiff paste made of wheat or barley-meal, and honey or mead; and they will be destroyed as surely as they eat of it. Some persons say that laying the skin of a deer in a room where they use to frequent, will drive them away.

If hog's-lard be mixed with the brains of a weasel, and distributed about a room in bits as big as a nut, they will not come thither. If oak-ashes are put into their holes, they will run amongst them, by which means they will get the scab, of which they will die.

Smallage-seed, nigella, origanum; the fumes of any of these burnt, will drive them out of your houses. Likewise lupins, or green tamarinds burnt in the room will rid you of these vermin.

Cork cut into small slices, and fried in suet, will certainly kill them, if it be laid where they come.

To kill Field-Mice and Rats.

Go out in the dog-days, when the fields are tolerably bare, and having found their nests or holes, which are in shape and size like an augre-hole, into which put hemlock-seed, or hellebore mixed with barley, and they will eat of it so as to destroy themselves.

To prevent your seed-corn from being destroyed by

these vermin, steep it in bull's-gall, and they will not touch it; or powder green glass, and mix with it as much copperas, beaten fine: add also as much honey as will make the whole into a paste, and all the rats and mice will quit your fields.

Fill up their holes with laurel or rose-leaves; or use a mixture of black hellebore, bitter almonds, wild cucumber, and hen-bane-seed, beat together, and made into a paste with barley-meal or oil. This will destroy them, if put into their holes, in fields or houses.

These vermin are very fond of artichokes: to prevent their devouring them, therefore, wrap wool about the roots, and they will decamp; or they may be driven away by strewing plenty of horse-dung or fig-tree ashes.

The best method to catch them in the field, is to fill an earthen pot half full of water, and put it in the ground, covered over with a board that has a hole in the middle; then cover the board with straw, hay, or such like, under which the mice taking shelter, creep to the hole, and will be drowned by falling into the water.

Some persons mix sand with their corn, which deters them from burrowing in it, by falling into their ears. See RATS, MICE, MOLES, &c.

VERNAL, something belonging to the spring season.

VETCH, the name of a well known plant, much cultivated in many parts of England, and of which there are several species.

Some sorts of this plant, the seeds of which ripen in autumn, grow naturally in most parts of England, in shady places among bushes, and by the sides of woods. The roots of these are perennial; but their stalks are annual, weak, and grow to so great a length, (for they will climb up to the height of six or eight feet wherever the tendrils which proceed from the end of their leaves can lay hold of boughs, branches, or the side of a hedge, to support them) that they are hardly fit to be cultivated in the field, though some writers have recommended them for this purpose: for as they cannot be supported there, they will trail so much upon the ground, that they will be apt to rot: nor do their shoots, which are less succulent than those of the vetch commonly raised, grow to a sufficient height to be cut for use till late in the spring, when there is a little want of green food for cattle.

Mr. Miller, after sowing for many years the common vetch or tare, which is much cultivated in the fields for fodder, seems to think that which has black seeds, a distinct species from the white; for he has never found either of them vary. Both these are annual, and perish soon after they have perfected their seed. Their stalks are angular, streaked, and hairy: they are weak, and want support, and generally trail upon the ground when they do not find any thing to fasten themselves to. Their leaves are composed of several pair of blunt lobes, and are terminated by tendrils. The flowers, which are pretty large, proceed from the wings of the stalk, and sit very close to the base of the foot stalks of the leaves. Two of these flowers generally spring from the same joint: those of the black seeded sort are purple, and those of the white seeded are white. They appear in June and July, and are succeeded by erect pods, containing three or four round seeds in each, which ripen in August and September.

The white vetch is rather the more succulent plant of the two, and therefore it is best for fodder: but many are unwilling to cultivate this sort, because their seeds, being white, are much sooner discovered by rooks and other birds, than those of the black, which bear a nearer resemblance to the colour of the ground. This objection may, however, be easily removed, by sowing them in drills, and then covering them carefully, instead of the usual method of scattering them with a broad-cast, and plough them in lightly.

The small black-seeded vetch, which some call rath-ripe, and others pebble, goat, or summer vetch, is much tenderer than either of the former, and therefore less cultivated. This must always be sown in the spring: whereas, the others may be sown in the spring or autumn.

But another species of vetch, viz. the Siberian, hardly known to the generality of farmers in this country, bids fair to become, perhaps, the most useful of all for fodder; for its stalks grow to a great length, and are well furnished with leaves, which do not decay in autumn, like those of the other sorts, but continue green all the winter, in defiance of the hardest frost: so that in February and March when there often is a scarcity of green fodder for ewes and

and lambs; this may be of singular service, especially if these plants are supported from trailing upon the ground. Their flowers, which appear in July, are of a light blue colour.

This, like our common vetch, may be sown in the spring, or in autumn; and when the plants are come up, they will not require any other culture than keeping them clear from weeds; a work which, if the seeds are sown thin in rows four feet asunder, as Mr. Miller rightly advises, may be easily done with the Dutch hoe, while they are young, and afterwards with the hoeing plough. By this thin sowing, the stalks of these vetches, which send out many branches, and extend very far, will be kept from matting so closely together as to rot each other by excluding the air; and by earthing up their stems in the same manner as should be done for peas and beans, they will be greatly strengthened, their leaves will grow the larger and more succulent, and they will consequently yield an increased quantity of fodder. The repeating of this as often as it may be found necessary to destroy the weeds in summer, which may be done at a very small expence, and is particularly proper when the growth is intended for the green food of cattle, will be attended with the farther important advantage of preparing the ground thoroughly for whatever other crop may afterwards be put upon it.

As the plants of this kind of vetch will not be in danger of being hurt by frost, they should not be cut till the spring, when the best way will be to take them as they may be wanted, green, for the feeding of ewes: but some of them should be left untouched, for seeds: for if those which are cut do shoot out again, they will flower so late in summer, that their seeds will not ripen, unless the autumn proves very warm. A better way will therefore to be sow a proper quantity of seeds for this purpose in a separate spot of ground: because when the other is cut, the ground may be ploughed for other crops; and if the seasons should be so mild as to produce a sufficiency of green food independent of this, the vetches may be ploughed into the ground, to which they will be an excellent dressing for other crops.

Mr. Miller, who has a high opinion of this sort of vetch, and whose recommendation of it ought to have very great weight, is now beginning to try it in the field, where he has not yet had experience of its culture; but the experiments which he has made with it for six years past, on small patches of it sown in gardens, in different situations, have fully answered his expectation: for he has found these plants continue in great verdure in all those places, when most of the perennial plants in the same situation have suffered greatly by the frost, and could have cut from only eight of them as much fodder as would have been equivalent to half a truss of clover.

Some years ago I had a few seeds of Mr. Miller of the Siberian vetch, and sowed them in a garden, against a south wall; they came up weak, and slender, and I found required to be supported. They run up pretty high, and the second year advanced to about five feet, and produced some seed. But they had very few leaves on their stems, and those which came out near their tops, were thin and dry; the stems and branches were also dry and wiry; so that I had no opinion of them for fodder to cattle, especially as they wanted to be supported; and therefore did not proceed in the culture of them: perhaps they were in an improper situation.

Vetches are generally sown either in autumn, or early in the spring: but the best time, in this country, is toward the beginning of August; because the rains which usually fall about that season will bring them up in a short time, and the plants will get strength before winter, and be fit to cut for the food of cattle early in the spring, when green fodder is most wanted; and if they are designed for seed only, these early sown vetches will come early into flower, and their seeds will ripen early, so that they may be cut and stacked in good weather, which is a great advantage; for those which ripen late are often stacked or housed wet, and then their seeds frequently sprout in the mow, and are spoiled.

Vetches will do well in almost any ground; not excepting even such as can scarcely produce any other plant. The common method of sowing them is in broad-cast, ploughing them lightly in, as was observed before; and the usual allowance is two bushels of seed for an acre of land, though some sow two bushels and an half. Either of these practices may do well enough for those vetches

which are intended to be cut for fodder in the spring, but when they are sown with a design to let them stand for seed, it will certainly be much better to sow them in drills, in the same manner as is practised for pease; and in this case less than half of the above-mentioned quantity of seed will be sufficient: for the rows should be at least three feet asunder, that the hoe-plough may have room to go between them, to destroy the weeds, and earth up the plants, which, when thus managed, will produce a much greater crop, and ripen better and earlier, than in the common way. These drills should be of about the same depth as for pease, and the seeds should be scattered at about the same distance in the drills, in which they should be carefully covered over as soon as they are sown; for otherwise the rooks will discover them; and when those voracious creatures once find the rows, they will speedily destroy them entirely, if they are not carefully watched. The preventing of this is another advantage which attends the sowing of vetches early in autumn, rather than in the spring: because there is more food for rooks and pigeons in the open field in the former of these seasons, and the plants will then appear much sooner above ground. Toward the end of October, by which time the plants will have acquired considerable strength, the horse-hoe should begin to work between the rows, provided the weather be dry: and in doing this, particular care should be taken to lay the earth up as high to the stems of the plants as can possibly be, without covering their tops. This will help to secure them against frost, and clear the ground of weeds at least till March, when the plants should be earthed up a second time, and the intermediate spaces between their rows be cleaned again, in the same manner as before. This will make them grow so vigorously, and they will meet and cover those spaces in a little time: whereas those sown in the spring will not grow to half this size, and will be very late in flowering.

When vetches are intended only for fodder, of which they generally afford two good crops in the year, in hot countries, or when the farmer designs them for ploughing in, by way of manure, they need not be sown in drills, or husbanded in the manner directed: the common broadcast way will then do well enough: but still it is most advisable, in either case, to sow them early in autumn; because, in the first place, they will produce the desired green fodder much earlier in the spring; and in the second, they will be fit to plough in much sooner the following year, and thereby have time properly to meliorate the land and prepare it to receive the ensuing crop, which they are generally allowed to do even more effectually than pease. Stiff clays are peculiarly benefited by this dressing; but it surely is bad husbandry to sow vetches for green fodder, where lucerne will thrive; because this last will yield greater plenty of still more nourishing food.

In some countries, especially abroad, they mix oats with their tares or vetches, an equal quantity of each, and sow them in February. The vetch, supported in some measure by the oat, grows the higher for it: and, about the middle of May, this mixture is moved, and given to horses and other cattle, which it fattens greatly. Mr. Mortimer likewise thinks it a good way to sow horse-beans and tares together: their seeds are easily parted with a riddle: and another observation, in which he agrees with the *Maisons Rustiques*, is, that more vetches should not be sown at any one time than can be covered the same day, because the dew is apt to spoil them: consequently they should not be sown till two or three hours after the rising of the sun; by which time the moisture will be exhaled from off the surface of the earth. But though their seeds cannot bear dampness, which would soon rot them, their plants, especially in sandy land, often perish in dry years, for want of water. To make them flourish well, they require a shower of rain every ten or twelve days. One ploughing to turn in the stubble of the preceding crop, and another at the time of sowing, are sufficient for this plant: but those who give only one ploughing, which is when they sow, and afterwards harrow in the seed, neither have, nor can expect, an equally good return.

When vetches are cultivated for their seeds, they should be cut soon after the pods turn brown, and stacked as soon as they are dry: for if they are suffered to lie out in the field, till they receive wet, and there then comes a hot day, most of the pods will burst, unless they happen to have been blighted; in which case they will not open so easily.

easily. Their haulm, when dry, and threshed, is esteemed good food for cattle, and some say that their seeds are as good for horses, as beans; which, if true, should render them the more valuable, because these will grow on the lightest sandy land, where beans will not thrive; and may therefore, as Mr. Miller observes, be a good improvement to some counties in England, where they do not even attempt to cultivate the bean. About three loads from an acre are reckoned a good crop.

Vetches, when threshed out, will be as good for sowing at the end of five or six years, as at first, if care be taken to turn them in the heap from time to time. Mr. Mortimer cautions the husbandman to lay them by themselves in some convenient place, separate from his other corn, because they will otherwise be apt to foul it.

It is commonly said, that the farmer cannot sow any thing more profitable than vetches; for that, besides enriching the land, a load of them will go farther than two loads of hay: but Mr. Lisle has a calculation tending to prove, that an acre of broad clover is worth twenty shillings a year more than an acre of any vetches, and that the clover should therefore be preferred, wherever the ground will bear it well.

"It would certainly, says Mr. J. Smith, an ingenious farmer of Essex, be of great national advantage, could our stock of cattle and sheep be increased without diminishing the quantity of our lands that are in tillage.

"This can no otherwise be done, but by encouraging the growth of artificial pastures, which the farmers have of late years fallen into.

"The turnep husbandry is not of very old standing in this island, yet has it made a very rapid progress. The immense utility of it, when properly practised, cannot but be evident, even to an ignorant common farmer, on the slightest inspection. This evident utility of it has occasioned its being almost universally practised in the counties of Norfolk, Suffolk, and Essex, whence it has spread to other parts of England, and is of late even adopted in Ireland, where I am informed, the gentry are very intent on improving their estates.

"The cole-seed plant has also its utility, and in many places is as universally sown as the turnep. I have, myself, very often raised this crop, as well for feeding sheep, &c. as for the sake of its seed, and have had no little success in this husbandry, being very fond of it, as cole-seed is an excellent crop to overpower, choak, and destroy weeds.

"I wish the burnet grass, so strongly recommended, may answer every purpose that is expected from it: it seems to promise very fair from the accounts given of it by Mr. Rocque; and if it has not too much prejudice to encounter withal, it may probably succeed, and the culture of it become as universally adopted, as is that of the turnep, or cole-seed plant, already mentioned.

"So much in general; but the particular reason of my now writing to you, was to recommend to the industrious farmer the cultivation of vetches as food for cattle.

"I have often sown this crop with great success, to prepare my land for wheat, and have always found that by growing to a large cover they destroy and choke up a great number of weeds, which would otherwise do me immense damage: indeed, I think them, for this purpose, next in rank to a hoeing crop.

"When I sow vetches before wheat, I always, in the spending my crop, have regard to the condition of my land. If my land is not in good heart, but wants mending, I not unfrequently fold my sheep on it, and feed off my crop in the field; but if it is inclined to be rank, or the wheat which is sowed on it, is apt to run much to straw, I often cut my vetches green, and feed my horses in the stable with them. I find no food agree better with them; they thrive well, grow fat, and are always in good health and spirits when thus fed.

"I sometimes also mow my vetches when they are in bloom, and make them into hay, in the same manner I manage my clover and meadow grass; all which I leave in grass cocks in the field, whilst it is haying, very seldom spreading it, for fear of rain; and after two or three turns it is generally fit to carry.

"The great art, in making hay of vetches, is to contrive in such sort, that the leaves do not drop off the plants, which, if left too long, or dried too suddenly, they are apt to do; and the farmer is to understand, that great part of

the peculiarly nourishing quality of the hay resides in the leaf.

"I say peculiarly nourishing, because almost every kind of cattle, as horses, oxen, cows, and sheep, are fond of it, and they all thrive on this food amazingly: this I have often experienced, and moreover observed, that they make no waste even of the stalks, which they eat with an appetite.

"In this manner I manage for my hay when I am inclined to have it very fine and fit for my cows and sheep; and in this manner it is no difficult matter to get it in good order, sweet, and wholesome: but when I intend it only for my horses, I generally let my crop stand something longer; that is, till the kid, or pod, is formed, and the seed about half grown within it.

"When the hay is made in the last way, the business is much more ticklish, and constant observation must be made to see when the crop is in proper order to cut, because if it is left too long, the stalks grow hard and sticky, and the leaves are apt to drop off.

"This hay is more nourishing, when cut in this last method, than I can well describe: it answers both for hay and corn; and with this food my horses will be in good flesh, health, and spirit, and be able to do a great deal of work. I have often proved this to be true, and can therefore the better venture to assert it.

"I have still another method of making these vetches into hay, which is to leave the crop, till the seed is grown to its full size in the pod, though not ripe: I then mow them, and, when dry, thresh them on a cloth in the field; by which means I procure a considerable quantity of pigeons meat, which fetches me a tolerable good price; and this pigeons meat sells better at market, than if the vetches had stood till the seed was thoroughly ripe: for by cutting the crop when the seeds are barely full grown before they begin to harden, they shrink in the drying, and thereby become of a smaller size than they are by nature, and consequently more proper food for pigeons than if they were larger.

"I own, the hay in this last method is not quite so good, as many of the leaves will, in spite of all the care that can be taken, drop off, and the stalks will be a little sticky: yet, after all, it serves very well for my ordinary cattle, and even for my plough and cart-horses, with the assistance of a few oats.

"Vetches are a very good plant to sow thick on land, and when they have formed a perfect cover, to plough them in, in order to the land's being sown afterwards with wheat on the ploughing. In this intention they answer to the full as well as buck-wheat, or clover.

"When a farmer intends to plough in his vetches, I would by all means advise him to do it some weeks before he sows his wheat, that they may have time to ferment and rot, or the consequences may be fatal to this crop: I once, myself, lost the chief part of a fine field of wheat by this oversight. *Museum Rusticum*, vol. II. p. 169.

"Vetches, says a gentleman farmer of Surry, are a grain often overlooked by the farmer; yet are they, when properly cultivated and applied to proper uses, highly valuable, and very beneficial.

"They are a very hardy grain, and resist the severity of a severe winter better than most other crops; besides which, they have the additional advantage of growing in almost any soil; but then the farmer is to expect a produce in proportion to the goodness of his land.

"I would by all means advise, where it is intended for early seed, or to stand for seed, that the small winter vetch be cultivated in preference to every other sort, because it is not only hardier, but also, being sown about Michaelmas, it is forwarder, to serve as fodder, or will be earlier ready to mow for seed, which is no inconsiderable advantage; for the vetch being a succulent plant, and forming a very thick cover on the land where it is a full crop, it will be in danger of rotting instead of drying, if it should be cut late, or the harvest weather should be very rainy; but if the winter vetch is sown early, it will, in general, be fit to mow in July, or the very beginning of August, when there is less danger.

"Few farmers allow more than one ploughing for vetches: I always allow two, notwithstanding what the neighbouring farmers tell me of turning the fresh soil again down to the bottom of the furrow: I find an advantage in this practice, and shall therefore continue it.

"I have generally experienced the first week in October, if

if the weather is fine, to be the very best time for sowing vetches; and I allow only two bushels of good seed to every acre, which I find full sufficient.

"I sow them broad-cast on the rough land, as the plough leaves it after the second ploughing, taking care to harrow the field length-ways and cross-ways, in order to cover the seed the better; after which I pass over it a roller, heavier or lighter, according to the nature of the soil and the dryness of the weather, observing, that if the weather is dry, and the soil light, I use a heavy roller, in order to close the pores of the light earth; but if the soil is stiff, and the weather damp, I use a lighter roller, lest I should knead and crust the field over, so as to stop the young shoot of the vetch.

"This crop will, in general, choke all the weeds that come up with it; but this must, however, be understood of the smaller sorts, for if there are many large rampant weeds, it will be necessary to have them extirpated with the hook.

"Vetches afford excellent food for sheep in the spring, make cows give a great deal of good milk, and horses are fonder of them, cut green, than almost any other food.

"The best way is to cut them fresh and fresh every morning as they are wanted; and if the farmer has occasion for them for this use only, he may sow in the spring, to great advantage, the large vetch, at different times; by which means he will have a succession of crops, which, to give green to his cattle, he should always cut just before the plant flowers, for it is then in its tenderest and most succulent state, and will afford most nourishment; whereas if he leaves it till the seeds are nearly ripe, the stalks harden, grow sticky, and are of far less value; besides that many of the lower leaves will, by this time, be withered, or dropped off, and entirely lost.

"I must not conclude without mentioning an important use to which vetches are often applied; I mean, a full crop of them is frequently ploughed into the land as manure, to prepare it for a succeeding crop of wheat.

"When vetches are sown with this intention, I would recommend the large sort, and that four bushels of good seed should be used, to be sown broad-cast twice in a place: but my way of sowing it is somewhat peculiar when I mean to plough it in; therefore I think it may not be amiss to relate it.

"Most farmers sow it by casting it twice in a place, immediately after the land is ploughed, and then harrow and roll the field; but I proceed as follows:

"As soon as the field is ploughed, I sow two bushels, broad-cast, on every acre; after which I harrow it length-ways and cross-ways. When this is done, I sow the remaining two bushels, and then harrow it twice again with a pair of heavier harrows, and finally scratch it twice over with light harrows to raise a mould, concluding my work by passing a roller over the whole field. By this management I scarcely ever miss of a full crop, which covers the whole land, chokes the weeds, and serves as excellent manure for the wheat that is to follow.

"I have always found that this husbandry succeeded best in light, hungry, sandy, or gravelly loams; and a brother of mine, who lives in Bedfordshire, tells me it does very well on a chalky soil provided there is any heart in it.

"The time I choose to plough in the vetches is just after the blossom fades, and the kid begins to form; and it is really surprising to see what a strong fermentation they raise in the soil.

"I have sometimes had my crops so heavy that I have been obliged to mow, or hook up, the vetches before I could plough the land: but this is not often the case; when it is, the farmer has reason to rejoice.

"There are, as I hinted in the beginning of this account, scarcely any soils but the vetch will thrive in, though ever so various in their nature. I am an old man, and in the course of many years experience have sown vetches often on a sandy and gravelly loam, a chalk, though not for ploughing-in, a gravel, a low damp clay, and a perfect brown loam. On all these varieties of soil have they succeeded with me; but I must note, that the farmer may expect a larger crop from a gravel (I do not mean a pure gravel) that has some heart and strength in it, than from the finest loam, which has been by a long-continued course of bad culture, starved and impoverished.

"The large vetch may be sown in January, February, March, April, or even the beginning of May, when designed for green fodder; but I would, by all means, have the industrious farmer avoid sowing it before Christmas, for

it is a tender plant, and if hard frost ensue, he may chance to lose his crop." *Museum Rusticum*, vol. III. p. 185.

Mr. Marshall, in his *Minutes of Agriculture*, says, "that the idea of tare-haymaking, is if the weather happens to be fine the fodder is incomparable, but one shower of rain sends it immediately to the dung-hill; but he is convinced from experience, that if tares are cut at a proper age, (that is while the underpods are filling and the halm still green at the bottom), it is not a shower that will hurt them, nor a whole day's rain that will spoil them. That with proper management nothing but a fortnight or three weeks rain can fit them for the dung-hill; and the chance is ten to one that such weather does not happen in July; therefore it is ten to one but tare-hay may be got in tolerably."

In his *Rural Economy of Norfolk*, he says, "when we consider the nature of the Norfolk soil, and the excellency of the Norfolk husbandry, we are, at the first sight, surprised that vetches are not more in use, as summer-food for farm-horses; and nothing, perhaps, but the established prevalence of clover can account for it. Clover is not only mown for foiling horses in the stable; but, as has been already noticed, horses are frequently roped or teddered on clover; as well as turned upon it loose.

"This practice was, probably, established when clover was new to the soil, and the crops of course large and luxuriant; and it was then no doubt the most eligible management: nevertheless, it may, now, when the soil is no longer the favorite of clover, be worth the attention of farmers, of the present day, to try whether more vetches, and proportionably less clover, would not be the most eligible management."

VINES; the following observations and directions relating to the culture of VINES, were made by a British merchant who resided many years in Madeira.

The best situation is on the sides of hills which have a south exposure, and the best soils are the rich and light of a reddish colour, or a mixture of the red and black, and which are not liable to receive and lodge drains of water which make the wine weak; for which reason flat lands and bottoms, though rich, seldom produce good wine, except in very dry summers.

The season for planting is from the middle of November to the end of February; the slips or cuttings are to be from a foot and a half to two feet and a half long; they are to be set two feet in the ground, about three feet distant, in straight rows or trenches about four or five feet asunder. After one trench is opened, and the earth taken out or laid on one side of it, forming a bank, the butt ends of the vines are to be put into the bottom of the trench, and the small ends extended sloping up the bank, then the trench is to be filled with earth dug from the sound land, the depth of the trench, breaking the clods, taking out the stones, hawling all the earth towards the vines, and thus making a second trench at the distance above mentioned from the first; in the same manner proceed to plant the whole vineyard. Thus the ground will be lightened all over as well as where it touches the vines, will be cleared of stones, the roots of trees, shrubs and grass, which are all to be carefully picked out. A vineyard planted in this manner will last fifty or sixty years in Madeira.

They are not to be pruned till they have been two or three years planted. The season for pruning is from the middle of November to the end of January, or later; in doing this, no part of the vine is to be cut, but the new shoots which are to be cut off every year, at the end of every second or third joint. The largest of these cuttings are to be saved for planting, and will keep several weeks above ground; but if they should be cut early, and not planted till late, the butt end should be covered with earth.

Supporting the vines, &c. is done three or four feet high, by sticking stakes in the ground from end to end of the rows, then lashing long slender poles near the heads of them, and across the poles are to be laid, both ways, reeds or canes, at the distance of two or two feet and a half, which are to be tied to one another and the poles where they cross, with split willow-twigs; the canes, if full grown and hard, will last two or three years. The second or third year after planting vines, they are to be raised and fastened to the stakes and poles with twigs, and the branches spread open, and loosely tied to the poles and canes, so that they may not be too thick in some places, and too thin in others.

The vineyards should be dug-up with narrow billing hoes every spring and fall, and the clods broken; this work is very laborious, as the people are obliged to perform it on their knees under the canes; but sometimes the canes are uncid, and after the ground is dug, tied on again.

The third year after the vines have been planted they generally produce a pretty good crop of grapes fit to make wine. When they are almost come to their full size, they are to be gradually exposed to the sun, by frequently thinning the leaves, till every branch lies open to the sun some part of the day; but if this should be done while the fruit is green, or; all at once, when near ripe, it would wither, and the juice would never be rich. The grapes must hang till they are very ripe, and many, on almost every branch, begin to turn to raisins, otherwise the wine will always be weak, harsh, or rough, and without much flavour; hence, it is evident, the grapes should not always be promiscuously gathered, all at once, but two or three vintages made, gathering only what are ripe each time.

The vine-press is a vat from six to nine feet square, according to the largeness of the vineyard, made of planks about eighteen or twenty inches broad, and two and a half or three inches thick, so fixed to a bottom of the same, or greater thickness, that they may be pressed close to it, and one another, at the corners, by the help of posts or studs, and wedges; it may also be caulked, if necessary.

On one side of the vat a spout is to be placed, on which a wicker basket is to be hung to strain the wine as it runs into a tub, which is commonly placed half way in the ground to accommodate it to the height of the vat. When the grapes are gathered they are thrown into the vat, and may rest near twenty-four hours, if so much time be required to fill it; then, the spout being stopped, people go into the vat and tread the grapes very well with their bare feet, then they open the spout and draw off the juice as long as it will run without pressing; when the spout is to be re-stopped, the grapes trod over again, then gathered to a heap in the middle of the vat, and confined with a large white rope tied round them, or with a haircloth, or layers of straw, and then with short planks and piles of blocks, laid across each other, pressed by a large beam, assisted with weights at the end, with a screw, or otherwise in the manner of a cyder press. The wine which runs without pressing is not so good as the first pressing, but better than the second or third. From the tub it is put into casks free from mustiness or any ill smell. To every pipe, which should not be above three-fourths full, there must be put two or three pounds of the powder of jesso, which is to be well mixed by stirring the wine strongly with a staff reaching to the bottom of the cask, and a little flatted on the sides towards the lower end; this stirring is to be repeated twice a day, for five or six minutes each time, till the wine has done fermenting, which may be known by listening at the bung, and by observing it to settle and clear; also by the taste.

Care should be taken to prevent any body from smelling at the bung or a vent-hole while the wine is working, the vapour being sometimes so strong as to kill people on the spot.

The jesso is a greyish soft stone, with a mixture something like chrystal; it is brought from Spain, and sold at Cadiz for six or eight ryals the quintal; it is prepared by breaking it into small lumps, then burning it for a short time in an open wood fire; it is then to be powdered in a mortar, and sifted through a common hair sifter, when it becomes as white as lime. The use of the jesso is to break the viscidty of the must or new wine, which is often so nearly of the consistence of a syrup, that its particles settle to the bottom of the vessel, and cannot, by their own gravity, disentangle themselves and bring about that motion called fermentation, without which the liquor would never be wine, but remain sweet or vapid; thus we see melasses, till thinned by water, will not ferment enough to yield much spirit by distillation, if any. From these considerations it is evident, that the quantity of jesso, necessary for a rich sweet must, would be too much for a poor thin one, would carry down too much of the sweetness, make it overwork, and leave it harsh, or perhaps turn it to vinegar, which is the usual effect of an over fermentation, or of a second one, without one of which good vinegar cannot be made; as the best wines may be, or are thus easily, turned to vinegar, it is of use to know how to prevent it, which may be done by racking the wine, when it appears to have worked enough, into another cask, well smoaked with a brimstone match hung by a wire in the cask till it is extinguished, the bung being lightly stopped all

the time. This operation is to be repeated once or twice, if this fermentation does not stop the first time. I have used this with success, but it is not practised by the Portuguese in Madeira. If the wine should have overworked and turned before this method is taken, it cannot be recovered.

Here I must give a caution never to smoak, with a match, a cask that has had rum in it, or any spirit, without washing it well with water; for the spirit would take fire, and, if the bung did not fly out immediately, would burst the cask.

When the wine is settled, and quite clear, it may be racked into clean dry casks as soon as you please, and if it has a finariness, like brisk cyder, the casks may be smoaked as above, to prevent a new fermentation.

Some people think it injures new wine to draw it soon from the lees, but it should never be suffered to stand longer on them than the beginning of the next spring after it was made, lest in the hot weather the lees should excite a new fermentation. The lees should be saved for distillation, and will yield a fifth or sixth part of brandy.

In Madeira the grapes are destroyed, when in flower, by foggy weather, misty rains, or when just beginning to knit, and such as do not fall grow no bigger than small currants. They are always hurt by rain after June; and, in general, the hotter and drier the summer, the better the wine is both in flavour and strength.

No good wine can be made in moist lands, or above one third of the distance from the sea towards the mountains, or on the north side of the island, though the lands there are good, and only the best sort of grapes are cultivated.

Wine is not to be attempted in countries subject to much rain in the summer season. A single shower of rain, if sufficient to reach the roots of the vines, will spoil a whole vintage, if the grapes are near ripe, unless they are suffered to hang till the new watery juices, acquired by the rain, have time to ripen again.

While the wine is working, the bung-hole is to be covered with a piece of loose board, and afterwards lightly stopped. The casks, after the wine is racked, should never stand full, but want four or five gallons.

After wine is drawn from the lees, it should be carefully racked every eight or ten weeks, for a year or longer, and the turbid wine in the bottoms put together to clear; but this wine will never be so good as the wine it came from, often turning sour.

The most convenient way of racking is by a large hole near the bottom of the head, which is to be stopped with a plug, wrapped round with a flag or banana bark; when this is taken out for racking, a short piece of cane is to be introduced in its room, to draw the wine through in pails or buckets.

The pipe should be gently tilted before any wine is drawn out of it, and secured by blocks or chocks to prevent its being disturbed. The driest and warmest stores are best for wine, and in warm countries those above ground are better than cellars. The brimstone matches are made by dipping a piece of linen rag, about three fingers broad and five in length, into melted brimstone, or is better done by dipping a long strip of linen, and gently twisting it round, to make it the easier to pass into the bung-hole than a broad flat piece would, cutting it when cold into proper lengths.

VINEGAR, an acid penetrating liquor, prepared from wine, cyder, beer, &c. of considerable use both as a medicine and sauce.

The process of turning vegetable matters to vinegar, is thus delivered by Dr. Shaw: take the skins of raisins, after they have been used in making wine; and pour three or four times their own quantity of boiling water upon them, so as to make a thin aqueous mixture. Then set the containing cask, loosely covered, in a warmer place than is used for vinous fermentation; and the liquor in a few weeks time will become a clear and sound vinegar; which being drawn off from its sediment, and preserved in another cask, well stopped down, will continue perfect, and fit for use.

This experiment shews us a cheap and ready way of making vinegar from refuse materials; such as husks of grasses, decayed raisins, the lees of wine, grounds of ale, beer, &c. which are frequently thrown away as useless. Thus, in many wine countries, the marc, rape, or dry pressing of grapes, are thrown in heaps, and suffered to putrefy unregarded, though capable of affording as good vinegar as the wine itself. In some places they bury copper-plates in these husks, in order to make verdegis; but this practice seems chiefly confined to the southern parts of France.

Our

Our present experiment shews us how to convert them to another use ; and the direction extends to all the matters that have once undergone, or are fit to undergo, a vinous fermentation, for that all such matters will afford vinegar. Thus all our summer-fruits in England, even black-berries ; all the refuse washings of a sugar-house, cyder-pressings, or the like, will make vinegar, by means of water, the open air, and warmth.

The whole process, whereby this change is effected, deserves to be attentively considered ; and, first, the liquor to be thus changed, being kept warmer than in vinous fermentation, it begins, in a few days, to grow thick or turbid ; and without throwing up bubbles, or making any considerable tumult, as happens in vinous fermentation, deposits a copious sediment.

The effect of this separation begins to appear, first, on the surface of the liquor, which gathers a white skin that daily encreases in thickness, till at length it becomes like leather ; and now, if continued longer in this state, the skin turns blue, or green, and would at last grow solid, and putrefy : therefore, in keeping down this skin as it grows, and thrusting it gently to the bottom of the vessel, consists much of the art of vinegar making, especially from malt. For the difference between vinous and acetous fermentation, see the article FERMENTATION.

Method for making Cyder-VINEGAR. The cyder (the meanest of which will serve the purpose) is first to be drawn off fine into another vessel, and a quantity of the must, or pouz of apples, to be added : the whole is set in the sun, if there be a conveniency for the purpose : and, at a week or nine days end, it may be drawn off. See CYDER.

Method of making Beer-VINEGAR. Take a middling sort of beer, indifferently well hopped ; into which, when it has worked well, and is grown fine, put some rape, or husks of grapes, usually brought home for that purpose : mash them together in a tub ; then, letting the rape settle, draw off the liquid part, put it into a cask, and set it in the sun as hot as may be (the bung being only covered with a tile, or slate-stone and in about thirty or forty days, it will become good vinegar, and may pass into use as well as that made of wine, if it be refined, and kept from turning musty.

Or thus : to every gallon of spring-water add three pounds of Malaga raisins ; which put into an earthen jar and place them where they may have the hottest sun from May till Michaelmas ; then pressing all well, tun the liquor up in a very strong iron-hooped vessel, to prevent its bursting : it will appear very thick and muddy, when newly pressed ; but will refine in the vessel, and be as clear as wine.

Thus let it remain untouched for three months, before it be drawn off, and it will prove excellent vinegar.

Method of making Wine-VINEGAR. Any sort of vinous liquor, being mixed with its own faeces, flowers, or ferment, and its tartar, first reduced to powder : or else with the acid and austere stalks of the vegetable from whence the wine was obtained, which hold a large proportion of tartar : and the whole being kept frequently stirring in a vessel which has formerly held vinegar, or set in a warm place full of the steams of the same, will begin to ferment a-new, conceive heat, grow sour by degrees, and soon turn into vinegar.

The remote subjects of acetous fermentation are the same with those of vinous ; but the immediate subjects of it are all kinds of vegetable juices, after they have once undergone that fermentation which reduces them to wine : for it is absolutely impossible to make vinegar of must, the crude juice of grapes, or other ripe fruits, without the previous assistance of vinous fermentation.

The proper ferments for this operation, whereby vinegar is prepared, are, 1. The faeces of all acid wines. 2. The lees of vinegar. 3. Pulverised tartar, especially that of Rhenish wine, or the cream, or crystals thereof. 4. Vinegar itself. 5. A wooden vessel well drenched with vinegar, or one that has been long been employed to contain it. 6. Wine that has often been mixed with its own faeces. 7. The twigs of vines, and the stalks of grapes, currants, cherries, and other vegetables of an acid austere taste. 8. Bakers leaven, after it is turned acid. 9. All manner of ferments, compounded of those already mentioned.

The French use a method of making vinegar different from that above described. They take two large oaken vessels, the larger the better, open at top ; in each whereof they place a wooden grate, within a foot of the bottom ;

upon these grates they first lay twigs, or cuttings of vines, and afterwards the stalks of the bunches, without the grapes themselves, or their stones ; till the whole pile reaches within a foot of the brim of the vessels : then they fill one of these vessels with wine to the very top, and half fill the other ; and with liquor drawn out of the full vessel, fill up that which was only half full before ; daily repeating the same operation, and pouring the liquor back from one vessel into another ; so that each of them is full, and half full, by turns.

When this process has been continued for two or three days, a degree of heat will arise in the vessel, which is then but half full, and increase for several days successively, without any appearance of the like in the vessel which happens to be full, during those days ; the liquor whereof will still remain cool ; and as soon as the heat ceases in the vessel that is half full, the vinegar is prepared : which, in the summer, happens on the fourteenth or fifteenth day from the beginning ; but in the winter, the fermentation proceeds much slower : so that they are obliged to forward it by artificial warmth, or the use of stoves.

When the weather is exceeding hot, the liquor ought to be poured off from the full vessel into the other twice a-day : otherwise, the liquor will be over-heated, and the fermentation prove too strong ; whence the spiritous parts will fly away, and leave a vapid wine, instead of a vinegar, behind.

The full vessel is always to be left open at the top, but the mouth of the other must be closed with a cover of wood, in order the better to keep down and fix the spirit in the heat of fermentation. The vessel that is only half full seems to grow hot, rather than the other, because it contains a much greater quantity of the vine-twigs and stalks, than that, in proportion to the liquor ; above which the pile, rising to a considerable height, conceives the more, heat and so conveys it to the wine below.

Vinegar is a medicine of excellent use in all kinds of inflammatory and putrid disorders, either internal or external : in ardent bilious fevers, pestilential and other malignant distempers, it is recommended by Boerhaave as one of the most certain sudorifics. Weakness, fainting, vomiting, hysterical and hypochondriacal complaints have also been frequently relieved by vinegar applied to the mouth or nose, or received into the stomach. Distilled vinegar has the same virtues, only in a stronger degree.

There are also medicated vinegars, as vinegar of antimony, of elder, litharge, roses, squills, treacle, &c. which derive their chief virtues from the vinegar.

VIPER, the name of a well known serpent, common in many parts of England.

The bathing the part bit by a viper with olive oil, or its own fat, is said to effectually prevent the fatal consequences that would otherwise attend it.

VIVES, a disease in horses, which differs from the strangles only in this, that the swellings of the kernels under the ears of the horse (which are the parts at first chiefly affected) seldom gather, or come to matter, but by degrees perspire off, and disperse, by warm cloathing, anointing with the marshmallow ointment, and a moderate bleeding or two. But should the inflammation continue, notwithstanding these means, a suppuration must be promoted by the methods recommended in the strangles. See the article STRANGLES.

When these swellings appear in an old or full-aged horse, they are signs of great malignity, and often of an inward decay, as well as forerunners of the glanders.

The mercurial ointment mentioned in the article STRANGLES may be prepared thus :

Take of crude mercury, or quicksilver, one ounce ; Venice-turpentine half an ounce ; rub together in a mortar till the globules of the quicksilver are no longer visible ; then add two ounces of hogslard.

Some authors recommend this ointment to be used at first, in order to disperse the swellings, and prevent their coming to matter ; bleeding and purging at the same time for that purpose ; but as in young horses they seem to be critical, the practice by suppuration is certainly more eligible and safe ; for want of properly effecting which, the humours frequently settle, or are translated to the lungs, and other bowels ; or falling on the fleshy parts of the hind quarters, form deep imposthumes between the muscles, which discharge such large quantities of matter, as sometimes kill the horse.

horse, and very often endanger his life. *Bartlett's Farriery*, p. 99.

Another author speaks of them as being "certain flat kernels much like bunches of grapes, growing in a cluster, close knitted together in the part affected."

"They center from the ears, and creep downwards between the chap and the neck of the horse towards the throat, and when inflamed they swell, and not only are painful to the horse, but prove mortal by stopping his wind, unless a speedy course be taken for the cure."

"They cause such a difficulty of breathing, and uneasiness, that he will oftentimes lie down and start up again, and tumble about after a strange manner."

"This distemper is occasioned by drinking cold water, after a violent heat; which causing the humours to melt down, they fall too plentifully upon the natural glands or kernels; also by eating too much barley, oats, rye, rankness of blood, &c."

"The cure. If the vives are not grown so large as that the horse is in immediate danger of being stifled, do not open the tumours, but rather endeavour to rot them, by taking hold of the kernel with a pair of pincers or pliers, and beating the swellings gently with the handle of a shoeing hammer, or bruising them with your hand, till they become soft enough, and they will afterwards disappear; but this is not to be done till the swellings are pretty ripe, which may be known by the easy separation of the hair from the skin, if you pluck it with your fingers."

"Having rotted (or in case of necessity) opened the vives, let the horse be let blood under the tongue, and afterwards in the flanks; wash his mouth with salt and vinegar; and blow some vinegar into his ears, rubbing and squeezing them hard to make it penetrate; for this will considerably assuage the pain which it communicates to the jaws."

"Then give the horse to drink a quart of wine with two handfuls of hemp-seed pounded, two nutmegs grated, and the yolks of half a dozen eggs, and wash him gently after for an hour."

"About an hour after giving him the draught inject the following glyster; boil an ounce and half of sal polychrestum, finely powdered in five pints of beer; when you have taken it off the fire, put it into two ounces of oil of bays, and squirt all in blood warm."

"As to our practice in England in the cure of this distemper; some cut holes where the kernels are, and pick them out with a wire, then fill the hole with salt, and at three days end it will run; and afterwards wash it with sage juice, and heal it with an ointment made with honey, butter, and tar, or with green ointment, and also use other means with it; but the efficacious receipts are these following:

Take tar, tried hog's-grease, bay-salt and frankincense powdered, of each as much as will suffice; melt them together; and with a clout fastened to a stick, scrub the place four or five mornings, until the inflamed part become soft and ripe; then slit the skin with your incision-knife, let forth the corruption, and heal it with tried hog's-grease, and verdegris, made up into fine powder: melt them upon a fire, and let not the stuff boil more than a walm or two; then put in some ordinary turpentine, and so still all together till it be cold, and then carefully anoint the sores therewith till it is healed."

"Another excellent way is, to take a pennyworth of pepper beaten into fine powder, a spoonful of swine's grease, mix them very well together, and convey the stuff equally into both the ears of the horse, so tie or stitch them up, then shake them that the medicine may sink downwards, and this being done, let him bleed in the neck-vein and temple-vein."

"But the most common way of cure, and such as our farriers use, is to let him bleed on both sides the neck-veins, then to scar the swelling with a small hot iron, from the root down to the bottom of the ear, till the skin looks yellow; the same iron being in shape somewhat like an arrow's head, with three or four small lines drawn from the body of it; and after searing, in order to take out the heat of the fire, and to make it sound again, anoint it with fresh butter, or with hog's-grease, and he will do well."

ULCER, a solution of the soft part of an animal body, together with the skin.

The first intention in the cure of ulcers is bringing them

to digest, or discharge a thick matter; which will in general be effected by the green ointment, or that with precipitate; but should the sore not digest kindly by these means, but discharge a gleety thin matter, and look pale, you must then have recourse to warmer dressings, such as balsam, or oil of turpentine, melted down with your common digestive, and the strong beer poultice over them; it is proper also in these kinds of sores where the circulation is languid, and the natural heat abated, to warm the part, and quicken the motion of the blood, by fomenting it well at the time of dressing; which method will thicken the matter, and rouse the native heat of the part, and then the former dressings may be re-applied."

If the lips of the ulcer grow hard or callous, they must be pared down with a knife, and afterwards rubbed with the caustic."

Where soft fungous flesh begins to rise, it should carefully be suppressed in time, otherwise the cure will go on but slowly; if it has already sprouted above the surface, pare it down with a knife, and rub the remainder with a bit of caustic; and to prevent its rising again, sprinkle the sore with equal parts of burnt allum, and red precipitate; or wash with the sublimate water, and dress with dry lint even to the surface, and then roll over a compress of linen as tight as can be borne; for a proper degree of pressure, with mild applications, will always oblige the spongy excrescences to subside, but without bandage the strongest will not so well succeed."

All sinusses, or cavities, should be laid open as soon as discovered, after bandages have been ineffectually tried; but where the cavity penetrates deep into the muscles, and a counter opening is impracticable or hazardous, where by a continuance, the integuments of the muscles are constantly dripping and melted down; in these cases injections may be used, and will frequently be attended with success. A decoction of colcothar boiled in forge-water, or solution of lapis medicamentosus in lime-water, with a fifth part of honey and tincture of myrrh, may be first tried, injecting three or four ounces twice a day, or some resin melted down with oil of turpentine may be used for this purpose: if these should not succeed, the following, which is of a sharp and caustic nature, is recommended on Mr. Gibson's experience."

Take of Roman vitriol half an ounce, dissolve in a pint of water, then decant and pour off gently into a quart bottle; add half a pint of camphorated spirit of wine, the same quantity of the best vinegar, and two ounces of Ægyptiacum."

This mixture is also very successfully applied to ulcerated greasy heels, which it will both cleanse and dry up."

These sinusses or cavities frequently degenerate into fistulæ, that is, grow pipey, having the inside thickened, and lined as it were with a horny callous substance. In order to their cure, they must be laid open, and the hard substance all cut away; where this is impracticable, scarify them well, and trust to the precipitate medicine made strong, rubbing now and then with caustic, butter of antimony, or equal parts of quicksilver and aquafortis."

When a rotten or foul bone is an attendant on an ulcer, the flesh is generally loose and flabby, the discharge oily, thin, and stinking, and the bone discovered to be carious, by its feeling rough to the probe passed through the flesh for that purpose. In order to a cure, the bone must be laid bare, that the rotten part of it be removed; for which purpose, destroy the loose flesh, and dress with dry lint; or the doills may be pressed out of tincture of myrrh or euphorbium: the throwing off the scale is generally a work of nature, which is effected in more or less time, and in proportion to the depth the bone is affected, though burning the foul bone is thought by some to hasten its separation."

Where the cure does not properly succeed, mercurial physic should be given, and repeated at proper intervals; and to correct and mend the blood and juices, the antimonial and alterative powders, with a decoction of guaiacum and lime-waters, are proper for that purpose. *Bartlett's Farriery*, p. 253."

ULIGINOUS, an appellation given to a moist, moorish, and fenny soil."

UMBEL, the extremity of a stalk or branch of a plant, divided

divided into several peduncles, or rays, beginning from the same point, and opening in such a manner, as to form an inverted cone.

UMBELLIFEROUS Plants, those whose flowers are produced in an umbel, on the top of the stalks, somewhat resembling an umbrella. Of this kind are the fennel, parsley, parsnip, carrot, hemlock, &c.

UNDER-DRAINING. See **DRAINING UNDER.**

UNDERWOOD, coppice, or any wood not accounted timber. See the article **COPPICE.**

VOOR, fallow land. See the article **FALLOW.**

URE, the udder of a cow, sheep, &c.

URINE, a ferous and saline matter separated from the blood of animals, and emitted by the canal of the urethra.

It is of excellent use as a manure, when deprived of its hot fiery particles by time, which will so alter its nature as to render it an extraordinary fertilizer of every kind of soil. Columella certifies that old urine is excellent for the roots of trees. Mr. Hartlib commends the Dutch for preserving the urine of cows as carefully as they do the dung, to enrich their lands; and instances a woman he knew near Canterbury, who saved in a pail all the urine she could, and when the pail was full, sprinkled it on her meadow, the grass of which looked yellow at first, but afterwards grew surprisingly. Similar to this is what Mr. Bradley relates, as of his own knowledge. Human urine was thrown into a little pit constantly every day, for three or four years. Two years after, some earth was taken out of this pit, and mixed with twice as much other earth, to fill up a hollow place in a grass walk. The turf which was laid upon this spot grew so largely and vigorously, besides being much greener than the rest, that, by the best computation he could make, its grass, in a month's time, was above four times as much in quantity as that of any other spot of the same size, though the whole walk was laid on very rich ground. The author of the English Improver is therefore very right in saying that human urine is of greater worth, and will fatten land more than is generally imagined by our farmers, whom he advises to take all opportunities of preserving this, and every sort of urine, for their ground, as carefully as is done in Holland.

Sometimes a horse is seized with an excessive flux of crude and undigested urine, resembling water, by which his strength is drained by degrees: it proceeds from heat and sharpness of the blood, or an inflammation in the kidneys, which, like a cupping glass, suck in the concocted serum from the veins.

The remote causes, are the immoderate and irregular working of young horses, cold rains in the beginning of winter, eating of oats brought over by sea, which, being spongy, draw in the spirits of the salt water.

As for the cure, the horse is to be fed with bran instead of oats; giving him a cooling glyster; next day let him bleed; the day following inject another glyster; the next day after that, bleed him again, not taking away above the quantity of two pounds of blood at a time; this done, boil two quarts of water, and put it into a pailful of common water, with a large handful of oriental bole beat to powder: mix

all well together, and let the horse take it luke-warm for his ordinary drink morning and evening, giving him full liberty to quench his thirst, which, in this disease, is excessive; for the more he drinks, he will be the sooner cured.

As for remedies to provoke urine in horses, which are often necessary,

Take about four ounces of dried pigeon's dung in powder, and boil it in a quart of wine-water; after two or three walms strain out the liquor, give it the horse blood warm, then walk him for half an hour, and he will stale if it be possible.

Another good remedy for a horse that cannot stale, is to lead him into a sheep-cote, and there unbridle him, suffering him to smell the dung, and roll and wallow in it; for he will infallibly stale before he comes forth, if he be not past cure.

This quick effect proceeds from a subtle and diuretic salt, that streams out from the sheeps-dung, and strikes the brain; since by reason of the correspondence of that with the lower parts, it obliges the expulsive faculty to avoid the urine.

The urinary passages are frequently stoppt by thick phlegm, which will scarce give way to the above-mentioned medicines, and therefore recourse may be had to the following receipt:

Take an ounce of saffra-wood with the bark, cut it small, and infuse it in a quart of white wine, in a large glass bottle well stoppt, so as two-thirds of the bottle may remain empty: let it stand on hot ashes for about six hours, then strain out the wine, and give it the horse in a horn.

This remedy will certainly afford relief, either by urine or sweat, the matter of which is known to be the same.

To cause a horse to stale for his benefit in some cholics, put two ounces of sugar of dialthæa to a quarter of a pound of Castile soap, beat them well together, make pretty big balls, and dissolve one of them in a pint and a half of strong beer scalding hot; when it is lukewarm give him a hornful, and let him fast an hour.

For the Stoppage of Urine, when a Horse cannot stale.

Pound half a pound of aniseeds, and a handful of parsley-roots; or if you have not them, half an ounce of parsley-seeds, pound them, and boil them in a quart of strong white-wine, or for want of that, as much old strong beer; then strain it off, and add a dram of oyster-shells finely powdered, give it the horse milk-warm.

URITH, etherings, or windings of hedges.

URIVES, nets to catch hawks with.

URRY, a sort of blue or black clay, lying near a vein of coal.

USTILAGO, the same with burnt grain. See the article **BURNT-GRAIN.**

UTENSIL, a domestic moveable of any kind.

W.

WAD, black lead.

WAGGON, a vehicle or carriage, of which there are various forms, accommodated to the different uses they are intended for.

WAIL, an estray, which, for want of the owner's appearance after it has been cried and published in the neighbouring markets, is forfeited to the lord of the manor.

WALK, among horsemen, is the slowest, and least raised of all horse's goings. It is performed by a horse's lifting

up his two legs on a side, the one after the other, beginning with the hind leg first. Thus, if he leads with the legs of the right side, then the first foot he lifts is the far hind-foot, and in the time he is setting it down, (which in a step is always short of the tread of his fore-foot on the same side) he lifts his far fore-foot, and sets it down before his near fore-foot. Again, just as he is setting down his far fore-foot, he lifts up his near fore-foot, and sets it down again just short of his near fore-foot; and just as he is setting it down

he lifts his near fore-foot, and sets it down beyond his far fore-foot.

WALL, the principal part of a building, as serving both to inclose it, and support the roof, floors, &c.

Walls are distinguished into various kinds, from the matter whereof they consist, as plastered or mud-walls, brick-walls, stone-walls, flint or boulder-walls, and boarded-walls. In all which these general rules are to be regarded: 1. That the right angle therein depending is the true cause of all stability, both in artificial and natural position. 2. That the massiest and heaviest materials be the lowest, as fitter to bear than be borne. 3. That the walls, as they rise, diminish proportionably in thickness, for ease both of weight and expence. 4. That certain courses or ledges, of more strength than the rest, be interlaid, like bones, to strengthen the whole fabric.

Brick-walls are the most important and usual amongst us. In these, particular care is to be taken about laying of the bricks; that in summer they be laid as wet, and in winter as dry, as possible, to make them bind the better with the mortar: that in summer, as fast as they are laid, they be covered up to prevent the mortar, &c. from drying too fast: that in winter they be covered well to protect them from rain, snow, and frost, which are all enemies to mortar: that they be laid joint on joint in the middle of the walls as seldom as may be: but that good bond be made there as well as on the outside. Care is to be taken that the angles be firmly bound, which are the nerves of the whole edifice. In order to which, in working up the walls of a building, it is not advisable to raise any wall above eight feet high, before the next adjoining wall be brought up to it, that so good bond may be made in the progress of the work; it may be worth notice, that a wall, a brick and a half thick, with the joint, will be in thickness fourteen inches or very near; whereas one hundred and fifty or one hundred and sixty bricks will lay a yard square measure upon the face of the building; and to the square of ten feet are usually allowed seventeen hundred or eighteen hundred bricks. Flints, or boulder walls, are much used in some parts of Sussex and Kent, for fence-walls, round courts, gardens, &c. A right and left-handed man fits well for this work, as they have a hod of mortar poured down upon the work, which they part between them, each spreading it towards himself, and so they lay in the flints. The mortar for this work must be very stiff. See FENCE.

WALLNUT-TREE, the name of a well known tree, formerly held in great esteem in this country, for its wood, which is, in fact, often very finely veined; but, on account of its aptness to be worm-eaten, it has of late given place to the beautiful and much sounder mahogany, with which our cabinet-makers have been pretty plentifully supplied from the British settlements in the West Indies.

As an useful fruit tree, independent of its timber, which is, however, still of good value, it merits the husbandman's attention; nor can the gentleman easily find a more stately one to adorn his park with, or to form a noble avenue to his mansion.

These trees are raised from their nuts, which it is best to keep in dry sand, with their outer covers on, till February; that being the right time for planting them. If they are intended for timber trees, they should be sown in the places where they are to remain, in order that the breaking or otherwise shortening of their roots, and especially those of the tap kind, may not stint their growth, and make them run out in branches: but if they are designed for fruit, their fertility will be increased by transplanting them, because their downright roots, which are those that chiefly encourage the luxuriant growth of wood in all sorts of trees, will be thereby checked, and they will be made, in lieu of them, to strike out numbers of lateral roots, which as experience has proved, always conduce greatly to the production of the largest and fairest fruit. The most proper season for transplanting them is when their leaves begin to decay; and the best age, when they have had three or four years growth in the nursery. Mr. Miller says he has frequently experienced that there is little danger of their succeeding, although they be eight or ten years old when they are transplanted: but, however that may be, it is certain that they will root best, grow largest, and last longest, if they are removed young. The less their branches are cut at the time of transplanting, or indeed at any time after, the better they will prosper; for much lopping often causes them to decay: but if there be a necessity for taking off any of their boughs, it should be done early in September, that the wound may have

time to heal before the cold and wet come on. It is likewise essential to cut the branch off quite close to the trunk, lest the stump which is left, should decay, and rot the body of the tree; to prevent which, especially if the wound be large, it will be right to smooth it well with a chissel, and then to cover it over carefully with a cement of clay or wax, as in the case of grafting, with a piece of tarpawling, or of sheet lead, over that.

These trees should not be planted nearer together than forty feet, and more may yet be better, if they are designed for fruit. They delight in a firm, rich, loamy soil, or such as is inclinable to chalk or marle; and they will thrive very well in stony ground, or on chalk hills, as is evident from those large plantations near Leatherhead, Godstone, and Carshalton in Surry, where great number of these trees planted upon the downs produce annually large quantities of fruit, to the no small advantage of their owners.

In order to preserve this fruit, it should be left upon the tree till it is thoroughly ripe, and then, as it would be exceedingly troublesome to gather it by hand, it may be beaten off, but not with such violence as is commonly used, from a mistaken notion that the tree is improved thereby; for most certainly it cannot be benefited by that rough way of forcing off the young wood upon which this fruit grows. The nut thus obtained should be laid in heaps for two or three days, after which they should be spread out, and when they have parted from their husks, which they will then soon do, and have afterwards been well dried in the sun, to remove the moisture of their shells, which would otherwise make them mould, they should be laid up in a very dry place, where neither mice nor other vermin can get at them. In this manner they will remain good for four or five months: or, which is a yet better way, and will keep them still longer, let them, when their outward moisture has been dried by the sun, be put up in jars, or other close vessels, with dry sand between their interstices. The laying of them for four or five hours in an oven gently heated, as is the practice of some, will indeed dry the germ, and prevent their sprouting: but if the oven is too hot, it will make the kernel shrink, and prevent their being peeled with any tolerable ease.

Were it only for the oil that these nuts afford, the trees which produce them would be worth some care. Mr. Evelyn says that one bushel of them will yield fifteen pounds of peeled kernels, and that these will yield half that weight of oil, which the sooner it is drawn, is the more in quantity, though the drier the nut, the better in quality. He adds, that the lee, or marc of the pressing, is excellent to fatten hogs with. Certainly it would be good manure for land; as are the cakes of linseed, rape, &c. after the oil has been squeezed out of them. The green husks boiled, without any mixture, make a good colour to dye a dark yellow. The kernel being rubbed upon any crack or chink of a leaking vessel, stops it better than either clay, pitch, or wax.

The French are very fond of the kernels of these nuts scooped out of the shells before they are hardened, with a short broad brass knife; because iron rusts, and communicates a disagreeable taste to the kernels. When scooped out, they are steeped in salt and water for a few hours before they are set upon the table, as well to take off all taste of bitterness, as to make them peel with the utmost ease.

WANG-TOOTH, a jaw tooth.

WANT, a mole. See the article MOLE.

WANTY, a broad girth of leather, by which the load is bound upon a horse.

WAPENTAKE, the same with what is commonly called a hundred, and generally used in the northern counties beyond the Trent.

WARBLES, small hard tumours on the saddle part of a horse's back, occasioned by the heat of the saddle in travelling, or its uneasy situation.

A hot greasy dishcloth at first frequently applied, will sometimes remove them. Camphorated spirits of wine are also very effectual for this purpose to disperse them, especially if a little spirit of sal ammoniac be added to the camphorated spirit. If there be a necessity for working the horse, care should be taken to have the saddle nicely chambered.

WARP, or miscarry, sink her calf.

WARREN, a franchise, or place privileged, either by prescription or grant from the king, to keep beasts and fowl of warren in; as rabbits, hares, partridges, pheasants, &c.

By statute 21 Edw. III. a warren may lie open, and there is no need of closing it in, as there is a park.

In the setting up a warren, great caution is to be used for the fixing upon a proper place, and a right situation. It should always be upon a small ascent, and exposed to the east or the south. The soil that is most suitable, is that which is sandy; for when the soil is clayey or tough, the rabbits find greater difficulty in making their burrows, and never do it so well; and if the soil be boggy or moorish, there would be very little advantage from the warren, for wet is very destructive to these animals.

All due precautions must be taken, that the warren be so contrived, that the rabbits may habituate themselves to it with ease. Many would have it, that warrens should be inclosed with walls; but this is a very expensive method, and seems not necessary nor advisable; for we find but very few that are so, and those do not succeed at all the better for it. See RABBIT WARREN.

WART, a spongy excrescence near the eye of a horse.

This imperfection proceeds from congealed phlegm lodged there, which in time causes the eye to waste, or to grow little, if it be not remedied.

For the cure:

Put three ounces of powder of copperas into a crucible, on a charcoal fire, keeping the matter stirring from time to time; but take care to avoid the steams; continue a pretty smart heat till the matter grows somewhat reddish; then take it off the fire, and when it is cooled, break it, and beat the matter to a very fine powder; then incorporate four ounces of this powder with five ounces of album rasis, and make an ointment to be applied cold to the warts; anoint them lightly every day, and they will fall off like kernels of nuts, without causing any swelling in the least.

But you must take care to anoint nothing but the warts, nor must you work or ride the horse during the application of the ointment.

As soon as the warts are fallen off, which will be in a month's time, dress the sores with the Countess's ointment, and it will compleat the cure in a month more; for the sores are usually very deep where the warts are large.

WASPS may be destroyed by smoking the thatch or hollow tree with any stinking combustible article, or by scalding them with boiling water. By putting cyder, verjuice, wine, or any four or sweet liquor into a short-necked phial, you may catch them in it. Lay sweet apples, the entrails of beasts or fish, or treacle, in an earthen dish, mixed with a little water, or any liquid they like, and by that means you may destroy great numbers of them.

Thrusting pieces of lighted brimstone-rags into the nests of wasps, and immediately covering their holes with earth, will destroy them.

A copper coin of any kind held for a short time to the part wounded by a wasp, is an excellent remedy.

WASTE, a name given to such lands as are in no man's possession, but lie common.

WATER, a simple fluid, and liquid body, reputed the third of the four vulgar elements. Sir Isaac Newton defines water to be a fluid salt, volatile, and void of taste: but this definition Boerhaave sets aside, inasmuch as water is a menstruum, or dissolvent of salts and saline bodies, which does not agree with the notion of its being a salt itself; for we do not know of any salt that dissolves another. This last-mentioned philosopher, therefore, defines water, a very fluid, scentless, tasteless, transparent, colourless liquor, which turns to ice with a certain degree of cold.

Though water be defined a fluid, it is a point controverted among philosophers, whether fluidity be its natural state or the effect of violence. We sometimes find it appear in a fluid, and sometimes in a solid form; and as the former, in our warmer climate, is the more usual, we conclude it the proper one, and ascribe the other to the extraneous action of cold.

Boerhaave, however, asserts the contrary, and maintains water to be naturally of the crystalline kind; since, wherever a certain degree of fire is wanting to keep it in fusion, it readily grows into a hard globe, under the denomination of ice. Mr. Boyle is of the same opinion. Ice, he observes, is usually said to be water brought into a preternatural state by cold; but with regard to the nature of things, and setting aside our arbitrary ideas, it might as justly be said, that water is ice preternaturally thawed by heat.

If it be urged, that ice, left to itself, will, upon the removal of the freezing agents, return to water; it may be answered, that (not to mention the snow and ice which lie all the summer on the Alps, and other high mountains, even in the torrid zone) we have been assured, that in some parts of Siberia, the surface of the ground continues more months in the year frozen by the natural temperature of the climate, than thawed by the heat of the sun; and a little below the surface of the ground, the water which chances to be lodged in the cavities there, continues in a state of ice all the year round, so that when, in the heat of the summer, the fields are covered with corn, if you dig a foot or two deep, you shall find ice and a frozen soil.

Water is generally divided into salt and fresh, with regard to the ocean and rivers. But, according to Dr. Shaw, it seems divisible into as many different species, as the earth is into beds. Thus there are mineral waters of various kinds, according to the mineral substance they run over, and become impregnated with; though this impregnation sometimes happens in the way of vapour and exhalation. Water, therefore, in general, may be as mixed a body as earth, and perhaps neither of them naturally exists in any considerable purity.

In a general analysis of water, the Doctor found, 1. That common warm water throws up numerous little bubbles, and explodes, in the exhausted receiver of the air-pump; for which reason, water contains what may by way of distinction, be called æther or spirit.

2. It contains a merely aqueous part, distinct from æther and the sediment, as appears from distilled common water.

3. It contains a dry solid matter, which is either earthy or saline, as appears upon a full evaporation, and from the insides of tea-kettles, which, after long use, are lined with a stony matter, that beats off in flakes or crusty pieces.

Water is not only contained in the earth as in a reservoir, but likewise floats in the atmosphere. In both cases, it is actuated, rarefied, and put in motion by heat, so as to prove instrumental in producing effects. Thus it produces clouds, rains, dews, springs, and rivers. It refreshes the earth, recruits vegetables, and is the support of fish and other animals by conveying nutriment to all their parts. It is also the first and immediate instrument of fermentation, putrefaction, corruption, and change in all vegetable and animal subjects.

But the nature and uses of water will best appear from the following experiments:

1. That water is contained in many solid bodies, and to appearance in dry bodies, was proved thus: a piece of the hardest and driest bone being procured, and distilled in an earthen retort, with degrees of fire, a very large proportion of water, along with much oil and volatile salt, was obtained: whence it appears, that animal matters are resolvable into the four chemical principles, water, oil, salt, and earth. This experiment holds true even of the oldest hartshorn, the driest and hardest woods, earths, and pulverized stones.

Whence it also appears, that water may be concealed in solid bodies, and make a constituent part thereof; for it is not meant that water insinuates itself into the superficial pores of bodies, such as wood, skins, &c. so as to swell them in moist weather, and leave them shrunk in dry; but that it remains permanently intermixed as an essential ingredient, or as a part of solid bodies.

2. That water may be collected from the driest air, or in the hottest climate, was proved by the following experiment:

Half a pint of common water was put into a cylindrical glass, wiped perfectly dry on the outside; then was added to the water, two ounces and three quarters of pulverized and dry sal ammoniac; these were stirred briskly together; whereupon the water floating in the external air, was, by the coldness thus produced, condensed on the outside of the glass as the salt dissolved within, and trickled down in small veins, into the shallow basin set underneath to receive it.

This experiment holds in all climates and places of different heights where it has been tried; whence, by the law of induction, we make it universal, till any contradictory instance appears. Thus, therefore, it may hold in the most parched countries and hottest seasons, so as to afford an agreeable method of cooling potable liquors, and render them more refreshing. For if the containing glass of the salt and water be set in any liquor, the liquor will be cooled

cooled thereby; and if any considerable improvement could be made in the contrivance, it is observed, that it might, in some measure, serve to supply the thirsty traveller in parched deserts, and the sailors with fresh water at sea.

3. To determine the proportion of water contained in an assigned portion of the atmosphere, we are directed by the following experiment:

Having by means of the air-pump, and an exact pair of scales, found the weight of a certain quantity of air, contained in a large glass vessel, there was included therein a certain known weight of well dried potential cautery, whose property it is powerfully to attract the moisture of the air. The vessel was kept close stopped for several hours; during which time, the potential cautery was grown wet, in which state being weighed again, it was found considerably to encrease; which must be either owing to the water attracted out of the air in the glass, or to a condensation of the air itself into an aqueous fluid; for such a fluid might now by distillation be obtained from the matter thus run per deliquium.

It is observed that there is room to suspect, that if this experiment were made in perfection, a weight of water almost equal to that of the air included in the vessel, might be thus obtained, which might prove an extraordinary discovery, and shew what some have endeavoured to prove, that the matter of common air is little more than water.

4. That an earthy substance is naturally contained in water, was proved as follows. Three several glasses were filled with pure rain-water, spring-water, and Thames-water, and suffered to stand, close covered, for some days before they were exhibited. There was an earthy sediment then deposited in all the three, but most in the Thames-water, the sediment whereof was not only larger, but also more foul and muddy than in the rain-water; though here, also, it was dirty, perhaps, because not carefully collected; whereas, in the pump-water, it was white, scaly, flaky, and shining, like fine spangles of talc. This experiment is also universal, so far as it has been tried with care, and holds true of the waters of all species, and all countries, particularly in those called mineral waters, from which an earthy substance may usually be precipitated by air in a considerable proportion.

Certain experiments carefully made, and repeated, shew that the terrestrial matter naturally contained in water, has a principal share in the growth and encrease of vegetables; all the plants thrive in water appearing to enlarge their bulk in proportion to the earthy matter they draw from the water. Whence pure elementary water seems but a kind of vehicle to convey this nutrimental or substantial part, and deposit it in the vessels through which the water moves, in order to its general exit at the surface of vegetables. But we are not here to exclude the instrumental efficacy of the two other elements, fire and air. And this appearing to be the general office of water, in the whole animal and vegetable kingdoms, the conveyance or distribution of the alimentary matter to all their parts, it may be proper to consider its physical properties, which would wonderfully fit it for this office.

This figure of its component parts appears to be smooth and spherical, like those of quicksilver; whence it becomes extremely moving and penetrating. Thus it readily enters the pores, leather, skins, chords, musical strings, &c. thus likewise it becomes capable of moving and agitating particles of matter less active than itself, and so proves the more immediate physical agent of fermentation, putrefaction, solution, &c. and thus it also conveys earthy and saline matters through our filters of paper, stone, &c. and even raises some proportion of them in distillations. Its particles likewise appear to be extremely minute, and so have a large share of surface.

Hence water is admirably fitted for a solvent, or for readily entering the pores of salts, and coming into full contact with all their particles; and thus it will pass when air cannot, on account of its moisture, or lubricating power, whereby it fastens mucilaginous matters, and will therefore soak through the close pores of a bladder.

The specific gravity of water, and consequently its goodness by its lightness, are to be directly judged of by the hydrostatical balance. This experiment is a good substitute for several other ways of examining the purity and goodness, of waters both common and mineral; for it appears by numerous instances, that light waters are, *ceteris paribus*, the best, purest, and wholesomest. That water is accounted

best and wholesomest, which is not only the lightest and freest from earthy sediment, but that which is most spirituous; and these properties are usually found in pure rain-water; that being naturally distilled from the ocean and rivers, or by the heat of the sun raised up into the atmosphere, from whence it is returned much after the manner of common distillation.

From the preceding, and other experiments of Dr. Shaw made upon water, he deduces the following axioms:

First, we have seen, That water is naturally contained in some of the driest and hardest bodies, and in the driest air. 2. That itself naturally contains an earthy substance. 3. That it is the proper menstruum of salts, dissolving more of one and less of another. 4. That one good sign of its purity and wholesomeness, is its levity. 5. That the ingredient of a mineral water may be discovered by chemical expedients: and, 6. That mineral waters are imitable by art, from such discovery.

Secondly, That water is of infinite use in all the works both of nature and art, as without it there could be no generation, nutrition, or accretion, performed in any of the animal, vegetable, mineral, marine, or atmospherical regions. The blood could not flow in the veins, the sap in the vessels of vegetables, nor the particles of minerals concrete and grow together without water. It is this that makes the largest part of our blood, our drink, and other aliments. There could be no corruption, fermentation, or dissolution, carried on without it; no brewing, no distilling, no wines, no vinegar, no spirits, made without it.

Thirdly, That we meet with water under an infinite variety of forms, and in an infinite variety of bodies, as that of air, vapour, clouds, snow, hail, ice, sap, wines, blood, flesh, bone, horn, stone, &c. through all which it seems to pass unaltered, as an agent or instrument that suffers no alteration by re-action, but remains capable of resuming the form of water again upon occasion.

Fourthly, That water, in its own common state, appears to be a combination of all the elements together, as containing a quantity of fire, which keeps it fluid: a quantity of air, and a quantity of earth; whence it can be no wonder that water alone, as it appears to the senses, should suffice for vegetation in some cases, where little earth is wanted, or for supporting animal and mineral life, where no great degree of nutriment is required; and hence it proves a gluten, or cement, to some bodies, and a solvent to others: thus it consolidates brick, plaster of Paris, stone, bone, &c. but dissolves salts, and subtile earths approaching to salts, and becomes the instrumental cause of their action.

Fifthly, That water conveys nourishment, or a more fixed and solid matter, to the parts of vegetables, where having deposited it, the finer fluid perspires into the atmosphere, which gives us the physical cause of the dampness and unwholesomeness of woody countries, as they remarkably find in America. For all large vegetables act after the manner of forcing-pumps, and continually draw in large quantities of water at their roots, and discharge it at their leaves, which intimates a method of collecting water in dry countries, and likewise of making salt-water fresh.

Sixthly, That the water in passing through plants, after having deposited its more terrestrial parts, does not always go off pure, but impregnated with the finer effluvia, or more subtile particles of the vegetable; thus making an atmosphere round every plant, according to its nature, odoriferous or otherwise, which supplies us with a rule for procuring the odoriferous waters of vegetables by distillation.

Seventhly, That the particles, not fine enough to go thus along with the water, are left behind upon the surface of the leaves and flowers of plants, being now thickened, or strained from the moister plants, and remaining in the form of honey, manna, gums, balsams, &c. according to the nature of the vegetable. And hence appears the physical cause of plants proving more odoriferous and sweet when the weather is both warm and moist, as immediately after a summer's shower.

Eighthly, That the chemical operator should form to himself an hygrometer, for the service of his laboratory, to determine the proportion of water at all times contained in the air, which continually mixes with his preparations, differently augments their weight, and promotes or hinders many of his operations.

Ninthly, That pure water makes the largest part of mineral-waters, where it is impregnated as a menstruum, with

with several ingredients that it dissolves or drinks up in its passage through the earth.

Tenthly, and lastly, The preceding enquiry affords considerable light for discovering practicable ways of making sea-water fresh and potable, and of preparing waters by art, so as to render them fitter for the common oeconomic uses, and the service of many particular arts.

But though water is absolutely necessary to the growth of vegetables, and experience hath long evinced the great advantages arising from the overflowing of pastures, it is but of late years that this very profitable improvement is become pretty general in England; nor is it, as Mr. Worlidge observes, "yet carried to near the perfection it might be advanced unto, if the following obstructions were removed.

"1. The several interests that are in lands bordering on rivers, hinder very much this improvement, because the water cannot be brought over several quantities of land so circumstanced, but through the ground of ignorance and cross neighbours, who will not consent thereunto (though for their own advantage also) under unreasonable terms; and some will not at all. Others, again, are not by law capacitated for such consent.

"2. A great and pernicious impediment to this improvement is the mills that stand on many fruitful streams; prohibiting the laborious and ingenious husbandman to receive the benefit and advantage of such streams and rivers, which carry in their bowels much wealth into the ocean, while the mills themselves yield not a tenth of the profit to the owners, that they hinder to their neighbours, and their work may be as well performed by the wind, as by the water.

"3. Another grand impediment is the ignorance of the countrymen, who are commonly possessed with a foolish opinion, that the water leaves all its fatness on the ground it first flows over, and therefore will not benefit the next; which is most untrue; for I have seen meadows successively drowned with the same water, to almost an equal improvement for many miles together. It is true, the water leaves behind it a great part of the fatness which it hath washed from the hills and high-ways in the time of great rains: but we find by daily experience, that meadows are fertilized by overflowing, as well in clear and dry weather, as in rainy, and that to a very considerable degree. The clearest and most transparent streams will improve even ordinary lands, so much as to render them very fertile meadows.

"4. From a greedy and covetous principle, the grass is suffered to stand so on the watered meadows, that it becomes much discoloured, grows haulmy, and is neither so toothsome nor so wholesome, as that of unwatered meadows.

"5. The former of these impediments might easily be removed by a law, which would be of very great advantage to the kingdom in general. The latter can be remedied only by the example of such industrious and worthy persons as understand better things: the generality of the world being rather introduced to an ingenious and profitable enterprize by example, than by precept: although some are so sordid and self-willed, that neither apparent demonstration, nor any convincing argument whatsoever, can divert them from their bias of ill husbandry."

The industrious Swiss, sensibly attentive to every means of benefiting their deservedly cherished country, have thought this branch of husbandry of sufficient importance to propose it for the first premium offered by their truly laudable Society at Berne, for the year 1760: and I gratefully confess myself indebted to the dissertations produced thereby, for several of the following remarks:

Water not only acts as a vehicle to the nourishment of plants, but also carries with it many particles which enrich the soil; especially after heavy rains. It then deposits a fertilizing sediment, which turns the mould to a blackish colour. The common saying, that watering makes the stones disappear, is true; not so much from their sinking into the earth, as for their being covered by the new supply of mould brought by the slimy muddy water, particularly after great rains. Watering likewise promotes the putrefaction of every vegetable and animal substance found in the earth, and thereby contributes greatly to meliorate the soil underneath the sward.

Plants which grow on dry pastures contain richer and more nourishing juices, than those which grow in moist places. Care should therefore be taken, that the quantity of moisture brought upon the pasture, be only such as shall give vigour to the plants, without over-charging their

vessels. In order to do this, every part of the pasture should be watered equally; and as little water as possible should be suffered to go where the land is naturally moist.

Extreme heat should also be avoided in watering; because heat draws the moisture too hastily up into the plant, which is thereby filled with a watery juice, rendered of so tender a texture, as easily to be killed afterwards by drought or cold.

If the spring proves dry, pastures may be watered as soon as the frosty season is over; and this may be continued till the grass begins to shoot. But if the winter has been severe, and the earth remains moist, no current of water should be admitted, till the earth loosened by the frost is settled, and the surface become pretty dry: for even the gentlest stream would carry off the fine mould loosened by the frost. After that the grass has begun to shoot, and the weather is become mild, the water should be administered more sparingly; that is to say, in such proportion only, as just to push the grass gently on, till it has made such a covering as can shelter the earth from the too great power of drying winds, or of a scorching sun. Watering should afterwards be used with great caution, and only in case of extreme drought; nor even then, unless the water be perfectly clear and sweet, lest it should foul the grass, or give it a bad taste. If it be admitted sparingly before the hay is cut, it will make the grass stand the better to the scythe.

For a little time after the hay is made, the water should be admitted only in the night; because the weather then generally is very warm: for it is observed, that rain which falls with a hot sun, or a hot sun that comes on a heavy dew, is prejudicial to plants. Watering, under the same circumstances, will have the same effect; to prevent which, the prudent husbandman will let in his water only in the evening, and will withdraw it again before the sun gets up. It is continued at this season only till the grass begins to shoot vigorously; and in case of very great drought it may be repeated, but very sparingly.

If a second crop of hay is made, the water may be used more freely; as the weather is then become cooler, and the earth is generally very dry. This flooding will bring up a plentiful after-math. If the second crop of grass is fed off, the water should be renewed in the same manner: only care should be taken not to suffer cattle to feed on the ground while the water is upon it, because their poaching would destroy the roots of much of the grass, and leave the surface uneven; which should be avoided in the pasture.

The latter end of autumn is the season in which watering is the longest continued: and considering the dryness and parched state of the earth at that time, this practice seems rational: for the water then, not only supplies the moisture wanted in the earth, but it dissolves every substance soluble in water, and thereby converts to an additional manure, what might otherwise have remained long in its original state. Care should, however, be taken, to drain off the water before the season of strong frost is expected; because frost is observed to destroy all kind of vegetables much more when the plants are full of sap, than when they are in a dryer state. We may easily comprehend that it must have this effect, when we consider with what force it breaks every vessel containing water exposed so as to be frozen: for frost dilates all fluids to such a degree, that the vessels in which they are must be broken thereby. Hence it is that succulent plants soon become a putrid mass after a hard frost: and thus it is that the strongest trees are sometimes burst with a loud report.

When the water is brought to the desired height, the main channel should be cut, with such a descent as only just to keep the water in a gentle motion. The channel should be made in the highest part of the pasture, and proportional to the quantity of water necessary to be introduced. If a hollow intervenes between the place at which the water is brought into the field, and another rising ground in that field, it will be worth the farmer's while to convey it across that hollow, by pipes made of wood, or any substance, laid either horizontally over that hollow, or underneath it. The motion of the water in this horizontal channel should be different, according to the quality of the ground. If it is a strong earth, the channel may be cut nearly horizontally; but if it is a light loose soil, a quicker current should be given to the water, in proportion to the degree of lightness of the earth; or great part of the water will otherwise be lost, by sinking into it. In a light soil of this kind, it may be proper to line this main channel with brick or stone, well cemented with lime, to hinder the water from escaping through the

erevices; or at least to cover it with clay well rammed. As to the degree of descent most proper for the main channel, in order to give a current to the water, M. Bertrand, to whom we owe one of the ingenious dissertations on this subject in the memoirs of the Berne Society, observes, that Vitruvius required six inches in an hundred feet, which is a great deal too much: but that the moderns, who have made the most exact experiments in this respect, are satisfied with two inches in six hundred feet, when they cannot have more, and recommend particularly the avoiding all sharp angles in the winding of the channel, and the making of its bottom quite smooth and even. He adds, that this is nearly the declivity of the aqueduct of Rocquancourt, by which the water is conveyed to Versailles; the distance three thousand four hundred yards, and the slope, in all, only three feet.

The main channel should be of breadth, rather than depth, sufficient to receive all the water that is intended to be conveyed through it, and that breadth should lessen gradually as the water is carried off in lesser channels, in order that the water may press into those smaller ducts, which are to issue all along from the chief. The lesser channels should be as shallow, and as numerous, as can be: for the more equally the water is distributed over the grass, the greater will be the improvement. They should be made particularly wherever the water collects itself into a stream: for though cutting so much turf may seem to waste a great deal of land, yet it proves not so in the end; because the quicker the water runs over the grass, the more it benefits the pasture.

To keep the channels in repair, they should be frequently cleaned, especially after every cutting of the hay. The slime then taken out of them should be spread upon the pasture, and the next growth of the grass will be greatly improved thereby. Care should also be taken to have drains to carry off the water, so that none of it may stagnate upon the land.

The best way of watering a flat meadow, which is usually surrounded with a ditch, is to stop the out-let of the ditch, and, bringing in a quantity of water, to overflow the whole meadow, for such time as shall be judged necessary to moisten the earth sufficiently: but the water should not be continued upon it so long as to wither the grass. If this can be done in a rainy season, it will be so much the better; because the water will then be loaded with the enriching mud and slime washed down from the higher grounds.

The first heavy rains which fall in the latter end of the autumn, and which carry with them the rich particles of putrified animals and plants, are thought to be more fertilizing than at any other season of the year, and are therefore brought into the pasture, as often as the absence of the cattle fed on them will permit.

The next best to rain, is clear and sweet spring-water, flowing from a copious source. Here it is generally objected, that spring water is hard, and therefore not fit for the nourishment of plants. But Dr. Home, who judges otherwise, expresses himself thus on this very occasion. "Is not hard water more nourishing for vegetables than soft water? I imagine that the salt of vegetables enters their vessels in such a form as hath the salt which is found in hard waters. The salt of hard waters seems likewise to be of the nitrous kind, of which the nourishment of plants is all supposed to be. This query thwarts the general opinion; for no gardener will make use of hard water, if he can avoid it. I watered some plants with it, and thought that they grew better than those which were watered with soft water."

This is confirmed by an ingenious correspondent of the Berne Society, who made several experiments on the qualities of different waters, and found that their greater or less hardness made very little difference in their effects, when used for watering of pastures. The water of an excellent spring, which, upon trial, was found to be hard, fertilized greatly the pastures upon which it was let in.

Spring water may be used later in the winter, than any other, because, being warm, a mild frost will not freeze it, even when expanded on the pasture. It should however be turned off soon enough to let the earth become a little dry before severe frosts set in. It may be used earlier in the spring than other water, and to better advantage, by reason of the warmth which it communicates to the ground while it flows: and it becomes extremely proper in the summer, because it cools during the night (the only time for watering at that season) the heated soil, and grass scorched by the power of the sun.

The equal warmth of spring-water, is what renders it peculiarly useful for watering pastures. The last quoted

correspondent of the Berne Society tried its heat, in Switzerland, on the twenty-sixth of May, when the earth had been very little warmed by the sun, after a long winter's cold. He then found M. de Reaumur's thermometer, placed in the spring of water, stand at eight degrees and a half (equal to forty-seven and a half of Fahrenheit's) above the freezing point. On the fifth of July, in the evening, when the heat of the air was very great, Reaumur's thermometer, again placed in the spring, stood at nine degrees and a quarter (equal to forty-nine of Fahrenheit). He afterwards tried whether the warmth of the spring was considerably increased towards the end of the summer, when the earth was extremely heated: but even then, Reaumur's thermometer scarcely reached ten degrees (equal to about fifty of Fahrenheit's). By this we see, that springs which yield a full and constant stream vary very little in their degrees of warmth.

For the same reason it also is, that a perpetual verdure reigns around such springs, even during the hardest frost; and if their water could be preserved from freezing when spread over a field during the winter, it would be right to let them in upon pastures in that season: but as they soon lose their heat when dispersed over the grass, this is by no means advisable.

Experience has taught the inhabitants of the Alps (and the same will hold equally true in all mountainous countries), that it is not advisable to water pastures with floods which arise from melted snow, or with the water of rivers fed thereby. One reason which seems to render the water that descends from mountains perpetually covered with snow the less useful for watering pastures, is, that as all vegetation is at a stand in such places, no vegetable matter can be mixed with this water; and it therefore cannot communicate the fertility which arises from water fraught with those rich substances.

We are frequently told of correcting the crudity of water, by making it turn a wheel, or putting it otherwise into violent motion: but I know not what good effect this can have.

What are commonly called barren springs, are sometimes corrected by mixing dung with their water in ponds made higher than the pasture intended to be watered. Yet this, though an old custom, is liable to some objections; one of which, in particular, is, the water will deposit its richness on the first part of the pasture over which it flows, and therefore improve the grass very unequally. But if dung hath this effect, it will answer equally well, if it be spread upon the land. Care should indeed be taken that the current of the water be very slow over a pasture newly dunged; because the fertilizing particles of the dung may otherwise be carried off by the stream, before they can have had time to penetrate into the earth.

When dung, marle, or lime, is laid on a pasture which has a considerable descent, the best way is to lay a larger proportion on the higher parts; because the common rain-water will wash some of their richer particles down to the lower.

As clayey soils retain water, and by that means chill the plants growing on them, they are the least fit for watering of any. If the water abides on them, they become poachy; and when dried again, they gape, and become so hard that no plant can pierce them. Some sensible farmers have likewise observed, that their clayey lands have always yielded less grass in wet years, than when the season has been dry; which is a manifest proof that a soil of this kind does not admit of watering, unless it be a little, in case its surface has become hard after the hay has been taken off, or when the grass is short. Such land are fitter for arable, if their situation permits it.

Hazel earth, which is a loam mixed with gravel, and of a clayey nature, is the strongest soil that can be watered with propriety; and that this has been surprisingly benefited thereby, is evident from several instances given in the Memoirs of the Berne Society, even of large tracts of such ground that have been vastly improved by this means: but I shall mention here only the following.

"In the summer of 1758, part of the pasture ground belonging to a farmer in Switzerland was so entirely covered with stones and gravel, by the sudden overflowing of a stream, that it looked like a bank of sand. As the removing of this quantity of stones and gravel would have cost a great deal of labour and expence, the owner of the land carried off only the largest stones, and threw over the gravel a reddish earth taken from a neighbouring hill; but so thinly,

thinly spread, as only to fill the interstices between the pebbles, without entirely covering them. He then sowed this spot with hay seeds, and let in upon it the waters of an adjacent spring and a neighbouring rivulet. These waters were let in sparingly at first, till the grass began to appear, and after that they were flowed more abundantly. The consequence of this prudent conduct was, that the grass thus raised, bore cutting once the first year, and after having been mowed twice in the second, promised an excellent after-math at the time when this account was written, which was in the beginning of the autumn of that second year. The very first year's crop grew so prodigiously, that the grass was lodged, even though the pebbles were then felt under foot, if one trod upon it." — See the article MEADOW.

When the land is above the level of the adjacent water, recourse must be had to some engine to raise it to a proper height, in order to overflow it; though this will be attended with a very considerable expence, especially at first.

The oldest instrument used for this purpose is known by the name of Archimedes's water screw, and is thus described by Mr. Emerson :

C p D (Plate XXVII. fig. 1.) is a cylinder which turns upon the axis C D. About this cylinder there is twisted a pipe, or rather several pipes, *n o, p q*, running spiral-wise from end to end. This cylinder is placed higher at one end, D, than at the other; and its use is to screw up the water from the lower end to the higher. A B is a river running in the direction A B, *a, b, c, d*, are several floats fixed to the cylinder. E F is the surface of the water. As the cylinder stands in an inclined position, the upper floats *a, b*, are set out of the water, and the under ones *c, d* within it: so that the water acts only upon the under ones *c, d*, and turns about the cylinder, in the order *a, b, c, d*. By this motion, the water taken into the spiral tubes at the low end is, by the revolution of the cylinder, conveyed through these pipes, and discharged at the top into the vessel G. If A B is a standing water, there is no occasion for the floats *a, b, c, d*; and then the cylinder is to be turned by the handle at D. Instead of the pipe, a spiral channel may be cut round the cylinder, and covered close with plates of lead. The closer these spiral tubes are, the more water is raised: but it requires more force. Also the more the cylinder leans, the more water it carries; but to a less height.

Where a considerable quantity of water is to be raised, a greater force is requisite, that can be applied to such a handle. Her royal highness the princess dowager of Wales caused an instrument of this kind to be erected at Kew, by the ingenious Mr. Smeaton, and by means thereof a sufficient quantity of water was supplied, for all the ponds, and other uses, in that elegant and extensive garden: but it is there worked by horses.

The most common engine for raising water is the Persian wheel, of which Mr. Worlidge gives the following description :

"This wheel is made much after the manner of that of an under-shot mill, viz. with a double ring, into which are let two pins, on which the floats are fastened. These floats are made hollow; the half that is the most remote from the wheel, holds the water which is taken in at the open place, above the middle of the back of the float, and as the wheel goes round, and the float laden with water rises, so the water, by degrees, tends towards that part of the float which is next the wheel; and as the float surmounts the cistern or receiver, the water empties itself into it, every float succeeding the one the other, emptying itself into the receiver: so that if one float contains a gallon of water, and there be thirty floats on the wheel, at one motion round, it delivers thirty gallons of water into the cistern. Such a wheel will be about fifteen feet diameter, the floats are eighteen inches distance, and will deliver the water at eleven or twelve feet above the level of your stream, and will go four times round in one minute, and carry up about one hundred and twenty hogsheads of water in an hour, with twelve or eighteen inches penning or stopping of but an ordinary current of water, which will water very well thirty or forty acres of land; for if your land be cold and clayey, too much water does it hurt; and if it be light, warm, or sandy, a little water does it much good. It is also to be observed, that this motion is constant, and will last many years without repair, so that it stands not still, for one side to dry and grow lighter than the other: also

observe, that the slower it moves, the better it delivers the water.

"The view of this wheel we have in Plate XXVII. fig. 2. *a a a a* signify the wheel; *b* the cistern that receives the water; *c c*, the trough standing on trestles, that conveys the water from the cistern to the place you desire; *d*, the hatch, or pen-stock that bays up the water to a reasonable height, under which the water drives the wheel; *e*, (fig. 3.) one of the floats presented open to your eye, apart from the wheel; *f*, the place that is to receive the water; *g*, the open place out of which the water issues; *h h*, the two pins or ledges rivetted on to the fore-side of the float, and where-with you are to fix the float to the two rings of the wheel. These, or such like wheels, are much used in Spain, Italy, and France, and are esteemed the most easy and advantageous way of raising water in great quantity, to any height within the diameter of the wheel, where there is any current of water, to continue it in motion, which a stream will do.

"How many acres of land lie on the declining side of hills, by the sides of rivers, in many places where the water cannot be brought unto it by any ordinary way! yet by this wheel placed in the river, may the land be continually watered, so far as is under the level of the water when raised."

Instead of raising the water by means of the hollow floats placed around the outer circumference of the rim of the wheel, as here described; M. Belidor proposes, for wheels of this kind, to raise it in buckets placed at equal distances upon the side of the rim of the wheel, and suspended by a pin, upon which they play, as at A fig. 4. When by the rotation of the wheel, one of these buckets comes to B, which is the summit of the wheel, the upright piece D, which is fastened to the sides of the trough C, turns that bucket upon its side, and thereby makes it empty itself into the trough C, from whence the water is discharged into a receiver at E.—As these buckets keep full of water till they are carried up to the top of the wheel, where they are turned over, a much greater quantity of water may, undoubtedly, be raised by them, than can be by the floats of the Persian wheel, from which much must be spilled as it is carrying up. The size of these buckets should be adapted to the force of the current of water they are to take up.

Another wheel for raising water, though not so great a height, is represented in fig. 4. This engine was first invented by M. de la Baye, of the Royal Academy of Sciences at Paris, and was used with great success by the honourable Mr. Hamilton, at his seat at Pain's-hill in Surry, where that gentleman has shewn how far a barren spot may not only be rendered useful but even an ornament to the adjacent country.

This machine consists of a wheel whose size is adapted to the height to which it is intended to raise the water. A perspective view of this machine is represented fig. 5. and its internal parts fig. 6. The wheel turns upon its axis at A, and has several curved pipes, B, C, D, E, fixed to it, as represented in the figures. The mouth of each pipe ascends as the wheel is turned round by the stream, in the direction indicated by an arrow, and the water descends from C towards F, till it reaches the hollow axis, A A, from the opening, at the end of which it is discharged into the trough G, and thence conducted by troughs, as H, or other channels, to whatever place it may be wanted.

But if there be a necessity to raise the water higher than the axis of the wheel, we would recommend an ingenious machine, used for above twenty years at Zurich, for supplying a large dye-house there with water from the Limmat, and of which a description in the German language appeared in the third volume of the Zurich Acts, from whence the following account is translated.

The wheel itself differs little in appearance from other water-wheels. Its diameter exclusive of the ladle-boards, is not quite three feet. It is coated all over with tin plates, and forms a short cylinder, or rather drum, of the above diameter, and one foot thick. On its periphery the ladle-boards are fixed, as in other under-shot water-wheels, and by means of which it is put in motion by the stream. It turns on a hollow axis (like the last machine) of proportional thickness and length, and has one of its flat sides applied against a projection, or ledge, made round the axis, to which it is pressed close, and held fast by a wedge driven through the axis at the other side. That part of the axis, which passes through the wheel is square, that the wheel may

may not slip, or be able to turn, without turning the axis with it: the remaining part of it is round. The wheel is hung in the water to about one third of its height, and supported in a moveable frame, so that it can be lowered, raised, or even taken out of the water at pleasure. In the periphery of the wheel are holes, by which the water enters. The axis turns as usual, on two pivots, one of which is of brass, considerably larger than the other, and hollow from end to end, communicating with the canal in the axis. The hollow pivot, which may be considered as a brass pipe, has its end fitted close to a leaden pipe, in which it turns. The leaden pipe by a double bending is confined to the wall of the dye-house, where it is bent perpendicularly upwards, and rises along the wall to the height of ten feet above the axis; it is there bent again under the eaves, and continued into the dye-house itself.

The singular and remarkable operation of this little wheel depends solely on its internal structure. The water entering at the circumference of the wheel, runs in a square spiral canal, which passes round the wheel, and consists of a number of circumvolutions, within one another, like the spring of a watch, till at length it comes into the axis. A necessary condition here is, that each of the inner circumvolutions be of the same magnitude with regard to their content, as the outer one; or that the width of the spiral canal be gradually enlarged in each circumvolution, in proportion as the diameter diminishes, that is, the bore of each of the inner spirals must be to the bore of the outer one, as the diameter of the latter is to the diameter of the former.

The wheel thus furnished with its spiral canal, is to be hung so deep in the river, that half a spiral, at least, may, in each revolution, be filled with water. To keep it in this state it would be necessary to immerse it to the axis, or further: but as its motion, at such a depth, would be extremely slow, a kind of scoop is made at the outer opening of the spiral pipe, which takes up so much water at once, as is sufficient to fill the due proportion of the outermost spiral in one revolution. One half of the outer spiral being thus filled with water, the other half remains filled with air: as the wheel turns, the water and air pass into the second spiral, then into the third, fourth, and so on, till a sufficient number of turns bring the water and air to the axis, from whence they pass into the upright pipe, as already mentioned: thus the entrance and discharge of water continue without intermission, so long as the wheel is kept in motion. When the wheel scoops up just the proper quantity of water, and turns with due velocity, the water may be forced up in the perpendicular pipe to a height equal to the sum of the diameters of all the circumvolutions of the spiral canal.

If we consider the operation of this machine, we shall easily see the necessity of the inner circumvolutions being made to widen in the proportion above-mentioned; and that, without this condition, the water passing from the large outer spiral, would be crowded and retarded in the inner, and in great part forced back.

It is also obvious that just half of one of the spirals must be filled with water at each revolution, for if less be taken in, there will be a diminution in a quantity delivered; and if more, it will be pressed too much together, and its quantity also diminished.

The velocity with which the wheel moves, or the number of revolutions it makes in a given time, is another essential point in regard to the quantity of water, and may considerably influence the quantity of water necessary to be raised. When this is known, and the height determined, it will be easy to construct a wheel in such a manner, as to answer the purpose intended.

We shall conclude our account of this ingenious contrivance, with the following directions for constructing it. The two flat sides of the wheel should be made of two strong circular pieces of good oak, the inner sides of which must be planed as smooth as possible, and fitted to one another; and to keep them from bending or warping, secured by pieces on the outside. The plan of the spiral lines is represented in fig. 7. Plate XXVIII. These spiral lines being marked out on the wood, a groove must be cut about a quarter of an inch deep, in order to make a channel for the partition, which must be formed of a thin piece of copper. The channel being filled somewhat more than half with good cement that will bear water, the piece of copper must be set in regularly, care being taken to

keep the cement warm, or previously to heat the metal. The scoop also, which at every revolution of the wheel takes up a proper quantity of water from the river, may be made of the same metalline plate. The piece of copper for forming the partition must be cut at first exactly straight, and of an equal breadth throughout. This work being finished, the wheel must be put on the axis as far the ledge made for it to rest against, and cemented. The second piece of wood requires little preparation: some cement must be spread all over it, and the whole surface covered with a thick piece of woollen cloth, which must also be done over with cement on both sides: while the whole continues warm, it must be put on the axis, and pressed close to the other part of the wheel, so as to cover the as yet open side of the spirals. The two parts are held firm together, by means of a wedge or key passing through the axis, and a proper number of screws, placed round the circumference: these screws are strong iron pins, somewhat longer than the wheel is thick, and a nut, when they are placed through the wheel is screwed on the other. Thus the inside of the wheel or drum is finished. The disposition of the ladle-boards, the shape of the axis, and the structure of the frame by which the machine is supported, will be partly understood from what has been already said, and more fully from fig. 8. Plate XXVII.

It has been already observed, that the wheel in the limmat is covered with tin plates; but this is of little or no consequence. It is however advisable not to have one large opening, for the entrance of the water, but either a perforated plate, or a wire-grating nailed before it, in order to prevent weeds, or any other filth from passing into the spiral tube, and preventing, if not wholly stopping, the course of the water.

The frame or scaffold which the wheel hangs, and the means of raising or lowering it in the river, without disturbing the course of the water in the machine, deserves particular notice. It is plain from fig. 8. that the wheel rests on two arms, which, for the greater security, are bound together by cross-pieces. At the fore-end they are both suspended by iron chains, which pass over a roller so as to be wound off or on: on the other end they move on two strong joints or hinges. The communication of the leaden pipe, with the brass one, or hollow pivot, at the end of the axis, is drawn on a larger scale, in fig. 9. This pipe is bent close by the pin, to a right angle, and goes horizontally along one of the arms of the frame as far as the hinge, (see fig. 8). where it is again bent to a right angle, opposite to the dye-house, and communicates in the same manner as the hollow pivot of the axis, with another horizontal pipe, in which it moves round freely, without any impediment to the passage of the water, in raising or lowering the wheel. This large pipe passes under a stage built along the wall of the dye-house, and thence up the wall, where it distributes the water in the manner represented in the figure.

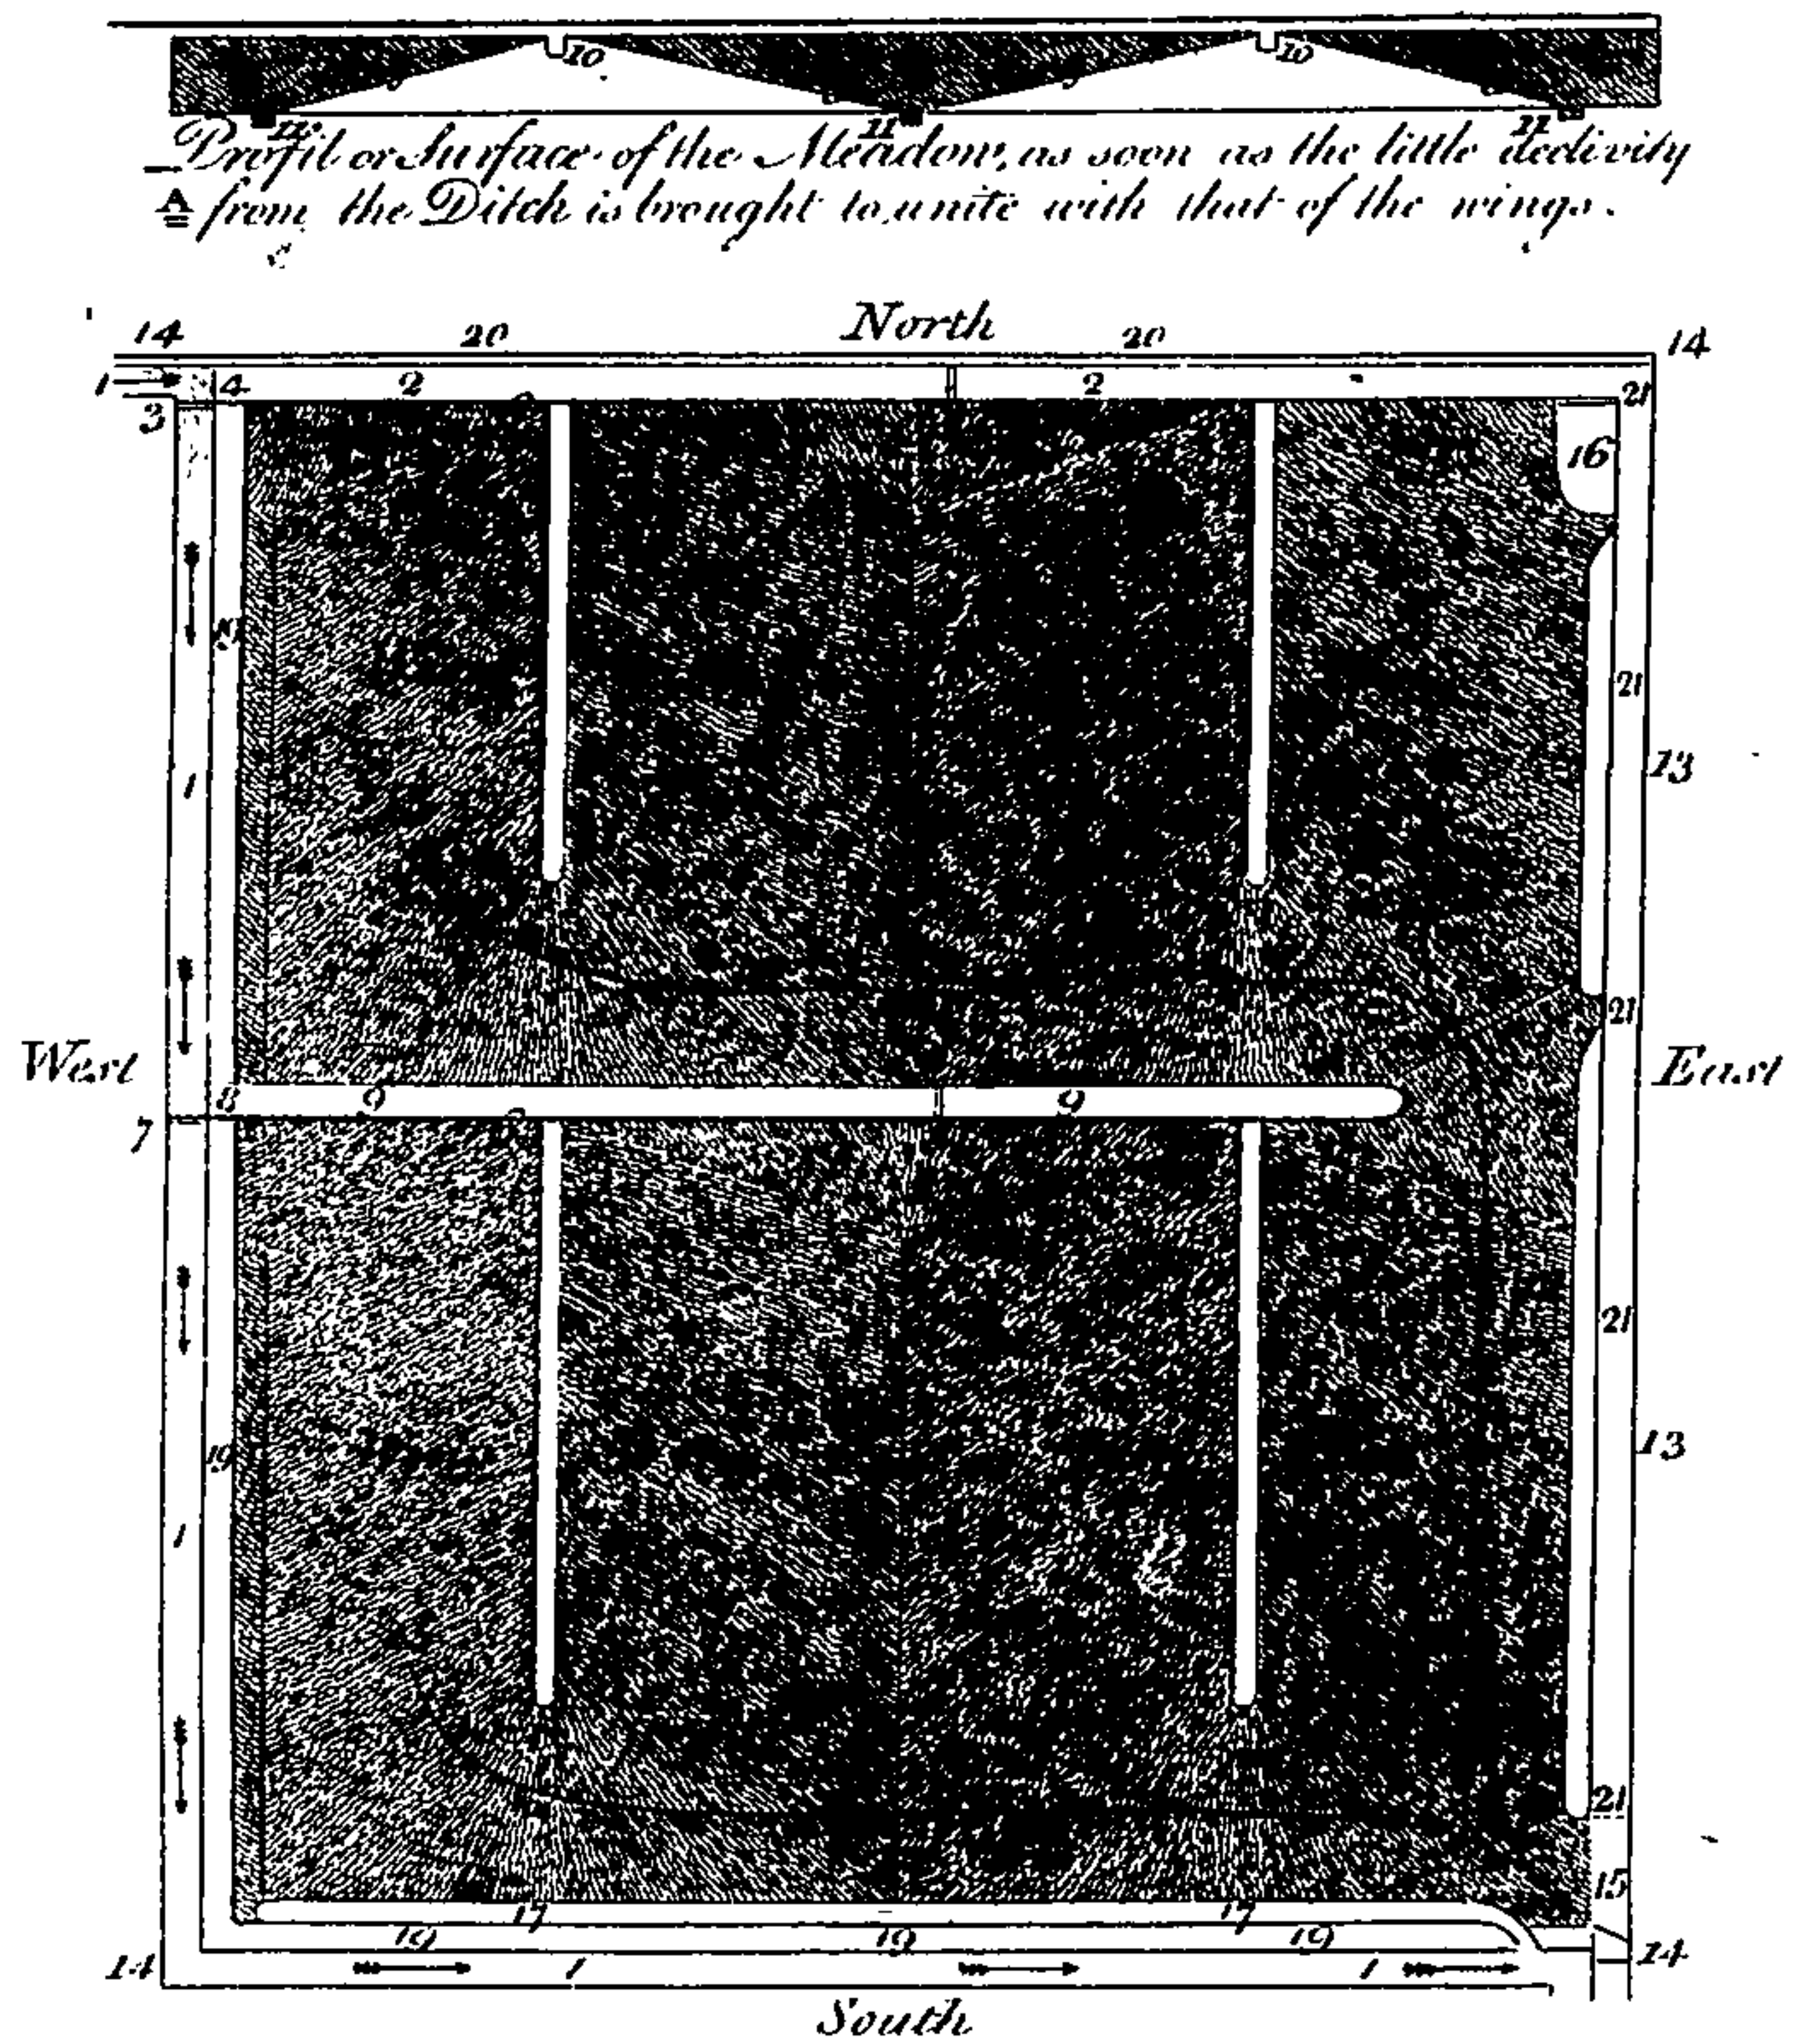

But though water is so necessary to the growth of plants, yet in lands that abound with it, there is a necessity for conveying it away, the best methods for doing which the reader will find under the articles BOG, DRAINING, MOOR, &c.

WATER-FARCY, a disease incident to horses, and is of two kinds; one the product of a feverish disposition, terminating on the skin, as often happens in epidemical colds; the other is dropical, where the water is not confined to the belly and limbs, but shews itself in several parts of the body, by soft swellings yielding to the pressure of the finger. This last kind usually proceeds from foul feeding, or from the latter grass and fog, that often come up in great plenty with continued cold rains, and breeds a sluggish viscid blood. In the former case, I have seen the limbs and whole body enormously swelled, and very hard, the belly and sheath greatly distended; which were as surprizingly reduced in four and twenty hours, by slight scarifications within-side the leg and thigh, with a sharp pen-knife, and three or four strokes on the skin of the belly on each side the sheath; from these scarifications there was a constant and surprizing large dripping of water, which soon relieved the horse; when a few purges completed his recovery.

In the other species of dropy the curative intentions are to discharge the water, recover the crisis or strength of the blood, and brace up the relaxed fibres throughout the whole body. To this end, purge once a week or ten days: and give intermediately either of the following drinks, or balls:

Take

WATERING MEADOWS

ARTIFICIAL PONDS

Take black hellebore fresh gathered, two pounds ; wash, bruise, and boil in six quarts of water, to four ; then strain out the liquor, and put two quarts of white wine on the remaining hellebore, and let it infuse warm forty-eight hours ; then strain off, mix both together, and give the horse a pint night and morning.

Take nitre two ounces, squills powdered three drachms, or half an ounce ; camphor one drachm ; honey enough to form into a ball ; to be given once a day alone, or washed down with a horn or two of the above drink.

Take of the leaves and bark of elder, of each a large handful ; chamomile flowers half a handful ; juniper berries bruised, two ounces ; boil in a quart of water to a pint and a half, to which add honey and nitre, of each one ounce.

Give this drink every night, or night and morning ; and to complete the cure, and strengthen the whole body, give a pint of the subsequent infusion every night and morning, for a fortnight, fasting two hours after it.

Take gentian root and zedoary, of each four ounces ; chamomile flowers and the tops of centaury, of each two handfuls ; Jesuits bark powdered two ounces ; juniper berries four ounces ; filings of iron, half a pound : infuse in two gallons of ale for a week, shaking now and then the vessel.

Before we close this article, we think proper to lay down the symptoms of an incurable farcy, that the owners of such horses may save themselves unnecessary expence and trouble in their endeavours to obtain a cure.

When a farcy by improper applications, or by neglect, has spread or increased ; or after long continuance resisted the medicines above mentioned ; if fresh buds are continually sprouting forth, while the old ones remain foul and ill-conditioned ; if they rise on the spines of the back and loins ; if the horse grows hide-bound, and runs at the nose ; if abscesses are formed in the fleshy parts between the interstices of the large muscles ; if his eyes look dead and lifeless ; if he forsakes his food and scours often, and his excrements appear thin, and of a blackish colour ; if the plate, or thigh vein continue large after firing, and other proper applications : these symptoms denote the distemper to have penetrated internally, and that it will degenerate into an incurable consumption : it is also most probable, that the whole mass of fluids are tainted, and become incurable by art. *Bartlett's Farriery, p. 193.*

WATERING MEADOWS. Anth. Songa, esq. in vol. II. of Mr. Young's Annals of Agriculture, says, "Iowards the expence of making a field, I may tell you, that I have expended about 30 per cent. of the whole value of the ground ; and I think about 10 per cent. more was wanting to finish it entirely and properly, before it could be perfect for rendering a great crop of hay ; which on only a moderate reckoning would give a revenue, according to what is esteemed, of about four times as much as when it was a corn-field watered occasionally.

"I call, finishing work, the making it perfect in the surface and regular declivity after subsiding of the earth, by correcting what is subsided by time, and cutting down every small protuberance ; the dunging it well ; the keeping in the greatest perfection of levelness and regularity, the borders of the ditches, from which the water issues upon the wings, as earth removed is apt to break down at the beginning, and till the roots of the grass have strongly fastened it. The dunging it properly wants attention to do it always more at the upper part of the wings, and where the surface shews itself poor, which is the case in many places, by such a great removal of earth to form the declivity of the wings ; and particularly towards the lower part of the wings, where almost only dead soil remained, notwithstanding the attention used to remove first the surface of cultivated earth to where the upper part of the wings were to be, and spreading it mixed afterwards on the lower part, when the wings were completed.

"That dead soil, deprived of the cultivated surface, was ploughed very deep twice, distant about two weeks one ploughing from the other, before the work of making its surface was begun. Every stone as big as a pigeon's egg

was taken away from the whole field, and put on the lane ; which lane, by it, was reduced as fine all the length of the field, as any body could wish for to pass on ; attention was used in doing it, that half the washing of the lane should run into the ditches of the meadow through the edge ; the other half runs into the ditch of the owners of land on the other side.

"Great care is given to this by every intelligent husbandman in that territory, as the washings of the roads and lanes are accounted a good helping manure, and every rain increases the rotten fattening earth in the ditches.

"The edges too are frequently hoed out, and the earth of their surface made use of for manure ; and by experience I know it is a good one : at the same time it is a cultivation of the edges.

"The only thing I would have done for the edges, was to plant them all with trees, as, by keeping them down properly for it, they make the best and strongest edges, and sooner than any thing else I know of.

"To spare the expence of doing by hand all the work of forming the wings of the meadow, the plough was used to form the first rough declivities, a very strong wheel-plough, drawn by four oxen, and a horse as a leader. If it had been clayey ground, or clay, six oxen would have been wanted for such a deep ploughing. *See Plate XXVIII.*

"After the meadow was made, it was sown with oats and clover, and a great deal of hay-loft sweepings and liftings of every sort of grass ; and for a foundation of a fine good meadow, with a quantity of seeds from the watery meadows about Milan, bought of a seedsman there. The oats and grasses were all cut for hay at the beginning of June ; another cut was to be made at the beginning of August when I came away, and my direction was to cut it no more that year, unless very luxuriant ; but in this case I recommended to do it soon, that much grass might remain on it before the frost.

"The growing of the oats did shew better than any thing else where the ground was richer or poorer. In some places they were above five feet high, and in others but a foot high. I have remarked to the farmer who was left in possession for two years, by dividing the hay in half the attention he was to use in dunging it more where the poor spots were, that it might be brought to an equality of product in all the surface, at least as far as it was possible.

"The harrow, the indented roller, and the plane, called there the spianatona, were not left idle in making the meadow, as all tend to spare the hand-work.

Explanation of the Plate.

1. Rivulet, about 3 feet wide, and 18 inches deep ; and carrying water about 6 or 8 inches deep.
2. Upper ditch, about 6 feet wide, and 5 feet deep.
3. Water gate, to stop the current of water in the rivulet, that it may run into that ditch.
4. Water-gate, to stop or let the water into the ditch.
5. Water, to hinder watering the easterly parts or divisions of the meadow when chosen.
6. Ditto, to hinder watering the westerly divisions of ditto.
7. Ditto, to stop the current of the rivulet, and throw the water into the lower ditch.

N. B. When the upper ditch has thrown water enough on the upper division of the meadow, the water begins to collect through the rills into the ditch of the lower division, but not enough to irrigate it. Then the gate, No. 3, is risen a little, that part of the water may run down the rivulet, and by stopping the gate, No. 7, and open the No. 8, it may run into the ditch, No. 9 ; by which, between the collecting water from above, and the supply from No. 8, the lower division begins to be irrigated. As soon as the upper division is well irrigated, which happens in two hours, more or less, according to the water the rivulet happens to carry at that time, the gate, No. 4, is shut down, and all the water is thrown, by opening entirely No. 3, into the ditch, No. 9, through its gate, the No. 8.

"3. Water, to hinder, to stop or let the water into the ditch of the lower division of the meadow.

"9. Ditch of the lower division, about 4 feet wide, and 4 feet deep.

"10. Small ditches, about 2½ feet wide, and 2 feet deep, that receiveth the water from the leading ditches, No. 2 and 9 ; and expend it very finely and regularly on the wings, with the greatest exactitude.

" 11. Rill, about one foot wide and one foot deep, at the bottom of the wings, to receive the waste water and carry it to the ditches below.

" 12. Ditches close to the edge towards the lane, like the rills, but made 3 or 4 feet wide and deep, to receive the waste water on that side, and on purpose to form rotten earth and mud.

" 13. Pasturano Lane, half of it belongs to the field, the whole length, and is comprehended in the measure for property and for land tax, except high roads; all the rest, either road or line, is in the same predicament.

" 14. Jermini's, half of the bed of the rivulet is measured with, and belongs to the field.

" 15. Passage or entry into the meadow for sledges to carry out the hay to be put on carts in the lane, and to carry the distribution of the manure, &c.

" 16. Heaps of manure thrown in from the lane Pasturano, on purpose that no carts may go into the meadow, to spoil the surface of it: to which heap is carried all the mud, and cleaning of the ditches and rills, and these are cleaned every year almost.

" 17. Ditch at the bottom of the meadow, to collect all the waste land; whose bed is about 4 feet wide, and 4 deep, and has only a small opening for discharge, on purpose that the water may remain the longer in it, and deposit therein all the richness possible before it runs into the rivulet again.

" 18. Rill about 1 foot wide, and 6 inches deep, for the discharge of the ditch into the rivulet at the bottom.

" 19. Bank close to the rivulet.

" 20. Ditto north of the upper ditch.

" 21. Edge on the border of the lane.

" All planted thick with forest trees, as oak, elm, poplars, &c. all polled, except from distance to distance, the best growing trees are left growing in the full natural way. The pollards are cut every 4 years for poles and faggots.

" 22. Two small rills, 6 inches deep, to discharge the water from No. 12, when superabundant.

" 23. Rills to carry irrigation to the little ground near the bank of the upper ditch, No. 2, till the declivity of the ground; these meet the declivity of the wings in the regularity of these. These rills are necessary if the southern bank is planted, because the trees make the border of the ditch irregular for the level.

" 24. Water-gates, that serve like No. 6, to hinder the water from the ditches, No. 2 and 9, to come in, and to keep the two ditches full of water always.

WATTLE, a kind of hurdle formed with split wood, and used for making folds for sheep.

WAX, or **BEES-WAX**, a substance formed by bees from the farina of flowers. See the article **BEE**.

WAY-BREAD, plantain.

WEANEL, an animal newly weaned.

WEED, any plant growing in a field different from what the farmer intended.

There is not a field where we do not find some of these; they grow in the greatest plenty on the richest soils.

Mr. Marshall, in his Minutes of Agriculture for the month of June, says, "weeds are now in their most succulent state; and in this state after they have lain a few hours to wither, hungry cattle will eat greedily of almost every species. There is scarce a hedge or nook, but what is at this season of the year valuable, and it certainly must be good management to embrace the transient opportunity; for in a very few days they will become real nuisances. The margin of every meadow is a fringe of weeds, which, if made into hay, not only spoil the stack, but fill the fields in summer, and the farm-yard in winter with weed-seeds; but by verdling with them while succulent, the cows which go to the common are benefited, and the fields, the stack, and the farm-yard left unencumbered; besides a fresh swath of fine grass, (if the weeds are cut early enough) ready to be mown with the rest of the field."

Weeds will appear impediments to vegetation, if we consider the following particulars.

They rob the plants we desire to cultivate of their food; they prevent these plants from branching out from the root, and they lessen the vegetable pasture in the land where they are suffered to grow.

Weeds are nourished by the same food that would nourish useful plants; and therefore, when allowed to grow along with them, must rob them of part of their food. Although it is allowed, that the food of all plants is not exactly of the same kind; yet as plants suck in whatever

juices or small particles of matter are touched by their roots, it may be justly said, that all kinds deprive the earth of that vegetable food which would nourish others.

Experience convinces the farmer of the truth of this: for he finds, that his crop is bad in proportion to the quantity and kinds of weeds with which his land is infested.

Weeds cover the surface of the land on which they grow, and thereby, confining the plants we desire to cultivate, prevent them from branching out from the root. For all plants, when confined by others at their sides, instead of branching out, as some of them are inclined to do, make vigorous efforts to get above those by whom they are confined.

Some persons have attempted to show, that corn never wants room to grow; and that it is the want of food alone which makes some plants decay, when they are set too thick. If this is true, weeds can do no harm to plants, by covering the surface, and confining them while they grow. But let a person cast his eyes upon a plantation of any kind, and he will immediately observe, that where the plants are placed very near to each other, they stretch out chiefly to the length; and where they are placed at a greater distance, they grow not so much to the length, but more to the thickness, and branch out on all sides. So that the proportion of nourishment which the plants receive, makes them grow either to the length principally, or to the thickness, and branch out, according as they are placed near, or at a distance from each other. The same thing happens, when there are many weeds growing amongst corn. Some fields are so much infested with weeds, that, though no grain is sown, the plants come up very thick. This obliges the farmer to give plenty of seed: in consequence of which the surface is quite covered; and the plants of corn being confined by the weeds, instead of branching out from the root, and producing two or more stalks, as they are naturally disposed to do, push up one stalk only, that so they may the more easily get above their rivals. The proportion of nourishment which they receive, makes them grow to the length, instead of branching out from the roots; makes them produce one stalk and ear only, instead of many. Experience confirms the truth of this. When land is rich, and at the same time much infested with weeds, the plants of corn grow tall enough; but seldom have more than one stalk.

Some kinds of weeds have great numbers of small roots, which they extend to a great distance. These roots bind the soil in such a manner, as to lessen the vegetable pasture; or rather make it very difficult to enlarge it by tillage. It may be observed, that when a field is much infested with quickening grass, the soil is so firmly bound together by the roots, that it is not possible to pulverize it. When ploughed, the earth of the furrow is turned over whole, and the harrows scarcely make any impression upon it.

It is of great importance, therefore, to know how to destroy these useless and noxious plants, that so all the vegetable food in the soil may be applied to the nourishment of the useful plants we desire to cultivate; that these useful plants may have room to extend themselves, and branch from the root on all sides; and that the vegetable pasture, which, by the rain that falls, and the natural weight of the soil, is always lessening, may be the more easily enlarged.

Different Kinds of Weeds.

Plants are commonly divided into two sorts; annuals, that is, such as in one year come to perfection, carry seed, and die; and perennial, that is, such as continue in life for more years than one. Annual plants are almost all propagated by the seed. Perennial are propagated, some by the seed, others by the root, and a third sort both by the seed and root.

Weeds may be divided in the same manner, into annuals and perennials. But, in treating of the methods of destroying them, we shall be better understood, if they are divided into these two sorts; weeds that are propagated by the seed, and weeds that are propagated by the root. It is needless to consider the weeds that are propagated both by the seed and the root, as a third sort. For when their seeds infest the land, they must be treated as weeds that are propagated by the seed; and, when their roots infest the land, they must be treated as weeds that are propagated by the root. It is necessary, however, to divide weeds into these

two sorts, into which we have divided them: for, in some cases, that kind of management proper for discouraging the one sort, tends to encourage the growth of the other.

But, besides these two sorts of weeds mentioned, it will not be improper that we likewise take notice of those shrubs by which some land is greatly infested. These, though they are not commonly reckoned in the class of weeds, and though some of them may have their particular uses; yet, as they are plants different from what the farmer desires to cultivate in his fields, they fall under the definition which we have given of weeds, and shall be reckoned by us a third class.

Methods of destroying Weeds.

The destroying of weeds is certainly one of the most important parts of agriculture. By allowing them to grow, dilloaw the land, as was formerly observed, to be robbed of its vegetable food, and its vegetable pasture to be greatly lessened.

It may be inquired, what becomes of this vegetable food of which they rob the land? It is either conveyed to the air, and sent to enrich other land, or it is turned into a form that renders it destructive.

When weeds wither and putrefy above ground, the salts and oils which they contain, and of which they deprived the land on which they grew, become volatile, and fly off into the air, and leave little more than their earth remaining.

When weeds carry seed, and shed it upon the land, and when the roots, by the nourishment they receive, are enlarged and extended; the vegetable food, of which they have deprived the land, is turned into a form that renders it destructive, into seeds and roots, by which the land is further exhausted.

The seeds and roots of weeds, though destructive to useful plants, by robbing them of their food, yet they contain vegetable food in themselves: and, when the seeds are picked up by birds, and the roots eaten by animals, the vegetable food is carried off. But, if these weeds are destroyed, and reduced to a state of corruption, the vegetable food, which they have taken from the land, and rendered destructive, is restored to it, and becomes beneficial: so that land that is poor, and unfit for carrying crops of useful plants, by being full of weeds, may be made rich and fertile, by destroying them.

From these things it appears, that the destroying of weeds is one of the most important parts of agriculture. As it is important, so likewise it is difficult.

There is scarcely a field, in which we may not observe weeds of the two first kinds mentioned; of the kind that is propagated by the seed, and the kind that is propagated by the root. Some of these, perhaps, it may be easy to destroy, as they are foreigners, and not adapted to the soil; but others of them being natural to the soil, in that kind of it that is most proper for them, it may be expected, not only that it will be very difficult to destroy them, but also, that, by the culture given to the land, they will thrive wonderfully, carry great crops of seed, multiply, and extend their roots. As the destruction of weeds is then so important and difficult, it is a work that must be particularly attended to.

Weeds have been divided into three sorts. To destroy these different sorts, different management is required. It is necessary therefore to treat of them separately.

Methods of destroying Weeds that are propagated by the Seed.

Weeds are very different in their natures. The seeds of some of them will putrefy in a few years, if they lie moist in the earth, and are prevented from vegetating. But the seeds of others will lie many years in this situation, without having their vegetative power destroyed. This we know from experience. Land infested with different kinds of weeds, has been frequently thrown out into grass, and allowed to lie only a few years; some kinds of weeds are found to be destroyed, when the land is broke up again; but, though it lie twenty years, some other kinds are found in as great plenty as before.

The first sort may be destroyed by turning the land infested with them, from tillage into grass, and allowing it to remain in that situation for five or six years.

Both sorts may be destroyed by bringing the seeds to ve-

getate, and then tearing up the young plants. Seeds will not vegetate without air. Some require a greater proportion, and some a smaller. The small seeds will not vegetate without a very great proportion of it. It may be observed, in fallowing land which is full of weeds, that great numbers of them appear after every ploughing. This shows, that some of the seeds had not a sufficient quantity of air, in their former situation, to make them vegetate. Now, to give these small seeds the proportion of air necessary for them, they must be brought near the surface, and the earth about them rendered free and open. If the land is frequently stirred and turned over, both these will be done. For every time the land is stirred and turned over, some seeds, that before lay deep, are brought near the surface, and the earth about them also rendered free and open: and, besides, the plants that have appeared are thereby torn up and destroyed.

Every farmer that practises summer-fallowing, is now fully convinced of the truth of this. For he observes, when the season is favourable, and his fallow is well and frequently ploughed and harrowed, and time allowed betwixt every ploughing and harrowing for the weeds to vegetate, that his land, for several years, is not so much infested with weeds as before.

It has been observed, that seeds will not vegetate without air, and that to give the smaller kinds the quantity which they require, they must be brought near the surface, and the earth around them rendered free and open. It is necessary likewise to observe, that water is as requisite to promote vegetation as air; and that the bringing seeds near the surface, and rendering the earth free and open around them, as it supplies them with air, tends to deprive them of water. In the performance, therefore, of those operations, by which the land is stirred and turned over, to promote the vegetation of the small seeds, great care must be taken to preserve the sap, as much as possible. This will be done, if, in stirring the land, the surface is made smooth and plain. It is obvious, that when the surface is rough and uneven, the drought has easy access; but, when it is smooth and plain, the winds have less influence, and the sap is better preserved. Every farmer will observe, that in dry weather, when land is allowed to lie some time after it has been ploughed, without being harrowed, the drought has easy access, the sap is exhaled, and the seeds in it, though near the surface, and the earth around them free and open; yet, being deprived of water, are prevented from vegetating: whereas, when the land is harrowed immediately after it is ploughed, the sap is preserved, and the seeds spring up. Hence the custom of sowing barley immediately after the plough. Barley is commonly sown in a dry season; and therefore the land is not allowed to lie long after it is ploughed, lest the sap should be exhaled; but is immediately sown and harrowed, by which the sap is preserved.

The vegetation of seeds in land is promoted, not only by stirring and turning over the land, but also by the application of dung and some other manures. Dung raises a fermentation; this opens the pores of the soil, allows the air to reach the seeds, and gives them liberty to put forth their roots. If dung, therefore, is laid upon land infested with weeds, and the land carefully stirred and turned over several times, all the seeds in it, by degrees, will be brought to vegetate; and thus the weeds will be destroyed.

It must be owned, that this practice, though proper for destroying weeds, may, in some cases, destroy some of the virtues of the dung, before it is applied to promote the vegetation of the useful plants we design to cultivate. Dung promotes vegetation, by producing a fermentation in the soil upon which it is laid; and, by this fermentation, separating its particles. If this fermentation is, in a great measure, over before seed is sown, the natural weight of the soil, making it subside, will render the vegetable pasture, while the plants are growing, much less than it would have been, if the dung had not been so soon laid on; and more harm may be done by this, than advantage gained by destroying the weeds. But, though it may be improper to follow this method, when seed cannot be sown for a considerable time after the dung is laid on, as is the case sometimes when summer barley is sown on fallow, yet it may answer very well, when seed is to be sown soon after, as is the case when wheat is sown. The advantages arising from the destruction of the weeds, though not in the first case, yet in the last, may probably do more than overbalance the loss arising from

from some part of the strength of the dung being exhausted before seed is sown.

It may, perhaps, be thought a little surprising, that dung should be proposed as a means of destroying weeds, when it is universally considered as a great encourager of them. It is certain, that the laying dung upon land makes more weeds appear than otherwise would do. If the seeds of these weeds are in the dung, it must be owned, that it increases, and not diminishes their number. But, if the seeds are in the land, and the dung only makes them vegetate, it becomes a proper means of destroying them.

It seems to be the general opinion, that the great plenty of weeds that appear on land after it is dunged, are produced from seeds mixed with the dung. But there are some reasons to believe that this is a mistake.

It is to be observed, that dung produces weeds, when it is taken from a dung-hill, so much heated as to destroy the vegetative power of any seed.

It is observed likewise, that the same dung produces weeds, according to the nature of the land on which it is laid. It often happens, that dung carried from a town is laid upon different soils; and it is certain that this dung does not produce the same kind of weeds on all soils, which it would do, if the weeds arose from seeds, mixed with it: but always produces the weeds, with which the soil upon which it is laid is naturally infested.

These observations make it very probable, that the great quantity of weeds produced by dung, is entirely owing to the fermentation occasioned by the dung; by which almost all the seeds near the surface, receiving a proper quantity of air, are thereby brought to vegetate.

To this it may be objected, that such numbers of weeds do not appear upon land that is new marled, as upon land that is dunged. But, in answer to this, let it be observed, that a great quantity of marle is laid on, and in large pieces, and that it is ploughed in with a shallow furrow: and therefore, though a fermentation may be raised, yet the undissolved marle prevents a great part of the soil from being exposed to the air, in such a manner as to make the seeds in it vegetate; and also occasions such a hollowness, that, after the seeds begin to vegetate, such of the plants as are tender (and several sorts of them are not so hardy as corn) are easily destroyed by drought or frost.

Before we leave this article, it is necessary to observe, that the seeds of some weeds, particularly the different species of the thistle, are carried to a considerable distance by the wind; and where any earth is thrown up in such a manner as to intangle them, as at the root of a hedge, or side of a ditch, there they appear in great plenty. It is surprising, that many farmers allow them to grow there undisturbed: the consequence of which is, that their seeds are carried in great plenty into the adjacent fields, and thereby great damage is done; which might have been prevented by cutting them down, at a small expence, before their seeds were ripened, which will prevent their ripening, and being blown into the adjoining fields, therefore if they are cut down green, and carried into the yard, they will raise manure, where they will ferment, by being left in heaps.

Methods of destroying Weeds that are propagated by the Root.

There are many different kinds of weeds propagated by the root, and these of very different natures. Some of them infest the land that is in tillage, and others the land that is in grass. Any person may satisfy himself of this, by inspecting our fields. The farmer is very sensible of it: he knows that some kinds of weeds flourish and increase in his land, while in tillage, if he does not take all pains to discourage them: and when he lays down his land in grass, other kinds that do not appear before, soon discover themselves; and if undisturbed, continue to increase while, the land remains in that situation.

The first sort, it seems, have such a tender blade, and such tender roots, that they cannot pierce earth that is hard; but are of a kind that increase very fast, when the soil is free and open.

The second sort have the blade and roots so strong, that there is scarcely any soil that, of itself, will become so hard and stiff, as to prevent them from making their way through it; but are of such a nature, as to be easily torn up, when the land is free and open; and do not easily strike root again when torn up.

The natures of these weeds point out methods of destroying them.

The first sort, as they chiefly infest land in tillage, may be destroyed by turning the land from tillage into grass, and allowing it to remain for some years in that situation. This is confirmed by experience. Land over-run with quickening-grass, and other root-weeds of the same kind, is frequently laid down in grass, and allowed to continue for some years without being ploughed. This land, when broke up again, if allowed to lie in grass for six or seven years, is found to be clean, and the roots of the weeds destroyed.

The number of years necessary for destroying the roots, depends upon the nature of the soil. If the soil is naturally hard and stiff, it is the sooner brought to such a situation, as to prevent the roots and blades of the weeds from piercing it. But, if it is naturally soft and spongy, it takes a longer time before it is brought to that situation. For while the blade, or roots of the weed, can pierce the soil, their vegetation is not prevented. In some soils it is six or seven years before the roots of the quickening-grass are destroyed.

The number of years found necessary for destroying these root-weeds, has, no doubt, been partly the occasion of establishing the practice commonly observed. Three crops of corn are taken, and then the land is allowed to lie six years in grass, or lea. At the end of these, the farmer supposes that the lea is come to maturity, and fit again for being ploughed. When it is only two or three years old, it is called, in some parts of the country, calf-lea; and, if ploughed at that age, is commonly very full of roots.

The sowing land with grass-seeds, instead of turning it out into lea, destroys the roots of these weeds some years sooner. For thereby a sward being brought immediately upon the surface, the land becomes firm, the blades of the weeds are unable to pierce it, and the roots are deprived of air. Ryegrass-seed, or the common hay-seed, is the most proper for this. For the plants arising from these, soon cover the surface, and, by the number and smallness of their roots, bind the soil. Clover, particularly the broad clover, is improper; for the roots of it being large, they open the soil in growing and extending themselves, and thereby prevent it from arriving at that degree of firmness, necessary for destroying the weeds so soon, as if no grass-seeds are sown, but the land immediately turned into lea.

The second sort may be destroyed by turning the land infested with them, from grass into tillage; and it is not necessary to continue it long in this situation, for the weeds commonly disappear after the first ploughing.

But as it may be inconvenient to turn a field infested with weeds, from grass into tillage, or from tillage into grass; it is necessary to consider, if there are any methods of destroying these weeds, without altering the situation of the land.

When land in tillage is infested with weeds, they may be destroyed by frequently stirring and turning it over in dry weather. For the weeds being removed out of their place, the drought prevents them from striking root again. The stirring the land in wet weather is rather hurtful than beneficial: for though the roots of the weeds are removed from their place, yet the weeds themselves are only transplanted. If the land is wet, they soon strike root again; and the quickening-grass in particular, having its pasture enlarged, makes quicker progress than ever. But, if the land is dry, the weeds do not so easily strike root again: or, if some of them should strike root, they continue for some time in a languishing condition, and if removed out of their place, while in the condition, are easily destroyed by the drought. If land then is frequently stirred and turned over, by degrees all the weeds will be destroyed: for, by every stirring or ploughing, such of them as are in a languishing condition are destroyed, while those that are strong and vigorous are weakened.

When land is to be free from seed-weeds, it cannot be made too fine, nor the surface too smooth; for the more perfectly these are done, the greater number of seeds are brought to vegetate. But, when land is to be freed from root-weeds, it cannot be turned up in too large pieces, nor the surface left too rough: for the larger the pieces, and the rougher the surface, the drought has the easier access, and the roots are the more effectually destroyed.

When

When land in grass is infested with weeds, and it is inconvenient to turn it into tillage, the weeds themselves must be pulled up by the root, or frequently cut : which are the only ways of destroying them.

Some persons assert, that sheep are very fond of the yellow rag-weed, by which light land, when laid out in grass, is very much infested. If this is true, the putting sheep to pasture upon this grass, for a season or two, will effectually destroy this weed. This may be the more safely recommended, as the trial, though it does not succeed, cannot be attended with any danger or loss.

Some land, after being a few years in grass, is liable to be over-run with fog. This, it is supposed, is owing to the soil becoming soft and spongy near the surface. If this is the case, rolling, which makes the surface firm, will be of some use to destroy this pernicious weed. It may be observed, that, when there is a foot path through a grass-field over-run with fog, not so much frequented as to break the turf, the grass upon the path is clean, without any mixture of fog.

There is a third sort of weeds found to infest both the land that is in tillage, and the land that is in grass. This sort has not only the blade and roots very strong, so as to be able to pierce the soil, though hard, but also are of such a nature, as makes it difficult to tear them up ; or have their roots of such a kind, that they may be divided into a great number of plants.

These weeds cannot be destroyed, either by turning the land infested with them, from tillage into grass, or from grass into tillage : but they may be destroyed by the methods mentioned, when the situation of the land is not changed. If the land is in grass, they may be destroyed by digging them out, or by frequently cutting them. And, if the land is in tillage, they may be destroyed by frequently stirring and turning it over in dry weather. This work must be performed with ploughs properly made for cutting their roots. This kind of weeds push their roots very far down, and their roots are so tough and hard, that our common ploughs seldom break them. If there are any stones in the land, they push their roots among the stones ; and, in such places, the plough not having freedom to act, they continue undisturbed. In this land too the plough, most proper for cutting these roots, cannot go with safety. But if the stones are dug out, and the land ploughed with a broad pointed share, the roots, by degrees, will be cut, and the weeds destroyed.

Besides these three sorts of weeds mentioned, there is a fourth that chiefly infests land that is wet. Frequent cutting, and even digging out by the root, have been tried to destroy them, but to no purpose. They are not to be seen on dry land, and, when on land only inclining to be wet, appear very weak. This points out draining to be the proper method of destroying them, which indeed does it effectually.

We shall now conclude this article with observing, that all kinds of root-weeds, and many kinds of the seeds of weeds, may be destroyed by depriving them of air. For air is necessary not only to the vegetation, but also to the life of every plant.

When land is in tillage, the weeds may be deprived of air, either by burying them deep in the earth, or covering the surface. Trenching does the one, and a good crop of peas, potatoes, or any other plants that lie thick on the surface, does the other.

Fog, by which some lands in grass are much infested, may be destroyed in the same manner. The method proposed is this : the grass must be kept from the month of March to the month of December, for winter-pasturing, and the next season preserved for a crop of hay. The fog being by this management covered for two seasons by the grass, is thereby destroyed.

As different methods are necessary in the extirpation of different weeds, and it is of some importance to know which of them are perennial, and which only annual, we have added a list of the most remarkable weeds which infest the arable and grass lands in England, ranged according to their duration. A pomp of names is carefully avoided, and those which Mr. Hudson has given in his *Flora Anglica* are chosen : it is a misfortune that many farmers will not know what plants are meant by some of these names ; but it is a misfortune scarcely to be avoided, since the English names of vulgar plants are so various, altering not only with the county, but with the place, and

even sometimes depending on the whim of a common labourer.

By far the greater number of annual weeds infest the arable lands : in grass lands the perennials chiefly flourish. The reason is obvious ; in the former the roots are continually destroyed by cutting ; in the latter they are made to spread by cutting or eating down the stems : perennials usually require more than a year to come to perfection ; and the seeds by which annuals are propagated, are not so readily received into the more compact turf, as into land whose parts are constantly undergoing a separation.

The annual Weeds which infest arable Lands and Gardens are chiefly these :

- Ivy leaved speedwell, or small henbit. April.
- Annual dandel-grass.
- Bearded oat-grass, bearded wild oats, or haver.
- Little field-madder. May.
- Cleavers, or goose-grass. May.
- Parsley-piert. May.
- Pearl-wort, or chickweed breakstone. This small weed is very apt to infest gravel-walks ; and if it be suffered to feed, will increase prodigiously, and grow very troublesome. June.
- Bastard alkanet. May.
- Small wild bugloss. June.
- Male pimpernel. May.
- Venus's looking-glass, or coddled corn-violet. June.
- Dodder, hell-weed, devil's-guts, or scald. July.
- This is found chiefly on beans ; it strangles the crop, and draws its nourishment from the plants about which it entwines itself. It infests also hops and flax.
- Small corn-parsley. August.
- Goosefoot of several kinds flourishes on dunghills, and is often suffered by the farmers to grow there unmolested by which the dung is much exhausted. August.
- Fool's parsley. This is generally allowed to be a strong poison, and is very common in gardens.
- Shepherd's needle, or Venus's comb. June.
- Common chickweed. The pest of gardens.
- Knot-grass. This plant is remarkably full of seed, and propagates itself surprisingly : it will grow any where, particularly in places that are much trodden. The sparrows, and other small birds, are very fond of its seeds. June.
- Black bindweed. June.
- German knot-grass, or annual knawel. August.
- Purple-flowered chickweed, or spurry ; on sandy lands. June.
- Cockle. June.
- Corn spurrey. August.
- Petty-spurge. July.
- Sun-spurge, or wart-wort. These are both very common in gardens. July.
- Red-poppy, or corn-poppy. June.
- Wild larkspur. This has increased so much of late years in Cambridgeshire, as to become one of the common weeds among the corn.
- Adonis flower, pheasant's eye, red maithes, red Morocco. Frequent in the corn-fields of Kent.
- Corn crowfoot. The seeds of this do not come forth till the second year after sowing. June.
- Upright ground-ivy.
- Red archangel, or dead-nettle. Common in gardens.
- Great henbit.
- Narrow-leaved all-heal.
- Nettle-hemp, or hemp-leaved dead nettle.
- Red eye-bright.
- Fluellin ; sharp-pointed, and round-pointed.
- Gold of pleasure ; among the flax. June.
- Shepherd's purse.
- White-flowered charlock, with a jointed cod. June.
- Yellow-flowered ditto.
- Wild mustard, or charlock. May.
- These three, particularly the last, are the *opprobrium* of the farmers : they who will not be at the pains to extirpate them by hand, might do well at least to run a scythe over the crops, while the weed is in flower, and before their spring corn (for it is that which is chiefly troubled with it) is got up too high.
- Pumitory. April.
- Yellow vetchling ; very common in the corn-fields about Cambridge.
- Common sow-thistle. June.
- Common groundsel.

Corn-marigold ; the pest of light lands ; it is not fond of dung. In Denmark there are laws for the extirpation of this weed. June.

Common chamomile, or corn-feverfew. June.

Stinking May-weed. June ; somewhat earlier than last.

Blue-bottles. July.

Pansies, or heart's-ease.

Lesser nettle. August.

Orace, of several kinds ; along with the goosefoot, on dunghills, and the gardens. August.

Annual Weeds in Pasture Grounds are only the following :

Purging-flax. May.

Knot-grass. This spreads chiefly by the path sides, and where dung or rubbish has lain.

Yellow rattle or cock's-comb, vulgarly penny-grass ; in moist meadows. This keeps its ground, for the seeds are ripe at the time of cutting hay. June.

Eye-bright ; in dry pastures.

Red eye-bright.

Heart-trefoil, or clover. This is alway mixed with clover, and particularly with the hop-trefoil, or non-such. It is a harsher plant, full of hard, prickly seed-vessels, and therefore not a good food for cattle : it is easily known from other clovers, by its seed-vessels, and the spots upon its leaves.

Common creeping mouse-ear. May.

Smooth succory hawk-weed. June.

Star-thistle ; in dry barren pastures, and by way sides. July.

Hairy sheep's scabious ; on high pasture.

Biennial Weeds in Corn.

Viper's bugloss, called in Cambridgeshire, &c. cat's tail. It infests the corn very much every third year. July.

Mithridate-mustard, or bastard cress.

Common melilot. The seeds of this ground along with wheat are known to give bread a very strong taste. June.

Spear-thistle. July. This with many other kinds of thistles and other weeds, with downy seeds, are suffered to stand on banks, way-sides, and fallow lands, in order to serve for a constant supply of weeds. If the waste places were run over with an old scythe, this evil would soon be prevented.

Biennial Weeds in Pastures.

Wild-carrot, or bird's nest. June.

Cow-parship. July.

Common-mallow. May.

Rough-succory hawk-weed. July.

Stinking hawk-weed. June.

Musk-thistle. July.

Wild carline-thistle. June.

Perennial Weeds in Corn.

Field fox tail, or mouse-tail grass.

Common wheat grass, dog's-grass, quick-grass, or couch-grass. As every piece of this most detestable creeping-weed will grow, there is no way of destroying it, but by ploughing up the ground thoroughly, picking it out, and burning it.

Common field-scabious. August.

Small bind-weed. This spreads its roots deep and wide ; and as every piece of them will grow, it is no easy matter to eradicate this pernicious plant.

Bladder-campion, white corn-campion, spatling-poppy. July.

White-campion. May.

Small-bramble, or dewberry-bush. June.

Corn-mint. August.

White-archangel, or dead-nettle ; chiefly in gardens and under hedges.

Corn rest-harrow, or cammock. The roots of this mat together with great strength, and are therefore very troublesome, where land is to be ploughed for corn. This property, however, makes it an excellent plant to set on sea and fen banks, to keep them firm and compact. July.

Tree sow-thistle. August.

Way-thistle. The fallows are usually well overspread with this weed, whose downy seeds are easily spread by the wind. July.

Great knap-weed, or matfellow. Its roots are very stubborn and hard. July.

Corn horse-tail.

Perennial Weeds in Pastures.

Devil's-bit. June.

Great-plantain, or waybread. June.

Ribwort, or ribwort-plantain. June.

Yellow ladies bed-straw, or cheese-renning. It is a vulgar notion, but a false one, that this herb will turn milk. The good women are fond of putting some favourite plant into their rennet, and thus attribute to it a quality which it has no right to claim. July.

Cowslips, or pagils. April.

Round-leaved bell flower. August.

Lesser throat-wort, or Canterbury-bells. July.

Meadow-saxifrage. August.

Burnet-saxifrage. August.

Cow-garlic. This gives milk and butter an insufferable strong taste. June.

Broad-leaved dock. July.

Common-forrel. May.

Sheep's forrel.

White saxifrage, or fengreen. May.

Agrimony. June.

Drop-wort. Hogs are fond of the roots. July.

Meadow-sweet. June. Only in very moist meadows. Goats are very greedy of this plant, which neither horses nor kine will touch.

Tormentil, or septfoil. June.

Creeping-crow-foot, or butter-cups. May.

Bulbose-crowfoot, or butter-cups. May.

Upright meadow-crowfoot. June.

The three last, which occupy so much room in almost all meadows, are not eaten by any sort of cattle, being of a very hot and acrid nature, so that the notion of their giving butter a yellow tincture, is as false as it is vulgar.

Pilewort, or lesser celandine. April.

Meadow-rue. June.

Bugle. May.

Self-heal. August.

Common yellow toad-flax. July.

Common ladies-smock, or cuckow-flower. April.

Crowfoot cranebill. June.

Common broom ; in dry pastures. May.

Rest-harrow, or cammock ; in barren grounds.

Dandelion. April.

Rough dandelion. May.

Yellow devil's bit. August.

Long-rooted hawk-weed. May.

Dwarf carline-thistle. July.

Common coltsfoot ; in watery days. March.

Common butter-bur ; in moist meadows. March.

Ragwort, or seagrim. Nothing touches this plant ; though a perennial, it comes up easily by hand, when young, or when the ground is moist. July.

Fleabane ; in moist places. August.

Common daisie. We do not find that any cattle willingly eat of this plant, which occupies so large a part of our pastures.

Greater daisie, or ox-eye. May.

Common yarrow, or milfoil. The roots of this creep abominably, especially where rubbish, or dung has been laid. May.

Common knap-weed, or matfellow. July.

Orchises of various sorts ; as,

Butterfly orchis. May.

Male fool-stones. May.

Female fool-stones. May.

Male-handed orchis. May.

Female-handed orchis. June.

Red-handed orchis. June.

Purple late-flowering orchis. June.

Little purple-flowered orchis. May.

Man orchis. June.

Frog satyrion. May.

Triple ladies traces. August.

Bee orchis. June.

Carexes of various sorts ; in low meadows and fenny grounds.

} In moist meadows.

} In dry pastures, chiefly in chalk.

grounds. These are all very harsh: they are, however, mowed to fodder cows with in winter.

Common nettle.

Adder's tongue; in moist meadows.

Female fern, or brakes; on dry barren land. It strikes its roots far and wide, and is difficult to eradicate even with the plough.

Mosses of various sorts. Old pastures are most infested with these. Ploughing is the only effectual way of destroying them.

We have added the time in which most of the foregoing plants begin to flower; because about that time it is proper they should be destroyed.

Though the reader will find an account of many of the weeds enumerated in the above catalogue, under their proper articles, yet we were persuaded that a general description of the perennial weeds would not be unacceptable here, as too much cannot be said to enable the husbandman to know these pernicious plants, and exterminate them as soon as possible.

Annual dandel-grass is called white dandel by Gerard, and in the southern counties crap; though, in Worcestershire, they call the buck-wheat by this name. It was a ridiculous old notion, that this weed, which has ever been stigmatized as one of the greatest pests of corn, is produced from bad seed of wheat. The French call it *yvraine*; because put into bread, or beer, it is supposed to cause drunkenness. It has always been reckoned bad for the eyes, and to occasion vertigoes. This plant is very like the red dandel-grass, which has been so much cultivated, under the name of ray-grass, or vulgarly rye-grass: but the spike is much larger and paler; and has beards, which the ray-grass is entirely without. It is likewise annual: whereas the ray grass has an abiding root. Its seeds ripen with the corn.

Bearded oat-grass, or wild oats, is very like the common oat in appearance, but generally over-tops it. The seeds are also of a dusky reddish colour, and hairy towards the bottom. The beards or awns are very long, stiff, and bent. As it ripens with the corn, or but little before it, the extirpation of it is not very easy.

Bastard alkanet is called, also, bastard gromill, or gromwell, and falfern. Nothing is more common among the corn, especially among rye, than this weed. It may easily be known, by its red roots, which yield a red tincture, and are used by the country girls in Sweden, to smear their faces with. From the root usually rises a single stem, about a foot high, rough, and branching out at the top. The flowers are small and white, surrounded with five long, narrow, hairy leaves, and succeeded by four white rough seeds.

The dodder is so remarkable a plant, that it cannot be mistaken by those who know the name. It is entirely without leaves, and does not depend upon the ground for nourishment; but when it is grown up, rots at the bottom, and lives upon the juices of other plants, about which it entwines itself by means of small threads of a red colour which it throws out. The flowers are small, and come out in roundish heads, or bunches, many of them together, here and there, from the stem.

Small corn parsley, though it is very common among corn, does not seem to be much known. It is a low branching plant. The branches grow thick together, and are knotted and crooked. The flowers grow thick together after the manner of parsley, &c. and are of a white colour inclining to yellow. The seeds are large in proportion to the plant, and are set about with little crooked bristles, which makes them adhere to the stockings in great plenty when the seeds are ripe, which is about, or a little after, harvest.

The lesser hemlock, called by Gerard, thin-leaved wild hemlock, is so well known under the name of fools parsley, as scarce to need a description. However, as it is a matter of consequence to distinguish poisonous plants from those which they resemble, we may observe, that though the leaves resemble parsley, yet they are much darker on their upper surface, but pale and shining underneath. The divisions of the leaves are much sharper, and they have no smell, nor scarcely any taste. When the plant is in flower, it is easily known by the three long narrow green leaves, which hang down from the little stem that immediately support the flowers.

Shepherd's needle or Venus's comb, has its name from the remarkable shape of the seeds with their appendage, re-

sembling in this respect the cranes bills: these would be alone sufficient to distinguish the plant. They succeed small white flowers, and come out in a bunch like needles, or the teeth of a comb set close together. The leaves are very finely cut.

Knot-grass is so called from its knots or joints, of which its slender creeping branches are full. After harvest, the lands, in many places, seem all coloured with the little red flowers of this plant. It is called also, swine's grass; and, in the north, bird's tongue.

Black bindweed has a stem that lays hold on any neighbouring plants, and twines about them from right to left. Its leaves are smooth, and shaped pretty much like those of the buck-wheat, which its seeds also resembles; being triangular, but smaller. It frequently ramps up in hedges, and gardens, and is also very common among corn.

Corn crow-foot has an upright stalk. The leaves are of a pale green, and cut into long, narrow, acute segments. The flowers are much smaller, and paler than in the crow-foots of the pastures; but the seed-vessels are the most remarkable, for they are covered all over with prickles. This is extremely common among corn.

Charlock, called also chadlock, catlock, carlock, and wild rape, is, I suppose, too generally known to need a description. The white and the yellow-flowered charlock, or wild radish, which are the only varieties of each other, and not so common as the former, may easily be distinguished from it, by the paleness of their flowers, and the form of their seed-vessel, which is round, smooth, and jointed. Almost the whole plant is covered with bent pellucid hairs.

Yellow vetching, or small yellow fetch, has long slender divided stalks. The leaves are triangular, and grow by pairs close to the stalk. Out of these leaves comes a tendril, by which the plant supports itself; and, on a long stalk, one small pea flower, of a yellow colour, which is succeeded by a flat pod, about an inch in length, containing six or seven roundish seeds.

Corn-marigold, or golden corn-flower, is the buddle, or yellow buddle of Kent. Its leaves grow close to the stem, in an alternate order. They are of a blue-green colour, and are cut about the edges. The flowers are like those of the marigold, large, and a beautiful yellow.

Yellow rattle is known by its leaves being firmly indented about the edges, its flowers being yellow; and its seed-vessel swelling into a dry, large, compressed bladder divided into two cells, and containing several compressed seeds, surrounded with a membrane.

Red eye-bright, or eye-bright cow-wheat, has a stem rising not more than a foot high; long narrow leaves, indented about the edges, and purple flowers growing in spikes. It flowers in July and August.

Viper's bugloss. The stalks are rough, round, solid, erect, undivided, and marked with black spots; the leaves are very rough, long, narrowing to a point, and placed without any certain order. The large specious flowers, of a beautiful blue colour, grow in long bending spikes. They consist of one petal, divided into five roundish segments, of different sizes, and resemble a horn in their figure, expanding by degrees, from a narrow beginning. The flower-cup consists of five narrow segments, and contains four rough seeds.

Melilot is well known by its trefoil leaves, which are indented, and, as it were, eaten about the edges; and by its long, thin spikes of small, yellow flowers, which are succeeded by short rough pods, containing two seeds.

Wild carrot, bird's nest, or bees-nest, is very like the cultivated carrot, of which it is indeed supposed to be only a variety. The wild sort, however, differs in its roots being small and sticky. In both sorts, after they have done flowering, the umbels contract themselves into the shape of a bird's nest.

Cow parsnip, wild parsnip, meadow parsnip, or madnep. This grows three feet high. The stalk is round, furrowed, and hollow. The leaves proceed from a large membrane, or sheath. They grow on long hairy stalks, and are divided and downy. The flowers grow in large umbels, are white, and consist of five irregular petals. Two oval, streaked, compressed seeds, surrounded by a wing, succeed each flower.

Stinking hawkweed may be discovered by its very strong smell like castor. As it is not a common weed, it is not necessary to be particular in the description of it.

Musk-thistle is known by its handsome purple nodding heads

heads of flowers, which come out rather sooner than most sorts of thistle. The smell of them is agreeable.

Carline-thistles is very different from the other thistles. The hard, woody root, sends up one round purplish stalk, beset with prickly leaves in no order. This is terminated with several flowers, growing in a head. The small ones, composing the whole, are of a dusky purple, and contained in a swelling scaly cup; the inner scales of which are very long, shining, coloured, spreading, and placed in a ring round the flowers. The stalks and heads remain all the year, with very little variation, upon the dry pastures.

Perennial Weeds in Corn.

Field fox-tail, small bastard fox-tail, or mouse-tail grass, is known by its long, round, slender, smooth spike, of a dusky purple colour. The spikes are so very long and slender, that they usually bend a little. This grass is found in the moist furrows of arable land, and in any places where the water is suffered to stand.

Common wheat-grass, or couch-grass, is universally known, by its long white creeping roots. It grows very tall, especially in hedges. The spike resembles that of wheat in the manner in which the seeds are disposed.

Common field scabious is all over rough and hairy. The stalk is upright; a foot, or a foot and a half in height, spotted, and branching. The lower leaves are oval, and indented about the edge. Those which grow on the stalk are divided, and of that sort which botanists call pinnatifid. The flowers are blue, of the compound kind, consisting of a considerable number of small flowers, each divided into four parts, and having one seed under them.

The taste of the plant is a disagreeable bitter.

Small bind-weed, called, also, with-wind, and hedge-bells, though these names should seem rather to belong to the great bind-weed, which ramps in the hedges; whereas this overspreads the arable lands. The common people, in their wrath, have given this pernicious weed the same opprobrious names with the dodder, viz. hell-weed, and devil's guts.

The stalks of this plant are weak, and twine about any thing. They come near, from left to right; and when they find no support, they trail along the ground. The leaves come out single. They are three cornered, shaped somewhat like an arrow head, smooth, and placed on long foot-stalks. From the bosoms of the leaves comes out one flower on a very long foot-stalk. It is bell-shaped, of a beautiful colour, purple, red, white, or variegated; and is succeeded by a small, roundish seed vessel, containing four large angular seeds. The whole plant is full of a milky juice.

Bladder-campion, white corn-campion, spatling poppy, white bottle, white ben, or frothy poppy. The stalks grow a foot and a half, or two feet high, round, smooth, jointed, branched towards the top; and at every joint is a pair of leaves, perfectly smooth. The flowers are white, and consist of five bifid petals. The empalement, or outward covering, is puffed out into a roundish form; and is smooth, often varied with red, green, and white, and beautifully veined all over, like a fine net.

White campion, admitted into gardens, when it has a double flower, under the name of white batchelor's-buttons. It has a long and large root, of a sharp bitterish taste, sending forth several stalks about two feet high: round, hairy, jointed, branching, of a red colour near the ground: a pair of leaves comes out at every joint, hairy, and sharp-pointed. The flowers are like those of the last: but the empalement, which is not puffed out like that, is oblong, with purplish streaks down along it from top to bottom. The flowers of this are imperfect: the male or barren, and the female or fruitful, growing on distinct plants.

Small bramble, or dewberry-bush is distinguished from the common bramble of the hedges, by the place of its growth, the trailing of its round branches, the smallness of its prickles which are fewer in number, and chiefly on the stalks; the leaves growing only three together, being green underneath, and the side ones divided into two parts; and the blueness of its berries, which consist of a very few large divisions.

Corn-mint. We are told, on undoubted authority, that this herb will hinder milk from curdling; and that when hungry cows have been put after harvest into a field where

this plant abounded, it has been scarcely possible to turn their milk for cheese.

Corn rest-harrow, rest-plough, cammock, pretty whin, or ground furze. The hard, stubborn, creeping roots send forth many woody, round, slender, hairy branches, red towards the bottom. The leaves grow three together. The flowers of the pea kind, of a beautiful red colour, and are succeeded by a swelling, villous pod, containing a few roundish seeds.

Tree sow-thistles. The root is very creeping, full of milk, and with difficulty eradicated. The stalk is about two feet high, smooth at the bottom, but hairy where it begins to branch out. The leaves are like those of the dandelion, deeply cut, ending in sharp points, and having the edges set round with tender prickles. The flowers grow several together; and resemble those of the sow-thistle, but are much larger, of a deeper yellow, and surrounded by a very rough, hairy, dark-coloured empalement. They have the smell of bitter almonds, and are succeeded by downy seeds.

Great knapweed, matfellow, or bulweed. This plant is about two feet high. The stalks are round, streaked, and hoary. The bottom leaves are oblong and undivided; but those which grow on the stalk, are cut and divided. The flowers resemble those of the blue-bottle in shape, but are of a red colour. The seed is small, oblong, reddish, and hairy in the upper part.

Corn horse-tail grows in moist places. In April, naked stalks come up, which bear the flower and seed. These are but of short duration. In May, other stalks arise, hollow jointed about a foot high, and sending forth all round, hollow jointed leaves, six or eight inches in length, subdividing into others at the joints.

Perennial Weeds in Pasture.

Devil's-bit is a kind of scabious. It differs from the common field scabious, in having undivided leaves, set thicker on the stalk; in the flowers not spreading out into a flat surface, but growing in a round form; and the small flowers, which compose the whole, being all of a size and regular: and, lastly, in the root looking as if it were bit off at the end.

Great plantain, or way-dread, is easily known by its broad leaves, spreading on the ground, and marked on the under surface with seven strong nerves. From the centre of these arise several naked, round, hairy stalks, sustaining a long, cylindrical spike of small flowers, set thick together.

Rib-wort plantain has much longer leaves, marked only with five nerves. The stalks are higher, and not round, but cornered, and the spikes of the flowers are shorter.

Yellow ladies bedstraw, cheese-venning, maid's-hair, petty mugwet. Its slender stalks rise to about a foot. The leaves come out in whorls, eight or nine together. They are long and narrow, and of a deep green. Towards the top of the stalk, two little branches usually come out, sustaining a considerable number of small yellow flowers, consisting of one petal, divided into four parts, and succeeded by two smooth roundish seeds.

Round-leaved bell-flowers. The bottom leaves are roundish: those upon the stalk long and narrow. The flowers are blue, bell-shaped, with the edge divided into five parts, and hang down.

Lesser throatwort, or Canterbury bells. The stalk is cornered and undivided, about a foot high, and hairy. The flowers grow at the top of the stalk close to it, several together. They are erect, of a beautiful purple colour, and are divided to the middle into five acute segments.

Meadows saxifrage, English saxifrage, or stone-break. The root has a sharpish, aromatic taste. The stalks are round, streaked, and reddish towards the bottom. The leaves are smooth, of a dark green, and divided twice into long narrow, sharp segments. The foot-stalks membranaceous at the base. The flowers grow in loose umbels, and are of a pale yellow. The seeds are oval, streaked, and red at the top.

Burnet saxifrage is of two kinds. The large is found in woods, and the smaller in dry pastures. Of this last there is a variety, differing only in the leaves, which are cut even to the root. The stalks are streaked, and branched. The flowers grow in umbels close together. They are small, white, and consist of five entire petals. These are succeeded by two seeds of an oblong oval form. The root has a very hot taste.

Crow garlick, or wild garlick. The leaves are round and smooth, resembling much those of rushes. From the midst of these rises a stalk, a foot or more in height, naked, slender, round, smooth, and hard; sustaining many purple seeds, or little bulbs, about the size of grains of wheat, collected into a round head.

White saxifrage, fengreen, or stone-break, has kidney-shaped leaves spread upon the ground, and divided about the edges, not much unlike those of ground-ivy, but softer and smaller, and of a faint yellowish green. Among these rises a round, hairy, branching stalk, about six inches high, bearing spacious white flowers, consisting of five entire petals. This pretty little plant grows in dry pastures, and may readily be known by its roots, which are made up of little knobs.

From a want of sufficient distinction in names, a strange confusion has arisen between the meadow saxifrage, burnet saxifrage, burnet, and white saxifrage. It is hoped these descriptions will contribute something towards avoiding this confusion for the future.

Agrimony has generally a single, round, rough stalk, with leaves placed alternately upon it, which are winged with small leaves, placed between the larger pairs. The yellow flowers grow alternately along the stalk, in a long row, after the manner of a spike, and are succeeded by rough seeds.

Dropwort is known by its winged leaves, the divisions of which are all regular, and sharply indented about the edges, by its white flowers, growing in a bunch like an umbel; but principally by its roots, which consist of a bunch of knobs hanging upon threads, from whence it has the names of filipendula, and dropwort. The flowers smell agreeably.

Meadow-sweet, or queen of the meadows. The stalk is angular, smooth, strong, branching, and of a reddish colour. The leaves grow alternately, are winged, and consist of three or four pair of lobes, and a very large one at the end divided into three parts, like a raspberry-leaf. They are indented about the edges, white underneath, and wrinkled, like the leaf of the elm. The flowers are similar to those of the dropwort. The whole plant has an agreeable smell.

Tormentil, or septfoil. The root is large, of a reddish colour, and an astringent taste. The stalks are weak, and lie on the ground at first; but afterwards rise up. The leaves are hairy, grow close to the stalk, and are divided into seven parts. The flowers are yellow, and consist of four petals. There is another species, not so common, differing from this only in having its stalks laying entirely on the ground, and the leaves growing on foot-stalks.

The crowfoots are too common every where to need a description. They are known under the names of king-cob, king-cup, gold-cups, gold-knobs, butter-cups, and butter-flowers. The bulbous crow-foot is distinguished not only by its round root, but by the divisions of the flower-cups being bent back, the stalk being erect, and that which sustains the flowers being furrowed. The upright crow-foot has the divisions of the empalement spreading out, as in the creeping sort; but the flower-stalks are not furrowed, as in that and the bulbous one. The leaves are divided, first, into three parts; and each of those again into several. The upper leaves are long, narrow, and undivided. This plant grows much taller than the others. The flowers of all three are alike, and of a fine shining yellow.

Pilewort, figwort, or lesser celandine. The root consists of oblong knobs. The leaves are heart-shaped, cornered, and placed on foot-stalks. The flowers resemble in general those of the crow-foots, but differ somewhat from them in having the cup divided only into three parts, the petals being about eight in number, and narrower. This low plant runs very much at the root, and choaks all plants which are near it.

Bugle, middle confound, sicklewort, or herb carpenter. It rises about half a foot high, with a square stalk. The leaves come out by pairs, of a purplish colour, and indented about the edges. The flowers grow in a spike, are blue, and have a very small upper lip.

Self-heal, hooke-heal, sicklewort, carpenter's herb, or prunell. This differs from bugle, in the leaves being longer and narrower, and in the flowers growing in a thicker spike; their upper lip being larger, and their filaments being forked.

Common yellow toud-flax, or flax-weed. It creeps very much with its hard woody roots; which send up several smooth stalks, a foot, or a foot and a half high, covered

with long, narrow leaves, placed without order. The flowers grow in close spikes, on short foot-stalks, at the top of the stalks. They are of a light yellow, shaped like a calf's mouth, and end in the spur behind.

Ladies-smock, cuckow-flower; in Norfolk, Canterbury bells. The stalk is upright, round, and smooth. The leaves are winged, with the lobes of the lower ones roundish; and of those upon the stalk oblong. The flowers are large, handsome, and white, or purplish; consisting of four obtuse veined petals. The seeds are contained in erect compressed pods, an inch, or an inch and a half long; divided into two cells, with which, when ripe, burst with a touch, and throw out their seeds to a considerable distance.

Crow-foot crane's-bill, or blue crane's-bill. The leaves are divided, almost to the middle, usually into seven parts. The stalk commonly divided into two branches, and each of these into two more. From the corner of each division comes a flower stalk supporting two large blue flowers; consisting of five roundish, entire petals, succeeded by a long seed-vessel, resembling a crane's-bill. This bill-like seed vessel is thick and rough, but not so long as in some of the other sorts.

Rest-harrow, or cammock, of the pastures, differs very little from the corn rest-harrow described before. The branches of this are armed with long stiff prickles. The flowers are of a higher purple, and come out single: whereas, in the other, they come out together.

Dandelion, or piss-a-bed, is well known in all pastures, by its milkiness, and its naked hollow stalks, supporting one large, yellow, compound flower, which is succeeded by a round ball of downy seeds.

Rough dandelion, or dandelion hawkweed. The whole plant is rough, with forked hairs. The flower-cup does not bend back, as in the common dandelion: and this is a taller plant.

Yellow devil's-bit, so called, because the end of the root seems as if it were bit off, is also known by the name of small hare's hawkweed. The leaves are smooth, long, narrow, and cut into long sharp pointed segments. The stalks, are a foot and a half, or two feet high, and branching. On the tops of these, grow many flowers, smaller and paler than in the dandelion, supported on scaly flower-stalks.

Long-rooted hawkweed. This has a very long tap-root. The stalks are a foot and a half high, or more; cornered, naked, and divided. The bottom leaves spread in a circle on the ground, and are jagged and rough. The flower-stalks are scaly. The flowers and down of the seed resemble those of the dandelion.

Dwarf, or small purple carline thistle. This lowly plant spreads its prickly leaves a foot round, and suffers nothing to grow beneath them. Its purple flower comes out in the midst of these, without any stalks, close to the ground.

Colt's-foot, sole-foot, horse-hoof, or bull-foot. In February, the scaly stalks arise, bearing one yellow compound flower, which is succeeded by a hairy white down. The leaves come out later. They are shaped somewhat like a horse's hoof, and are downy underneath.

Butter-bur, or pestilent-wort, resembles colts-foot in many respects: but the flowers are purple, and grow in a thyrse. The leaves come out after the flowers decay; and are like those of the colt's-foot in shape; but are three or four times as big.

Ragwort, ragweed, stagger-wort, stancer-wort, St. James's-wort, seggrum, or seagrime. The stalk is usually single, round, streaked, solid, and of a purplish colour in some parts. The leaves are very much jagged, smooth, and of a dark green. The flowers are yellow, radiated, and grow many together. When we affirmed that this plant comes up easily by hand, when young, or the ground is moist, we spoke from experience. The fact, in few words, was this. Some closes were notoriously over-run with this weed. The owner, just before the time of flowering, and after some rain, turned in a man and woman upon them; ordering the woman to pull up all she could by hand, and the man to root out the rest, with his docking-iron. The rag-wort was not indeed left in a lane for the down seeds to ripen, and to be carried on again to the closes, by the wind: but the plant was thrown in heaps and burnt, and the ashes were spread upon the grass. It was not, indeed, all destroyed at this first attempt: but the few plants which came up the following year were soon pulled up by the woman; and scarce a plant has now appeared in these closes for several years past.

Fleabane, middle fleabane, or fleawort. The stalk is round, bending, solid, and hoary. The leaves are oblong, sharp-pointed, wrinkled, downy, and embrace the stalk, on which they grow very thick, without regularity. The flowers are yellow, radiated, and inclosed in a flower-cup, made up of narrow scales like bristles. Mr. Ray tells us that if the leaves or tops of fleabane be squeezed, they smell like soap. Gerard says, the herb-women call it herb Christopher.

Greater daisie, ox-eye, or maudlin-wort. The stalk is five cornered, solid, and branching. The leaves are jagged and embrace the stalk. The flowers are large, and radiated. The ray is white, and the disk yellow: the seeds have no down.

Common yarrow, milfoil, or nosebleed. The stalks are slender, round, streaked, stiff, and hairy. They are divided towards the top into several branches; and these again into flower-stalks, supporting small white or purplish flowers, growing thick together in a kind of umbel. The leaves are cut very fine, and divided twice.

Common, or black knapweed, or matfellow, black matfellow, or bullweed. The root is hard, thick and woody, and has a disagreeable astringency. The stalks are round, rough, streaked, strong and very tough. The leaves are irregularly placed, oblong, and of a dark green. From the wings of the leave arise stalks, supporting one, two, or three heads of flowers, which are purple, and inclosed in a scaly cup: the scales are black, and surrounded with fine hairs, like the eye-lashes.

The orchises may be known by their roots; which are either a double bulb, resembling a pair of testicles; or a bunch of long fleshy roots, like the fingers of the hand. The flowers, by growing in a spike, make a handsome appearance. The colour is red in most sorts.

Adder's tongue is hid among the grass in low meadows. From a very low stalk arises a single, thick, smooth, oblong leaf; from the bosom of which, issues a kind of tongue, ending in a point, and indented on each side like a file.

Mr. Marshall, in his Rural Economy of Norfolk, says, "Hand-weeding is carefully attended to by farmers in general; and is, generally, performed by the acre: a practice I have not met with elsewhere; though most eligible to be adopted in every district: a farmer has not a more disagreeable task than that of attending to weeders by the day. The price is, of course, proportioned to the foulness of the crop to be weeded:—from sixpence to five shillings an acre is given."

WEEVIL, an insect of the beetle kind, resembling a small May bug, with a long sharp pointed head, to the hinder part of which are fixed two antennæ. It is black, and therefore easily distinguished in any corn: but its principal and favourite food is wheat, of which, either old or new, it devours great quantities; without however communicating any bad smell to it, as the moth does. Some call it the corn-louse, because it bites animals more strongly than fleas do. This has made it to be looked upon as a carnivorous insect; and many have pretended that it devours both the worm and the chrysalis of the false moth: an opinion which M. Duhamel does not think improbable, because, in effect, very few of those moths are ever found in corn where there are many weevils.

Upon thrusting one's hand into a heap of corn, one may easily perceive by its heat, whether it contains many of these insects, which generally lie pretty much collected; and the particular places where they are most numerous, feel much warmer than the rest. This observation soon led M. Duhamel to think, that a considerable heat is probably necessary for the hatching of their eggs; and that in this case, even if they should live, they will not be able to breed, in his ventilating granaries.

To ascertain this fact, he put some weevils into wheat (not stove-dried) in one of those granaries, in May 1751. It was well ventilated from time to time, and opened in August 1752, when none of them were found. He did the same with wheat which had been stove dried: and when the granary was emptied, a year and a half or two years after, not a weevil could be seen.

He again put some weevils into a ventilating granary in which wheat of the year 1754 was laid up, without having been stove-dried. This corn was taken out in May 1756, and sifted over a fine screen; which gave him an opportunity to observe whether the weevils had increased. The number seemed to him nearly the same as that he

had put in: and a further reason which induced him to think they had not multiplied, was, that this grain, instead of being heated, as corn is well known to be whenever weevils breed in it, was so cool, that a country fellow employed for this work could hardly remain bare-footed among it.

In 1755, Dom Edward Provenchere, procurator of the Carthusians of Liget, near Loches, in the province of Touraine, intending to make some experiments on the preservation of corn, chose for that purpose a large cask, at one end of which, a little above the common bottom, he put a floor of lattice work, and over that a canvas. This cask was filled with wheat of the harvest of 1754, of which it contained 1080 pounds. He then fixed to it a pair of middle sized bellows, so situated that they might easily be worked; and nearly in the centre of this corn, he put as many weevils as weighed six drachms; which is pretty considerable for that quantity of grain.

The bellows were blown an hour every week. In the beginning of September 1756, when that operation had been neglected for some time, the corn began to heat: but it was soon cooled again by using the bellows. The 15th of October, on taking the corn out of this cask, in which it had kept perfectly well, not above twenty weevils were found in it. Dom Edward says, he saw that insect come out of the vent-holes every time the bellows were blown. He perceived in many places several grains of corn linked together by threads, certainly formed by moths that were in his wheat (which had not been stove-dried), and, not dying immediately, had had time to spin their web.

Dom Edward filled another cask with nine hundred pounds of barley, not stove-dried, and put into it six drachms of weevils. Though care was taken to ventilate this cask as much as the former, which was filled with wheat, that is to say, during an hour every week, yet this corn heated prodigiously: the bellows could not cool it, and the weevils multiplied in it exceedingly.

"This," says M. Duhamel, is the very thing that happened to me in my larger experiment on the same kind of grain. Barley probably contains a great deal of moisture; and the question is, whether stove-drying can be able to preserve it. The increase of the weevils here seems to prove that this insect cannot multiply in corn which retains a proper degree of coolness."

Though the above experiments seem to prove pretty clearly, at least that the weevil cannot breed in corn which is kept properly cool, and that if any sure way to destroy this insect be ever discovered, it will be most likely to succeed by means of the ventilating granary; yet M. Duhamel, with his constant candour and unvaried zeal for the welfare of mankind, exhorts the naturalists, the philosopher, the lover of the public good, not to rely too much on any thing that he has said in this respect; to look upon the trials which he has related, as steps only which may help to lead to that desired end; and to continue their endeavours to render to the world the important service of shewing how this creature may be effectually exterminated, by any safe and practicable method.

"I have tried," continues he, in his latest writings upon agriculture, many of the receipts most vaunted in books of husbandry, as remedies against the weevil, and have not found the least benefit from any one of them. All that they have taught me, is that this animal will endure a great deal before it can be killed. It will live a long time without eating; cold will benumb it so as to make it appear to be dead; but I have put some of them, in that state, into a warm place, and after keeping them there for some time, have found that they were perfectly alive: the great coolness of my granaries has seemed to prevent their increase: but it has not killed them. They bear easily a heat of from forty-five to fifty degrees of Reaumur's thermometer (from one hundred and fifteen to one hundred and twenty-four of Fahrenheit's). I kept corn in which there were many weevils, during half an hour, in a place heated to upwards of eighty degrees of Reaumur's thermometer (two hundred and ten of Fahrenheit's): some of them perished; but others remained alive. They, therefore, who would destroy them by such a degree of heat, must let their corn be exposed to it during seven or eight hours at least.

"I grant that the smoke of sulphur will kill any insect; but that method is not practicable in granaries: for this vapour, which is very light, ascends to the top of the granary, and scarcely acts at all upon the corn on the floor.

It is true, that the corn may be so disposed as to let this smoke pass through it, and all the insects in it will then be destroyed. But, at the same time, this smoke will give the corn a very disagreeable and lasting smell, which depreciates it entirely. Consequently this method will not do.

"It is confidently said, that the weevils may be driven away by turning the corn with shovels rubbed with essence of turpentine. To try whether this essence really displeases them, I ordered two large casks to be made: the inside of one of them was rubbed with essence of turpentine; both of them were filled with corn in which there were many weevils; and the insects remained as quiet in the one as in the other. It is true, that when corn infested with weevils is turned with a shovel, several of those insects quit the heap, and hasten towards the walls of the granary. This may have been imputed to the rubbing of the shovel with oil of spikenard or essence of turpentine: but the same thing happens when the shovel has not been rubbed with any drug whatever; and the fugitive weevils soon return to the heap of corn.

"When corn is sifted in a sieve (and the same is applicable to a screen) fine enough to retain the grain, the weevils then agitated, shrink up their legs, and are, in that posture, generally so much smaller than the good corn, that very many of them drop through the sieve. The greatest part of them may therefore be destroyed by this method, which is a very good one: but unfortunately, there will still remain enough of them among the corn, to do considerable damage. This sieve or screen should be of wire; and under it should be placed an earthen or copper vessel, pretty deep, to receive the insects, and smooth on its inside, to prevent their getting out easily.

"Of all the methods I have tried, that which has seemed to me to be the best, is to dry the corn in a stove, or oven, heated to eighty or ninety degrees of M. de Reaumur's thermometer (from two hundred and ten to two hundred and thirty of Fahrenheit's, and to let it remain there twelve hours. I exhort all those who wish the welfare of the public, to study the means of destroying the weevil, and, in consequence thereof, to make particular experiments: but I beseech them not to publish their discoveries till they have made repeated trials of them, and that in different granaries: for I have sometimes seen these insects forsake a granary, when no cause could possibly be assigned for so doing."

WELD, or DYERS WEED, the name of a plant much used by the dyers to give a yellow colour to woollens, silks, cotton, and thread.

Its root, which is composed of a few ligneous fibres, does not pierce deep; from this root it puts forth leaves about four inches long and half an inch broad, of a lively green, soft to the touch, and spread circularly near the ground, with some gentle wavings at their edges, but obtuse at their points. Its stem, which rises from amidst these leaves to the height of three feet, or even more, if the soil and culture be very good, often branches out, and is garnished with leaves like those below, though smaller in proportion as they approach the flowers, which grow in long loose spikes at the end of the branches or stem. These flowers, which appear at the latter end of June, are each of them composed of three small irregular petals of a greenish yellow, to which succeeds a globular berry of the same colour, terminated by three points, and in which are inclosed small brown spherical seeds. These seeds ripen in September, the plant becomes entirely yellow when it is dry, and the whole of it, but especially the berry, is used in dying. The slenderest weld, and particularly if it inclines to a russet colour, is accounted the best: that which is larger, and of a dull green, is much less esteemed.

This plant grows naturally along the sides of high ways, upon dry banks, and on old walls, in many parts of England, France, Spain, and other countries where the winters are not very severe: but the cultivated sort is far preferable to the wild, both for the quantity and the goodness of the colour which it yields. It will thrive tolerably on almost any soil, provided it be dry and warm: but the richer the land is upon which it is sown, the greater will be the produce; and in proportion to the care with which it is cultivated, the more vigorous and fit for dying will it be.

The ground for this, as for every other plant, should be in fine tilth at the time of sowing it; though here, un-

less it be very poor indeed; it will not require dung. The seed should be that of the preceding year; for if it be older, great part of it will not grow. Both Mr. Worlidge and M. Duhamel are of opinion that weld seed should, on account of its smallness, for it is but little bigger than that of purslane, be mixed with ashes, buckwheat, oats, or some other similar ingredient, in order the better to avoid sowing it too thick; for the plants of weld thrive best when they are about six inches asunder. For this reason, as was before observed in regard to all plants which require being hoed, it is best to sow weld in rows. Some sow it on barley, or oats after they have been sown and harrowed, this requiring only a bush to be drawn over it; for it should not be covered deep. A gallon of weld seed thus used in the broad-cast way will be sufficient to sow an acre of land. It will not grow much during the first summer, when it is thus sown; but it will thrive apace after the corn is taken off.

The beginning or middle of August is a proper season for sowing weld in this country. The only care that it requires whilst growing, is to keep it clear of weeds, which might choke it, or at least weaken its growth.

The French, in general, sow their weld in March, and pull it up in July or August of the ensuing year, when part of its seeds are ripe, and the plant is still of a greenish yellow: they then dry it and thresh it upon cloths, to get the ripest of the seed, and after this they tie their stalks up in bundles, and sell them to the dyers. But Mr. Miller rightly judges, that the best time to pull the weld for use is when it begins to flower, that is to say, about the latter end of June, because, like all other vegetables, it is then in its greatest vigour, and consequently best fitted to yield the greatest quantity of dye. For a produce of new seeds, it is much better to sow a small piece of land on purpose, or to set apart for this end a suitable portion of the field of which the plants are intended for use, rather than let the whole stand too long, that is to say, till part of the seeds are ripe; because, by letting the plants stand till then, their quality is injured far beyond the value of the seeds that are got from them (the berries being, as was observed before, the part which yields the finest dye); and besides, the seeds thus obtained will of course be a mixture of ripe and half-ripe ones, on the growing of which there cannot be a due reliance. The common way of drying these plants is to set them upright in small handfuls in the field, and when they are dry, to tie them up in bundles. They must also be housed dry; and care must be taken to stack them so loosely, that there may be room for the air to pass between them, to prevent their fermenting.

The plants which are intended for seed should be pulled as soon as their seeds are ripe, and then be dried and beaten out for use; for if this is deferred, or if they are let stand too long, the seeds will scatter.

The method of cultivating this plant at Oissel, in Normandy, where great quantities of it are raised for exportation to Holland, independent of the consumption in France, is thus related by M. Dambourney, in the Memoirs of the Royal Society of Agriculture at Rouen.

"In the month of July, just after the kidney beans then in bloom have been hoed for the second time, and earthed up, especially if there be an appearance of approaching rain, weld seed is sown among them, very thin, as equally as possible. Careful husbandmen bury this seed by dragging over it a small bush of thorns. Whilst the weld rises, the beans ripen and are gathered; after which the ground remains, of course, planted with weld only. This is hoed about Michaelmas, then left in that condition during the winter, and in the ensuing month of March, when the danger of frosts is judged to be over, it is hoed again, to extirpate such weeds as may have come up in the mean time. Towards the end of June in this second year, when the weld has done blossoming, when its berries form, and when the plant begins to turn yellow, advantage is taken of the first fair day after a rainy one, to pull it up. Two men will then pull up as much of it in one day, as four men can when the ground is dry and hard. It is carried off in large bundles: but these are untied before the weld is laid up for keeing, and the plants are spread out and set upright against walls or hedges well exposed to the sun, the heat of which completes their drying in two days. They are then laid upon a cloth, to prevent the loss of the seed, which drops very easily out of the now open capsules; and finally, after being tied up again in bundles, weighing about thirty pounds apiece, they

they are piled up loosely in a barn or other well covered place where they complete their ripening, and generally shrink to less than half of their former weight.

"Weld raised on rich ground is apt to be greasy and too full of stalks: that which grows in sandy places is of a better quality, and has only one main stem: but, in return, the produce here is much less than in the former case.

"As soon as the weld has been pulled, sheep are turned in upon the land, to eat up the grass it may have produced: it is then ploughed once; and after another ploughing at the end of October, it is sowed with wheat, or great rye, without using any other compost or dung. If the land is light and destined for spring-corn, turneps may be sown upon the first ploughing after the weld; for they will have time to grow big enough to be pulled before the ploughing for oats or small rye; which last crops it will be proper to help with a little shavings or raspings of horn.

"If it be intended to raise weld after peas, the ground should be ploughed, and the seed sown very thin: to do which the more effectually, this seed, like that of turneps, should be taken up only in pinches between the middle finger and the thumb, and the fore-finger should remain extended, the better to help its spreading when it is dropped. This seed should be sown in rows sufficiently distant for the plants to have full room to grow; and the best way is to leave an alley after every third row. When sown, it is harrowed in, and the only farther care that the weld requires is to keep the plants free from weeds, by hoeing the ground at Michaelmas and in March, as before directed.

"The weld which is sown after peas does not injure the land it grows on; and therefore in this case, as after the kidney-beans before spoken of, wheat may be sown in October without any previous manure.

WELL. See DRAINING.

WHEAT, the name of a well-known plant, greatly cultivated in many parts of the world, especially in England.

As a crop of wheat, is, in general, the principal riches of farmers whose farms consist of arable land, we shall be very full in describing every method yet practised with success for cultivating this useful species of grain; and in order to this, shall begin with the method of preparing the soil by ploughing, harrowing and rolling.

Ploughing increases the food of plants, by opening the soil to receive the vegetable food from the air, and by enlarging the surface, and thereby exposing a greater quantity of the soil to its influence.

Ploughing enlarges the pasture of plants, by opening the soil if too solid, and making it firm, if too light.

Ploughing prepares the vegetable food for entering the roots of plants, by reducing vegetables to a state of corruption, and dissolving oils.

Ploughing destroys weeds, by making their seed vegetate, and then tearing up the young plants; and by exposing the roots to the drought.

Ploughing removes wetness, by laying up land in proper ridges.

It may be said, therefore, that ploughing is one of the most important operations in agriculture; and that the greatest care is to be taken in the performance of it.

Though ploughing in general serves all the purposes mentioned, yet commonly one of them only is chiefly in view; and according to the design in view the work is to be performed.

When the design of ploughing is to increase the food of plants, the surface cannot be made too uneven: for the more uneven that the surface is made, the greater quantity of the soil is exposed to the influence of the air, and the greater quantity of food procured.

When the design of ploughing is to enlarge the pasture of plants, that kind is best that goes deepest, (provided the soil allows) and most effectually breaks the mould; for the deeper that the plough goes, the greater quantity of soil is employed in vegetation; and the more effectually that the mould is broken, the larger is the pasture in the same quantity.

When the design of ploughing is to destroy root-weeds, the surface cannot be left too rough, nor the earth of the furrow raised in too large pieces; for the rougher that the surface is, and the larger the pieces of earth raised, the drought has the easier access, and more effectually operates in the destruction of the roots.

When the design of ploughing is to destroy seed-weeds, the surface cannot be made too smooth, nor the mould too much broken: for the smoother that the surface is made, and more effectually that the mould is broken, the seeds are the more exposed to the influence of the air, the sap better preserved, and their vegetation the more encouraged.

When the design of ploughing is to remove wetness, the land must be laid up in high and narrow ridges; for the greater number that there are of furrows, there are the greater number of drains; and the higher that the ridges are, the more easily the water finds its way to the furrows.

Thus we see how this operation of ploughing is to be performed, according to the chief design in view. It often happens, however, that land is in such a condition as to require more than one of these advantages which ploughing is intended to promote. These are sometimes consistent with each other, and the land may be ploughed in such a manner as best to promote all of them. Thus land is sometimes, at the same time, poor, and wet, and full of root-weeds: now it may be ploughed in such a manner as is most proper for increasing its food, removing its wetness, and destroying its weeds: for by one ploughing, its surface may be made uneven, which fits it for receiving an increase of food: it may be formed into narrow and steep ridges, which best remove its wetness; and the earth may be raised in large pieces, which best expose the roots of the weeds to be destroyed by drought.

At other times the land is in such a situation, that the advantage which it requires from ploughing are inconsistent with each other, and it cannot be ploughed in such a manner as is most proper for promoting all of them. Thus land at the same time may be full both of seed-weeds and of root-weeds: now, it cannot be ploughed in such a manner as is most proper to destroy both: for by one ploughing it cannot be raised in pieces and left rough, which is necessary to destroy root-weeds, and have the mould broke and be made smooth, which is necessary to destroy seed-weeds. This makes it necessary to have one of these things chiefly in view at first, and to consider which of the two it is proper to begin with, and how the work may be performed in such a manner, as the other may most easily succeed. Thus, in the present case, the land should be ploughed, so as to be raised in pieces, and to be left rough: and in that condition it should be allowed to lie, till the drought may be supposed to have destroyed the roots; and then it may be reduced, the pieces broke, and the surface made smooth, in order to destroy the seeds.

In ploughing there are some general rules to be observed, whatever is the design of it. Thus land is never to be ploughed when it is wet. When land is ploughed wet, the design of ploughing, whatever it may be, is frustrated; and this holds true in every kind of soil.

When stiff soil is ploughed wet, by drying too suddenly, it becomes so hard, that it can receive no benefit from the air, and the pasture in it is entirely shut up: root-weeds strike root again before the drought reaches them; and if there are any seed-weeds, the surface crusts so soon, that they are prevented from vegetating.

When light soil is ploughed wet, though it may receive some benefit by exposing a larger surface to the influence of the air, yet its pores, being full of water, will prevent its pasture from being enlarged: and the root-weeds that are in it will not be destroyed; they will rather flourish by being transplanted into a new pasture. In both kinds of soil the labour is very severe upon the cattle, and the land is greatly damaged by their going upon it, and treading it down with their feet.

Thus it is also to be observed, that whatever is the design of ploughing, the quantity of firm land taken off from the surface of the plough in going, ought not to exceed the wideness of the furrow which the plough makes below. If it does, the land is not clean ploughed; it is only scratched, and a quantity of the soil is left below untouched betwixt every furrow that the plough makes.

The quantity of firm land to be taken off by the plough, depends upon the design of ploughing, and the nature of the soil.

When the design of ploughing is to increase the food of plants, and destroy root-weeds, whether the soil is stiff or light, as great a quantity may be taken off as the plough can take conveniently; because the greater that the quantity is which the plough takes off, the rougher and more uneven

uneven the surface is made, the more food is procured, and the root-weeds more effectually destroyed.

When the design of ploughing is to enlarge the pasture of plants and destroy feed-weeds, though a large quantity may be taken off in a light soil, that naturally falls in pieces when turned over, yet a small quantity ought to be taken off in stiff land that is not so easily reduced; because the smaller that the quantity is which the plough takes off, the soil is the more effectually broken, and the surface made the smoother; and the more effectually that the mould is broken, and the smoother that the surface is made, the pasture is the more enlarged, and the weeds more effectually destroyed. This is agreeable to the ordinary practice, introduced no doubt from experience; for we find that a much less quantity is taken off when land gets the seed-furrow, the chief design of which is to enlarge the pasture, than at any other ploughing.

In the directions which we have given about ploughing, we have had chiefly in our view land employed in tillage; it is necessary to add something with respect to the ploughing lea, or opening up grass ground.

The English writers on agriculture, when giving directions about the opening of grass ground, always suppose that the land is to be summer fallowed; and they recommend to plough as deep at first as the nature of the soil will allow. They assign this reason, that it is not possible to plough deeper afterwards. They likewise direct to turn the earth upside down, or on its back, as we have called it. The reason they assign for this is, that the sward or turf may be the sooner rotten.

Some persons tried this method of breaking up grass-ground in Scotland, but they found great difficulty in reducing it; and we have reason to believe that many find it so likewise in England: for Mr. Tull, in his chapter upon ploughs, tells us, that if the turf lie long without being turned, the grass from the edges will spread and form a new turf, and that the roots often set up new heads, and the former heads are converted to roots. As Mr. Tull's design is to shew the necessity of the four-coultered plough, we need not doubt but he has a little exaggerated the matter; for, upon a narrow inspection, it will be found, that if turf is turned upon its back, the grass will grow only from the sides. However, we may conclude, from what he says, that the land in England is not so easily reduced in this manner, as some pretend.

On the rich lands in Scotland, they follow a method the very reverse of this which has been mentioned. They commonly sow after one ploughing of grass-ground, and plough, as shallow and narrow as possible; and also set the turf as exact as possible upon its edge. It is not our business in this place to consider the propriety of sowing after one furrow. We may only observe, that if the land is good, a good crop may be expected; and if there is a good crop, the turf will be completely rotten before next season. What we have to consider is, which is the most proper method to break and reduce the turf. It is certain that the thinner and narrower the turf is taken off, the more easily it is torn asunder, and the more that it stands on its edge, the harrows in going across take the firmer hold, and make the greater impression.

If this kind of grass-ground is ploughed before winter in the manner mentioned, shallow and narrow, and the turf set upon its edge, it may be expected, if we are favoured with a little frost, that in the spring the turf will be in such condition, as to be easily torn asunder by the harrows, and the land itself in a proper condition to be sown with oats, or to be summer fallowed, and sown with wheat.

Their barren lands they break up in the same manner as in England. They plough deep, and turn the turf over on its back. It seems that the plants which grow on these lands have tougher and stronger roots than those that grow on rich lands. This makes it more difficult to break the turf. If the earths of the furrows are set on their edge, the harrows turn them back, instead of tearing them asunder. This happens whether the land is ploughed deep or shallow. But when the earths are turned on their back, and the land ploughed deep, the harrows raise a kind of mould upon the back of the turf, by which the hollows betwixt the earths are filled up, and nourishment afforded for the seed, the greatest part of which falls into these hollows.

There is another method proposed for opening up grass-ground, and that is by trench-ploughing. This manner

of ploughing is performed by one plough following another in the same track. The plough that goes first, turns over the sward or turf; and the one that follows turns up some inches of soil upon it. By this method there is sufficient nourishment provided for the crop, and the sward is rotten before next season.

This kind of ploughing needs not be confined to the opening up of grass-ground; it may be used in any soil that is deep; for by it some new soil is turned up, and a greater quantity employed in vegetation.

It has already been observed, that ploughing in ridges is proper for removing wetness. Every furrow becomes a kind of drain: the rain that falls upon the ridge, makes its way to the furrows, and by means of them is conveyed away from the field.

Ploughing in ridges is also proper for enlarging the surface. It is certainly an advantage to have the surface enlarged. Thereby not only a greater quantity of soil is exposed to the influence of the air, but also a great quantity of it actually employed in vegetation. There is no more soil added to the field by enlarging the surface; but some of the soil that lies buried, while a field is in its natural state, is exposed to the air and brought within reach of the roots of plants, when it is laid up in ridges. Some of the plants which we cultivate in our fields, have what are called horizontal roots, that is, roots that creep along the surface, and go down but a short way. Now, it is obviously an advantage to these plants, to have a quantity of the soil below, to which their roots cannot extend, brought within their reach, which is done by enlarging the surface.

The tap-rooted plants, that is, such as push one principal root perpendicularly downwards, have also horizontal roots, by which they are nourished; and therefore it must likewise be an advantage to them to have the surface enlarged.

To illustrate this further, let us suppose, that the roots of plants upon a field extend themselves through the whole soil within four inches of the surface. Now, it is obvious, that there is more soil within four inches of the surface, when the surface is enlarged by ridges, than when the land is lying quite flat.

From these things then it appears, that a field contains more food, and has a larger pasture when in ridges, than when laid down level.

It must be acknowledged, that some considerable persons are of a different opinion; and as this is the case, it will not be improper to consider what is advanced by them.

There are some who mention the perpendicular growth of plants, as an evidence, that a surface, however much extended, can support no more plants than the horizontal base. Though the fact is allowed, that plants grow perpendicularly, and that it is impossible to place more of them upon the surface than when the base; yet it does not follow, that a field, when its surface is enlarged, can nourish no more of them; and it is to be remembered it is not more room which we contend for, but more nourishment. We may further observe, with respect to the growing of vegetables, that the enlarging the surface has this other advantage; it gives the plants more air, and thereby prevents them from falling down and lodging.

Mr. Du Hamel, to show that the enlarging the surface by ridges is a real disadvantage, observes, that supposing the slope in ridges is one foot in six, yet the surface will be to the horizontal base only as seventy-six to seventy-five, which he says, is but a small advantage, when compared to the loss by the furrows.

In answer to this, it needs only be said that there is no loss by the furrows, unless when they are a real advantage to the rest of the field. When land is dry, the corn is as good in the furrows as in any part of the ridge; and when the land is wet, the furrows serve for drains, and the loss by them is more than made up by the advantage which the rest of the field receives by being drained.

We may therefore conclude in the general, that the way of ploughing in ridges is preferable to the way of ploughing without ridges.

Having shown, that ridges are advantageous, as they remove wetness, and enlarge the surface, it is necessary now to consider what kind of ridges are most proper for answering the ends proposed.

As ridges remove wetness, when the soil is wet, the ridges ought to be narrow; for the greater number there are of ridges, there are the greater number of drains.

When the soil is wet, the ridges ought also to be steep. For the steeper that the ridges are, the water more easily finds its way to the furrows.

When the soil is very dry, it is submitted, if narrow ridges are not proper likewise. For by altering the ridges, and turning the furrows into the crowns, and the crowns into the furrow, a quantity of fresh soil is always employed in vegetation. When the crown of a ridge is turned into a furrow, it is obvious that some fresh soil is turned up, which was not employed in vegetation in its former situation; and the greater number there are of ridges, there is the greater quantity of fresh soil employed.

When the soil is just so wet as to occasion loss in the furrows, then the ridges should be somewhat broader. For, in this case, the fewer there are of furrows, there is the less loss.

It is proper to observe here, that a difference should be made betwixt the situation of land in the winter, and its situation in the summer. It may be convenient sometimes, when winter-grain is to be sown, or when the land is to get winter-fallowing, to make the ridges very narrow; and, when summer-grain is to be sown, to make them broader.

As it is an advantage to have the surface enlarged, the ridges ought to be made high in the middle, or crown. For the higher that the ridge is made, the more is the surface enlarged.

When the soil is shallow, the ridges, if broad, cannot be raised, without depriving the furrows of soil: and therefore, to enlarge the surface on such land, the ridges must be made narrow. For this both enlarges the surface, and prevents the furrows from going below the soil.

When the soil is deep, the ridges may be made broader: for though the ridges are raised in the crown, yet still there is soil left in the furrows. But then the ridges must not be made too broad: for it is evident that narrow ridges give more surface than broad ridges, of the same degree of steepness, and do not cover the lower parts of the ridges so much from the influence of the sun and winds.

It is necessary to observe, that though, in the general, it is recommended to raise the ridges in the crown, to enlarge the surface, and to allow the water more easily to find its way to the furrows; yet, in some low flat-lying land, it is proper to make the ridges as flat as possible, in order to raise the furrows. For the higher that the furrows are raised, there is, in some cases, the greater command of the water, and it is the more easy to find a fall for conveying it away.

It is necessary to observe likewise, that flat ridges have this advantage over steep ridges; they can be sown with greater exactness. It is obvious from the method of sowing, that, in sowing steep ridges, it is not possible to prevent a great proportion of the seed from falling into the furrows. It is obvious likewise, that this proportion is increased by harrowing. Whereas, in sowing flat ridges, the seed is equally scattered, and the harrows do not remove it from its place.

From these observations, it is obvious, that soils in different situations require to be laid out in different kinds of ridges. It is absurd, therefore, to assert, that, in every case, one kind of ridges is preferable to another; that narrow ridges are better than broad ridges, and flat ridges better than steep ridges. In some situations, one kind of ridges is most proper; and, in other situations, another kind is most proper. Every person ought, therefore, to consider the nature of the soil he has to deal with, consider the advantages and disadvantages of each kind of ridges, and then determine which are most proper.

When there is nothing in the nature of the soil to determine what kind of ridges are most proper, then narrow ridges are to be preferred; for this reason, that a quantity of land in narrow ridges is sooner ploughed than when in broad. It is obvious, that the two first furrows which the plough takes off from the ridge, are wider than any taken off afterwards, especially if the plough begins in the furrow, as is frequently the case; so that the greater number there are of ridges, the field is the sooner ploughed. Besides, when ridges are broad, it is obvious that the plough has more work, and must take longer time in turning, than when they are narrow. But then it is supposed that the ridges are straight and equal. If they are not, the greater number there are of them, the greater is the trouble, and the more time is spent in ploughing. This, however, it must be owned, is of no great importance

because it seldom happens that the kind of soil does not determine what kind of ridges are most proper.

Having considered the kinds of ridges proper for land, according to its different situations; it is proper to inquire, whether there are any qualities which ridges ought to have, whatever is the situation of the land.

It will easily appear, that all ridges ought to be made straight. Crooked ridges, it is obvious, are attended with several inconveniencies. In ploughing them, the cattle are not always going exactly in the same direction with the plough; short turnings are often necessary, as fields are generally bounded by straight lines, or lines not crooked in the same manner with the ridges; and, when there is a small descent, the water, as it runs in the furrows, meets with resistance.

It is obvious, that when the plough goes in a curve, as it does in ploughing crooked ridges, the draught is not in the same direction with the beam, but is either to the right or left of it; and this gives the plough either too much or too little land.

It is obvious likewise, that, when ridges are crooked in a manner different from the lines by which a field is bounded, in ploughing the ridges upon the sides, one part of them must be finished before some other parts are near done; and thus short turnings are necessary, which hurt the land much by the treading of the horses.

It is obvious likewise, that as a crooked furrow is continually altering the direction of the water, and has a less descent than a straight furrow, the water, as it runs along it, must meet with greater resistance, and thus penetrates the soil, and makes it more difficult to convey it away.

These inconveniencies are removed by making the ridges straight. For, in ploughing straight ridges, the cattle are always going in the same direction with the plough; no short turnings are necessary, as fields can be made of an equal breadth in all places; and the furrows having a greater descent, the water meets with less resistance, and is more easily conveyed away.

Straight ridges not only removes the inconveniencies with which crooked ridges are attended, but it is found that they are to be attended with no inconveniencies themselves: they require indeed a little attention in the ploughman, which is itself an advantage; and therefore, upon all occasions are to be preferred.

As, in all kinds of soil, ridges ought to be straight, so likewise they ought to be equal, equal one to another, and the same ridges equally broad in all places. Unequal ridges are attended with inconveniencies, as well as crooked ridges. It is difficult to sow them with exactness; it is difficult to alter them, when necessary; and the plough must often turn in the middle of the ridge, which does great harm, by the treading of the horses, or it must be driven empty to the end.

These inconveniencies may be removed by making the ridges equal. Equal ridges may be sown with greater exactness, and consequently with less seed; it is easy to change them, one into two, or two into three, as occasion requires; and the same furrow that finishes the ploughing of the ridge in one place, finishes it in all places; so that there is no necessity to turn the plough in the middle of the ridge, or to drive it forward the shortest space, without turning up a furrow.

In many places of England and Scotland the ridges are still crooked and unequal; and, in many places, they are much broader, and much higher raised in the crown, than the nature of the soil allows. Were the ridges altered, and the fields laid down in a proper manner, as the soil requires, it would be a great advantage. At the same time, it may be observed, that much harm is done, by proceeding in this matter with too much precipitancy. It is necessary, therefore, that we consider it as an affair of some importance.

It is necessary to observe, in the first place, that ridges must not be rashly altered: on the contrary, great caution is to be used.

If the soil is very dry, ridges may be altered without great danger, though high; and they may be made straight without being levelled. For, though the old furrows are still lower than the rest of the field, yet this is attended with no bad consequences in dry land; and by degrees, they are filled up in ploughing. But then, it is to be observed, that there is not much land in Scotland, on which the ridges, at present, are high raised, in its nature so dry, as to allow this to be done.

If the soil is wet, the ridges cannot be made straight till the

the ground is level, without great danger. For the water will lodge in the hollows of the old furrows, from whence it will not be possible to force it. Some persons that make their ridges straight, before they are sufficiently levelled, draw water-furrows along the hollows of the old furrows, to carry off the water that is apt to lodge there. This is of some use, but does not fully answer the purpose. A quantity of loose earth, in ploughing, is thrown into the old furrows. The water, as it falls, penetrates this loose earth, and is retained by it, notwithstanding the water-furrows. Besides, these water-furrows must be neatly cleaned out with a spade, and made deeper in the places where they are intercepted by the crowns of the new ridges, otherwise they are of very little use.

Before ridges can be properly made straight, it is necessary therefore that the land be made as level as possible.

But it must be observed, that it is as dangerous to level ridges rashly as to alter them before they are levelled: for if ridges are levelled too fast, and thereby a great depth of loose earth thrown suddenly into the furrows, it will not be possible to convey away the water that falls upon them. The water as it falls will sink to the bottom, and there will lodge and chill the soil; and the earth thrown into the furrows being loose, the cattle in ploughing must sink to the bottom likewise, by which the land is very much poached.

It is recommended therefore to every person, seriously to consider the nature of the soil he has to deal with, before he proceeds to the altering old ridges; and if the soil is wet, to level the ridges very gradually. When the soil is deep, and inclining to be wet, and a sufficient slope for carrying off the water, it is probable, that the loss arising from the levelling steep and broad ridges suddenly, may exceed the profit of many years, arising from the ridges being properly laid down; and therefore, if a view to inclosing makes it necessary to straighten the ridges, the levelling them should be the work of several years. Even supposing that the soil is shallow, and the ridges raised so high, that there is nothing but grass left in the furrows, yet still it is improper to level the ridges too fast, though levelling in this case is necessary.

In levelling ridges a great hollow is made in the crowns. This is occasioned by frequent successive cleavings, which is the method commonly used for levelling ridges. It is obvious, that by the first cleaving a hollow is made in the crown of the ridge equal to the depth and breadth of the furrow which the plough makes; whereas the parts on each side of the ridge are but little levelled, and at each successive cleaving this hollow is made greater. Such a quantity of new earth immediately turned up, is not fit for vegetation. Besides, this hollow becomes so great, and the parts of the ridges on each side of it become so steep, that it is impossible to plough them in a proper manner.

In this case, when levelling is still thought proper, some furrows from each side must be thrown back by the plough into this hollow, by which a new small ridge is formed upon the crown of the old one, and then the remaining parts of the ridge may be levelled as before. Some persons, instead of this, plough across the ridges. This method serves the same purposes; it both throws some earth into the hollows, and levels the ridges; for the plough in going carries off some earth from every height, and leaves some in every hollow. But then land must not be left in this situation during the wet season, unless the water-furrows are drawn along the furrows, and also in some cases along the crowns; for unless this is done, the water that falls upon the field cannot be conveyed away. At the next ploughing, the whole old ridges may be levelled in the same manner as at the first ploughing; or, if thought more proper, may be divided into two equal ridges, ploughed in such a manner that the furrows betwixt them may be exactly in the crown of the old ridge, and the other furrows exactly in the furrows of the old ridge. By this operation the old ridge is raised from the furrows, and levelled from the crown.

When a person is upon a scheme of levelling, this method of dividing the ridges into two, will be found very proper, either when winter-grain is to be sown, or when the barley-land gets the winter-ploughing.

Though land may be in such a situation as to allow the ridges to be levelled with safety, yet unless it is remarkably dry, and in no case in danger of being damaged by too much water, the ridges should not be altered, excepting when the land is summer-fallowed; and in that case, besides the ploughing that alters the ridges, there ought to be another before the wet season comes on, that so the bottom may be sufficiently firm to resist the water.

We have observed, that ridges serve to remove wetness, and to expose the soil to the influence of the air, and we have shown what kind is most proper for these purposes. But this is not enough; it is necessary likewise to consider in what manner ridges ought to be placed. This is a matter of some consequence: for, according to the position of ridges, water may be either conveyed away or retained; and some assert likewise, that by this the soil may be better exposed to the influence of the sun and wind. These things therefore must be kept in view in the placing of ridges.

When the land is wet, as is often the case, it is certain that ridges ought to be placed with a view to the conveying away the water: but when land is dry, as is sometimes the case, then ridges should be placed with a view to the retaining the water.

The most common way of placing ridges where there is a slope, is along the declivity in a straight line from the top to the bottom; and land is commonly laid out with a view to this. Where the declivity is gentle, this is, no doubt, a very proper way of placing the ridges; but if the declivity is great, this way of placing the ridges allows the soil to be washed away by the rain. It is obvious, that water, in running off of the land, carries a part of the soil along with it, and the quantity is great, in proportion to the violence with which it runs. In climates where there are heavy showers of rain, the damage done by this is not inconsiderable. Therefore, in this case, placing ridges across the declivity is the most proper way; for when ridges are placed across, the water meets with many interruptions in its course, and does not run off with such violence as when placed along from top to bottom, and therefore does not carry off such a quantity of the soil along with it.

Instead of this some persons make the ridges very narrow. This serves the same purpose; for in proportion to the number of furrows, there is the less water in each furrow, and consequently it runs with less violence. However, placing the ridges in this manner is not so proper for this purpose as placing them across the declivity, and, besides, is not so proper for retaining the water in a dry season.

When land is very dry, and in no danger of being damaged by the stagnation of water, the ridges ought to be placed across the declivity, as near the level as possible; for this retains both the water and the soil. It is obvious, that when ridges are placed in this manner, the water cannot get off by running along the surface, by which the soil is in the greatest danger of being carried away. As the furrows stop it in its course down the hill, it can get off in no other way than by penetrating the soil. By this a part of it is retained; what of it gets off is clear, and carries no soil along with it.

When land is dry at the head of the ridges, and wet at the foot, and no proper fall for carrying off the water, as is frequently the case, the ridges should be placed in the same manner, directly across the declivity. For, in this case, every furrow in some measure retains the water that falls upon the ridge above, and thereby prevents it from sinking towards the bottom of the field, and lodging there. By this way of placing the ridges, the dry part of the field is rendered wetter, and the wet part of the field is rendered drier than otherwise they would be.

This is likewise a very proper way of placing the ridges, even when the declivity is but small, if the land is in the situation mentioned, dry at the head, and wet at the foot. It must be owned, however, that this will not entirely answer the end proposed; for the water will penetrate the soil; and when it is resisted by till or clay, will find its way along these to the bottom of the field. But this will not be so sudden as in the other way of placing the ridges: and the soil at the head, which is naturally dry, will receive more benefit from the rain as it falls.

When land is wet, and the water may be conveyed away from the bottom of the field, the ridges should be placed across likewise; not directly, but with a small slope to a drain or furrow on the side of the field from top to bottom, by which the whole water is conveyed away. In this case every furrow becomes a drain to the ridge below, and prevents the water from running over it.

When land is wet from the breaking out of small springs, this way of placing the ridges is also very proper. The furrows convey away the water as it rises, and prevent it from doing any damage.

It is necessary to observe, that ridges placed in this manner, to serve these purposes, should not be altered; for when the furrow

furrow is kept in one place, it is a more proper drain than when altered. When the furrows are kept in one place, the bottom is always firm, and the water runs easily along it; whereas, if changed, it may fall upon places of the field, where the surface, being raised by former ploughings, will prevent them from reaching the firm bottom. Besides, if the springs break out in the furrows, by changing their place, they may break out in other parts of the ridge.

It is necessary to observe likewise, that ridges placed in this manner should not be raised in the crown, but kept quite flat; that so, by the natural descent of the ground, the whole water that falls upon the ridge may be conveyed into the furrow below.

It was before observed, that some persons assert, that, by a proper position of ridges, the soil is better exposed to the influence of the sun and air. These persons recommend the paying a regard to this. But it cannot be done excepting when the land is quite flat, and when the placing of the ridges makes no difference as to its wetness. However, as this is represented by those persons as important, some attention shall be given to what they say.

Some advise the placing the ridges south and north; and the reason which they assign for this, is, that thereby the sun may have an equal influence upon all parts of the ridge.

Others, again, advise the placing the ridges east and west; and the reason which they assign, is, that they may shelter each other from the cold north wind.

Which of these advantages is the greatest, is uncertain. It is even uncertain whether they can be called advantages at all.

It may be disputed whether in the winter season, cold or heat is most beneficial to land. That heat is beneficial, and cold destructive to plants, is certain. But cold possibly may be as proper as heat for preparing land for the nourishment of plants. It is allowed, that the coldness of the north wind is, in some measure, owing to the quantity of salts that it carries along with it. These salts are beneficial to land; and therefore an exposure to the north seems to be rather a benefit than a disadvantage. This is confirmed from observation. The lands on the north side of rising grounds are, generally speaking, more fertile than those on the south-side. It is certain, that the richest lands in Scotland have this situation, and are exposed to the north.

It may be disputed likewise, whether the north or the south side of an east and west ridge has most benefit from the sun in summer. It is not to be denied, that the rays of the sun fall more directly on the south side of the ridge; but then let it be observed, that the north side has the benefit of the sun's rays in the mornings and evenings, when the sun is so low, that the south side is under the shade; which may possibly balance the loss sustained by the greater obliquity of the sun's rays about mid-day.

These things have been mentioned, to shew, that it is uncertain, which way of placing ridges exposes the land best to the influence of the sun and air: and therefore, that, in placing them, it is needless to have any view in this. When the placing of ridges makes no difference as to the wetness of land, then we are chiefly to have in view the conveniency of ploughing and laying out the land in proper breaks.

There are three different ways of ploughing ridges: gathering, casting, and cleaving.

Gathering keeps the crown and furrows of the ridge in the same place in which they were before. The plough begins in the crown, and ploughs out the ridge, turning the earth towards the crown, where it entered. Every ridge is ploughed by itself; or, instead of this, the halves of two contiguous ridges may be ploughed together. By this method of ploughing, the ridge is higher raised than before. It is obvious, that, as the earth on each side is turned upon the crown, and thrown up out of the furrows, the ridge is raised, both by making the crown higher, and the furrows lower.

Casting keeps the crowns and furrows likewise in the same place in which they were before. The ridges are ploughed in pairs. The plough may enter in the furrow betwixt the ridges, and plough out the ridges, turning the earth towards the furrow, where it entered. Or, the plough may enter in the furrow on the right side of the two ridges, then turn to the one on the left, and plough out the ridges, turning the earth to these furrows, and from the furrow that is betwixt them. By this method of ploughing, the ridges are kept of the same height in the crown,

and one of the furrows made a little higher, and the other a little lower than before. The earth is taken from one furrow, and thrown into the other; and this is done alternately through the field. If this is reversed at next ploughing, that is, the earth turned into the furrows from which it was taken at the former ploughing, thereby the ridges are preserved in the same situation.

Cleaving is the reverse of gathering. The plough enters in the furrow on the right side of the ridge, turns to the furrow on the left side, and ploughs out the ridge, turning the earth from the crown towards the furrows. Every ridge is ploughed by itself; or, instead of this, the halves of two contiguous ridges may be ploughed together. If the ridge is raised in the crown, by this method of ploughing it is made flatter. It is obvious, that, by this method of ploughing, earth is thrown into the furrows, by which they are made higher; and that earth is taken from the crowns, by which they are made lower. If the ridge is already flat, by this method it is changed, and the crown turned into the furrow.

When a field is laid out in the manner judged most proper with respect to the breadth and height of the ridges, it should be ploughed in one or other of these ways mentioned, according to its situation. If the ridges are broad and high, casting will be found to be the most proper method of ploughing. For this is the only way by which they can be ploughed, and yet kept in the same situation: cleaving will make them flatter; and gathering will raise them higher. If they are flat and narrow, cleaving will be found to be the best method. Cleaving flat ridges, and thereby turning the crowns into furrows, and the furrows into crowns, has these peculiar advantages: a field is much sooner ploughed in this way, than in any other; and a quantity of fresh earth, at every ploughing, is exposed to the air, and employed in vegetation; and the ridges being kept level, are sown with exactness. In no case gathering is proper, unless when the proper situation of the ridge renders it rather too wet for winter grain.

It may not be improper, in this place, to consider a method of ploughing, used in some places, called ribbing. This method of ploughing is performed by making furrows about two feet distant from each other: one half of the surface is untouched by the plough, and the other half, which the plough turns up in making the furrows, is thrown on the top of what remains fast. The land may be ploughed in this manner, either without regard to ridges; or the plough may be made to enter and turn, as it does in gathering, casting, or cleaving; that is, a ridge may be ribbed in the way of gathering or cleaving; and two ridges may be ribbed in the way of casting. This kind of ploughing is seldom practised, but in the beginning of winter, and upon land to be sown with barley, after two more clean ploughings. It does not prevail so much as formerly, and is very much condemned by our modern improvers. But, however much it may be condemned, it certainly has its uses. It keeps the land dry; the rain that falls is confined to the furrows, from whence the loose earth is taken, and easily finds its way off. It facilitates the rotting of the stubble, by covering it and keeping it dry; it makes the frost penetrate a greater quantity of the soil; and it also exposes a larger surface to the influence of the air. These things make this kind of ploughing, in some cases, preferable to a clean ploughing.

There is also another method of ploughing called bout-ing. It is performed by throwing the earths of two furrows towards each other upon some fast land. This is certainly an improvement upon ribbing, and better answers all the purposes of it.

By this method ribs are placed where furrows were before, and furrows where ribs were before; and the surface is entirely changed, what was above turned down, and what was below turned up. These two ploughings may be performed with the same strength, and in the same time with one clean ploughing; and, it is probable, that, upon trial, in some cases, will be found more beneficial.

As a further improvement of this method of ploughing, it is proposed to rib the land, and, at the same time, to plough it clean. This is done by throwing the earths of three or four furrows together in such a manner, as to leave no fast land below; and in the same thing with ploughing the land in ridges about three feet broad, from the middle of one furrow to the middle of the other. This serves all the purposes of the other kinds of ribbing, and, besides, has these further advantages; the land being clean ploughed,

ed, weeds are more effectually destroyed, and the soil is better opened for receiving benefit from the frost and air. This method may likewise be reversed by another ploughing. The surface may be entirely changed, and the ribs turned into furrows, and the furrows into ribs.

These different methods of ploughing, the last two excepted, are known to every common ploughman, and they should be attended to by every improver as of importance; without a proper knowledge of them he cannot give directions to his servants, nor prevent them from falling into blunders in the execution, which they are but too apt to do. The ignorance of a master in things which his servants are acquainted with, is attended with bad consequences; it gives them an indifferent opinion of his knowledge of farming, and makes them despise every new thing which he proposes, as absurd and whimsical.

It was observed, that ploughmen are apt to commit blunders in ploughing. Thus, in gathering ridges, if care is not taken in beginning the ploughing of the ridge, some firm land will be left in the crown, and the crown itself so much raised above the rest of the ridge, that no seed will lie upon it. It is sometimes observed, that just on the crown of a ridge, where the soil is deepest, there is less corn, and more root weeds, than in any other part of the ridge. This is certainly occasioned by allowing firm land to remain there in ploughing, and by raising the crown like a peak above the rest of the ridge. The ploughman, instead of turning back the earth of the first furrow, and the firm land below it, keeps at such a distance, as to lay the earth of the second furrow up to it, or on the top of it. This leaves firm land betwixt the furrows, and raises the crown of the ridges to a peak. But if he is directed to draw the furrows so near, as to turn back the earth of the first in making the second, no firm land will be left, and the earth, that by the other method is thrown upon the crown, will be scattered.

This blunder is oftener committed when flat ridges are cleaved. In cleaving, if the ridges are ploughed out turning the plough always to the left, it is impossible to prevent the two furrows, laid together in the crown of the new ridge, from being at too great a distance, and raised higher than the rest of the ridge. When ridges are cleaved in this manner, the earth of the first furrow that the plough makes, is turned over upon firm land, and backed by the earths of the other furrows in their course. This makes it impossible to get at this firm land in ploughing the next ridge, without turning up the firm land itself, and the earth of the furrow laid over it, upon the top of the earth of the second furrow, by which the crown of the ridge would be raised to a high sharp peak. Now, to prevent this, the ploughman, in ploughing the next ridge, keeps at a proper distance, and does not touch the firm land, over which the earth of the first furrow is laid. But it may be observed, that he must either keep at such a distance as to leave firm land in the crown of the new ridge equal to the breadth of two furrows, or he must turn the earth of his furrow upon the top of the earth of that first furrow. By this the crown of the ridge is still high raised, and some firm land still left.

But ridges of this kind may be cleaved without leaving any unploughed land, or without raising the crown much above the rest of the ridge. The method of doing it is this: after the plough has made the first furrow, instead of turning to the left, and making a furrow on the other side of the ridge, it turns to the right, and throws back the earth of its first furrow along with the firm land below it, and after going round again in the same course, turns to the other side of the ridge, and goes twice round in the same manner, after which the ridge betwixt the two firings, as they are called, is ploughed out, as it is first proposed. When the ploughing of the ridge is finished, a new firing is made in the next furrow, by the plough going twice round, as before directed, and then the ridge betwixt the last made firing and the ploughed land is ploughed out in the same manner as before; and in the same way the firings are made till the whole field is ploughed. By this method there is no firm land left below the earth of the furrow; and the earth that is turned towards the crown being scattered, and not laid all in one place, the crown itself is not much raised above the rest of the ridge.

It may be observed likewise, that in casting ridges, if care is not taken, the furrow towards which the earth is thrown will be so filled up as to be improper for a drain. The plough enters the ridge near the furrow, and throws

the earth towards it, turns to the right, and throws the earth from the opposite side towards it likewise; and then goes in the tract of the old furrow, betwixt the earths of the furrows made on each side. This furrow, towards which the earth is thrown, is sometimes so filled up as to render it improper for a drain. We have shown how the earth around it is ploughed. The furrow which the plough makes going in the track of the old furrow, betwixt the earths of the furrows on each side, is called a gore-furrow. On the left side, the plough having no mould-board, the loose earth falls back into the furrow behind the plough, and fills it up, or at least makes it unfit for a drain, which in wet land is a great disadvantage.

But this may be prevented by proper care; the furrow may be made clean, and fit for a drain. The method of doing it is this: the plough enters about two feet from the furrow, and instead of turning to the other side, returns on the same side, turning back the earth, and then goes round again in the same course; after this, turns to the other side of the furrow, and does the same, going twice round. By this the gore-furrow is made quite clean, and, like the crowns of ridges, formed at about two feet distance on each side.

Some other things of a like nature might be mentioned. These have been insisted upon, to show that it is necessary to attend every circumstance of ploughing, that so this important work may be performed in the most proper manner.

The chief design of harrowing land is, to smooth the surface. By this weeds are destroyed, and seed, if sown, is covered.

Root-weeds that are loosened by the plough, are sometimes torn up by the harrow, and thus are destroyed. When this is the design of harrowing, the harrows should go across the ridges, or rather across the way that the plough has gone. Because, by going across the earths of the furrows, the teeth of the harrow are apter to catch hold of the roots, than if it should go in the same way with the plough.

Though the harrow may bring some part of the roots above ground, yet commonly some other parts continue below, which will grow if undisturbed. This makes it necessary for persons to follow the harrows, and gather all the roots which they observe brought up, and carry them off the field, or burn them.

If harrowing does not actually tear up the roots, it encourages their vegetation, by filling up the hollows, and thereby defending them against their greatest enemy, the drought. On this account harrowing is improper for destroying root-weeds, excepting after a spring-ploughing, when the land is soon to be ploughed again for seed. For at this season the drought is seldom violent, and it has not time to operate in the destruction of the roots; and therefore whatever the harrows bring out is so much destroyed.

The same things that make harrowing improper for destroying root-weeds, also make it very proper for destroying feed-weeds. The smoother that the surface is made, and the more effectual that the mould is broke, the seeds near the surface are the more exposed to the air, and the sap, which is in the land, the more effectually retained. Both these are necessary to promote the vegetation of the seeds; and they must vegetate before they can be destroyed. But harrowing not only promotes the vegetation of the seeds of weeds, but also destroys the young plants when sprung up; so that one ploughing, if the season is favourable, and soil allows, may be attended with several harrowings, and thereby several crops of weeds destroyed.

If land rises in hard clods, the harrow makes but little impression; at least before the clods are broken, the land is made so firm by the treading of the horses, and the weight of the harrows, as to render the work useless, and sometimes destructive. Great care should therefore be taken to prevent land from being brought to this situation. If land once rises in hard clods, it is vain to expect to break them with the harrow, so as to cover the seed. Unless the season is very wet, it will remain in this situation through the summer, and afford but little nourishment for the crop. Sometimes it will remain in this situation after men have attempted to break the clods with malls.

If the soil is light and spongy, it can scarcely get too much harrowing; for the more that it is harrowed, it becomes the firmer. But if the soil is stiff, the less harrowing it gets the better, if the purposes proposed are answered. The ef-

fects of harrowing are in this case contrary to those of ploughing. Ploughing renders stiff soil more free and open, but harrowing renders it still more firm and solid.

The ordinary way of harrowing after seed is sown, is first along the ridges, then across, and then along again. If ridges are flat, they may be harrowed either along or across; and the work may be begun or ended either way. But if the ridges are steep, it is improper to begin by harrowing across, because thereby too much of the seed will be drawn into the furrows. If the ridges are very steep, for the same reason, it is improper to harrow across at all. For another reason it is thought improper to harrow across ridges when the land has been ploughed immediately out of lea or grass. In ploughing this kind of land, the sward is for the most part turned over whole; so that when the harrow goes across, instead of tearing the sward, it is apt to turn it back into the furrow from whence it was taken. When ridges are gathered or cast, this will probably happen. In casting, the earths of the furrows on one side of the ridge are turned towards the crown; and, in gathering, the earths of the furrows on both sides are turned the same way; and therefore the harrows, when drawn from the crown to the furrow, are apt to take hold of the unbroken sward, and turn it back. But this does not so readily happen when the ridge is cloven. Because in cleaving, the earths of the furrows on both sides of the ridge being turned from the crown, the harrows, in going up from the furrow, are not in such danger of turning them back. In ploughing lea, the earths of the furrows are sometimes placed as exactly as possible upon their edge, that so they may be the more easily torn by the harrows. When these are turned to the crown, they do not support each other; and are therefore easily turned back by the harrow, in going from the crowns to the furrows: but when the earths are turned to the furrows, so they support each other by their weight; and therefore are not so easily turned back by the harrows in going up from the furrows to the crowns.

Rolling of land is practised with success, both on land lying in grass and on land in tillage. It is of advantage to land in grass, by pressing down mole-hills and mole-runs. Some say, that it also destroys fog.

When land is laid down in grass for hay, rolling is of use in smoothing the surface; and, when laid down in grass for pasture, it makes the grass stool, or tiller, and grow thicker.

There is a kind of land, which, when clover is sown upon it, throws out the young plants after frost. Rolling, in the beginning of winter, and immediately after the frost is gone, it is said, will, in some measure, prevent this. The first rolling prevents the frost from penetrating so deep, as otherwise it would do; and the second makes the land firm, after having been loosened by the change from frost to open weather.

Rolling may also be used with advantage upon land in tillage. When the land is naturally stiff, and may be reduced by the harrow, rolling is very improper: for it makes this kind of land still firmer than the harrow does. But if the land rises in clods, which the harrow does not reduce, rolling is very proper; for it smooths the surface, and breaks the clods, more effectually than harrowing.

When the land is light and spongy, the roller should always be applied after seed is sown; for it is scarcely possible to make this land too firm.

It was observed, that, to destroy root-weeds, land should be made rough, and raised in as large pieces as possible; and that it should be allowed to lie for some time in that situation. Rolling, after this, is of great use, for without it, if the weather continues dry, it will not be possible to make the land fit for receiving another ploughing.

If the land is soft below, and some hard clods upon the surface, which the harrow does not break, rolling may be used with some advantage: for, besides smoothing the surface, it will break some of the clods; and such of them as are pressed down, will be dissolved by the natural fermentation of the soil, if in good heart.

Sometimes in stiff land, ploughed dry, after a former wet ploughing, or when, by any accident, it has been much trod upon, the whole rises in hard clods, which the harrows cannot break, so as to cover the seed. In this case rolling is of great use. It bruises some of the clods; and, when followed by the break-harrow, these clods are raised up and broken. Though rolling should do no service but smooth the surface, yet, on that account, it should be prac-

tised. For when the surface is smooth, the corn may be cut down more expeditiously than when it is rough and uneven. When grass-seeds are sown for hay, it is absolutely necessary to smooth the surface: the roller is most proper for this. Some use it before, and some after sowing. When it is used before sowing, the seed is more equally scattered.

Grass-seeds must be sown in such a manner as to lie near the surface; otherwise they will not vegetate. The making the land firm by rolling is therefore an advantage, as, by it, the sap is better preserved; and this does not so much damage to grass as to corn, for the several kinds of it are commonly better foragers.

But however all the operations of ploughing, harrowing, and rolling are performed, something will be still wanting to promote vegetation, and this want is effectually supplied by certain substances called manures. To apply these substances in such a manner, as most effectually to promote vegetation, it is of importance to know their natures, and the ways in which they operate. This is the more necessary, as, without it, we cannot know how to apply them in the most proper manner to the different soils.

Manures operate, by communicating to the soil with which they are mixed, the vegetable food which they contain; by communicating to it a power of attracting this food in greater plenty from the air: by enlarging the vegetable pasture which it contains; and by dissolving the vegetable food which it is already possessed of, and fitting it for entering the roots of plants.

Manures are very different in their natures. Some of them operate in all the ways mentioned; and there are none of them that do not operate in more ways than one.

Great mistakes have arisen from supposing that manures operate only in one way. None have been attended with greater loss, than supposing that they serve only to divide the soil, and that tillage may be substituted in their place. This is Mr. Tull's opinion, and is, indeed, the fundamental principle of his horse-hoeing husbandry.

Before one changes the ordinary practice of agriculture, in so important a point as banishing manures from his fields, the good effects of which are so obvious; he must be certain, that the principle which determine him to so important a change, is itself well founded.

Mr. Tull has endeavoured to prove, that earth is the food of plants; and hence infers, that to divide the earth into minute particles, by which it is fitted for entering their roots, is all that is necessary in agriculture: and this, he asserts, may be done by tillage, without manures.

When treating of the food of plants, we have attempted to shew, that other principles, besides earth, are in the composition of this food: and, if this is true, the want of manures, which provide these other principles, cannot be supplied by tillage.

But supposing we allow, with Mr. Tull, that earth is the food of plants, yet still it does not follow, that tillage may supply the place of manures. It is certain, that every particle of earth which we observe, is not of the kind that is the food of plants. Every soil is a composition of different earths; several of which, it is obvious, are not of this kind.

The great difference in soils equally pulverised, is a plain and convincing evidence of this. Now, let it be observed, that the earth contained in dung is of this kind; it has already been food to plants, and therefore, though all that is contained in the greatest quantity of dung laid on at one time, is but small in proportion to the quantity of soil employed in vegetation, as Mr. Tull justly observes; yet it may be considerable in proportion to the quantity that is really the food or pabulum of plants. If the quantity of earth contained in the quantity of dung commonly laid on at one time, is compared with the quantity of earth contained in the rich crop, it will be found several times larger; and therefore, by the laying on of this dung, food is provided for several good crops.

Besides, let it be observed, that the mechanical action of the plough cannot increase the number of the particles by which plants are nourished; they are so small as not to be observed in water. Mr. Tull supposes, that they are as small as those upon which the colour of bodies depends. Now, though pounding earth in a mortar may perhaps do something to increase them, yet the action of the plough can never be supposed to do it. The plough can do no more

more than open the soil, or enlarge the pasture of plants, and allow them to extend their roots in search of their food, but does not increase the quantity of it; and therefore tillage cannot supply the place of dung, which not only opens the soil by its fermentation, but also increases the vegetable food by the earth which it contains.

It may further be observed, that the fermentation raised by dung continues for a considerable time; so that though by ploughing, the soil may be as completely divided as by the fermentation of dung, yet it will not continue so: for after seed is sown, the artificial pasture raised by ploughing is continually decreasing while the crop is growing; whereas the artificial pasture, raised by the fermentation of dung, is continued by the continuance of this fermentation; and therefore, though in the horsehoeing husbandry the want of dung may be supplied by hoeing, yet, as Mr. Tull indeed observes, dung is still necessary in the old husbandry.

If persons attentively consider the effects of manures, it will appear that they operate in all the ways mentioned.

Manures are found to enrich the best pulverised soil, and to do this again and again, after it is exhausted by crops. It is also an universal practice in Scotland, to lay dung upon land that is kept constantly in tillage once in three, four, or five years. It is observed, that after the dung is laid on, the land becomes rich, and that the crops turn gradually worse and worse, till the whole virtues of the dung are exhausted; and it is also observed, that immediately upon the dung being again applied, the land becomes rich as before. It is natural to conclude from this, that dung promotes vegetation by increasing the quantity of the vegetable food.

It is found, that some manures lose part of their virtues by being long exposed to the air. After dung is sufficiently rotten, the longer that it lies it becomes of less value, and does not enrich so large a quantity of land as when used in proper time. The dung of cows dried upon their pasture, gathered and laid upon other land, is scarcely to be discerned in its effects on the crops produced: the same quantity applied, whether carried from the byre, or by folding the cattle, enriches the land. From this it is obvious, that this kind of manure contains the vegetable food in itself, and does not receive it from the air.

It is found, that some manures operate the sooner, and with the greater violence, the longer that they are exposed to the air before they are used. Lime and marles are of this kind; the longer they lie exposed, they operate the sooner; and it is observed, that they have a strong power of attracting the virtues of the atmosphere. From these things it is reasonable to infer, that these manures operate, by communicating to the soil with which they are mixed, a power of attracting the vegetable food from the air.

It is observed, that some manures exhaust land of its vegetable food, and do not restore it again when immediately applied. This is found to be the case with lime. Land thoroughly limed has been found to carry many very good crops: by degrees, however, the virtues of it have been exhausted, and the land reduced to a worse situation than before the lime was laid on. In this situation lime has been applied a second time, but its effects found to be far inferior to what they were when first applied. This is sufficient to convince us, that this manure operates by dissolving the vegetable food which it meets with in the soil, and fitting it for entering the roots of plants.

It is certain, that all kinds of manures open the soil. Any person will be convinced of the truth of this, who will take the trouble to compare a piece of land, on which dung, or any other manure has been laid, with a piece contiguous that has not been manured; he will find the one much softer, much more free and open than the other. It must be allowed, therefore, that all manures operate by enlarging the vegetable pasture.

Manures are commonly divided into classes. Some divide them into natural and artificial; others divide them into the fossil, the vegetable, and the animal; and treat of them in order, as belonging to each of these classes.

The manures belonging to some of these classes, differ both in the nature and operation from those in the other classes. Some of them likewise differ from others in the same class. The dividing them into classes, therefore, serves no purpose. All that is necessary is, to treat of the different particulars which the farmer can command, without considering to what class they belong.

The manures generally procured are dung, marles,

ashes, soot, sea-weed, shells, sown vegetables; and water.

There are several other things that are very rich manures, such as rags, leather, &c. But as these are to be procured only in small quantities, it is needless to treat of them separately.

Dung is commonly used to signify not only the excrement of animals, but also all rotten vegetables, when used as manures.

Dung is the food by which animals are nourished, reduced to a corrupted state. The stomach dissolves the food of the animal, and reduces it to a state of putrefaction much sooner than is done by the air. It is by being in this state of putrefaction that the juices fit for the nourishment of the body are conveyed by the guts into the blood. While bodies are in a sound state, their parts adhere firmly together, and they are incapable of being turned into the parts of other bodies. To render them capable of this, they must be reduced to their first principles. This is done by corruption. It is observed, that by corruption all the parts of bodies are relaxed, and the salts, oils, and other juices which they contain, from being fixed, are made volatile. It is by being reduced to this state in the stomach, that the things which the animal feeds upon become nourishment to it, and are turned into parts of its body.

All the juices contained by the things which animals feed upon, are not exhausted by the guts; many of them, along with the earthy part of the food, are thrown out. There is no doubt that some of the earthy part of the food goes also to the nourishment of the animal; but as the earth is rendered volatile by the salts and oils, there must be but a small quantity of it in proportion to the quantity of these exhausted by the animal; and therefore in the dung there must be a great quantity of each in proportion to the other principles. However, as the dung contains all the principles of the food, we may consider the dung of those animals that feed on vegetables, as vegetables in a putrified state.

Of the same nature is the dung of animals that feed upon other animals. Vegetables are the original food. All animals either feed on pure vegetables, or on other animals that feed on vegetables. Animals that feed on vegetables are made up of the same things with vegetables, only under a different form; and therefore the dung of animals that feed upon these, is still to be considered as vegetables in a putrified state.

Chemists inform us, that dung is compounded of the same principles of which vegetables are compounded, of water, air, oils, salts, and earth. The earth which it contains is of the absorbent kind, and attracts the other principles. They also inform us, that dung attracts and ferments with acids, and by this fermentation produces salts. A quality of salt, as was before observed, is to attract and dissolve oils, and make them capable of being mixed with water.

If these qualities of dung are considered, it will appear that it promotes vegetation in all the different methods before-mentioned.

It promotes vegetation by increasing the vegetable food. It is compounded of the same principles of which the vegetable food itself is compounded, as we endeavoured to shew, when treating of the food of plants. This is also confirmed by the experience of all places and of all ages; and it is what no person will doubt of, who considers that it has the same effect upon land of all kinds, and in all situations.

It promotes vegetation by enlarging the pasture of plants, it attracts acids from the air and soil; and by raising a fermentation with them, thereby separates the particles of the soil with which it is mixed. Every farmer knows the truth of this from experience. The land upon which dung is laid, though naturally stiff, becomes soft and mellow, and is more easily ploughed than before.

Dung, we have said, enlarges the pasture of plants, by attracting acids, and fermenting with them. These acids are in the soil and air. They are in the soil; for the soil produces acid plants. Chemists tell us, that the natural salt found in soil is compounded of an alkaline salt, such as is found in vegetables, and an acid spirit. All alkalis are strong attractors of acids, so that, in the process of an experiment upon soil, perhaps it may be difficult to keep them separate, though they may exist separate in it. The acid plants prevent these from mixing; or, perhaps, have a stronger power in their vessels to separate them, than other plants have. But

But though there may be no acids in soil, excepting in the compound of neutral salts, yet there is no doubt, but they are in the air. Chemists find this by innumerable experiments. Ashes, when exposed to the air, produce neutral salts; the application of acids has the same effects. Any person may observe a salt adhering to the lime of old walls; this salt is not in the lime, it is produced by the air. The same salt is produced by acids. Other experiments might be mentioned, but these are sufficient.

Dung promotes vegetation, by communicating to the soil a power of attracting the vegetable food from the air. The earth which it contains, is of the absorbent kinds, and attracts all the other principles of the vegetable food; and the salts which it contains and produces, attract oils.

It likewise promotes vegetation, by preparing the vegetable food for the nourishment of plants. By the salts which it contains and produces, it not only attracts oils, but also dissolves them, and makes them capable of being mixed with water. It is probable, that oil is a principal part of the food of every plant which we cultivate in our fields, at least is the ingredient of which it is easiest to exhaust the soil, and which it is most difficult to restore to it again. In proportion to the quantity of oil contained in any plant, in proportion it robs the soil by which it is nourished of its vegetable food. But the nature of oil must be changed before it can enter the roots of plants. This change is made by salts; they dissolve it, and make it to mix with water.

Though dung promotes vegetation in all these ways mentioned; yet, as there are other bodies, they are much stronger attractors of acids, by which many of its effects are produced; it is probable, that it principally operates by increasing the food of plants. Its effects in dissolving the vegetable food in the soil, must be very trifling. The salts which it contains and produces, having its own oils to work upon, and being along with them conveyed into the roots of plants, cannot operate with any violence upon the oils which the soil contains. This is confirmed by the experience. When the virtues of dung are exhausted, the soil is no poorer than before it was laid on.

Some new improvers are pleased to ridicule the old farmers, because they are so fond of dung; but none will do this who attentively consider the virtues of it. Such other manures as can be obtained, are to be used; and tillage is carefully to be attended to: but none of these are to supersede the use of dung, which can be employed to so great advantage.

Though dung in general has all the qualities mentioned, yet there are some kinds of it possessed of some of these qualities in a higher degree than others. There are as many kinds of dung as there are of animals, and in some respects they all differ one from another.

The difference betwixt one kind of dung and another is commonly supposed to arise from the different food of the animals. Green herbage, straw, or hay, do not contain so much vegetable food in the same quantity as grain does. Hence it is supposed, that the dung of cows is not so rich as that of horses, nor the dung of horses so rich as that of fowls.

But this difference must partly arise likewise from the nature of the animals, if it is true, that the dung of horses, cows, sheep, hogs, and geese, all differ one from another, though fed upon the same pasture. Some animals digest their food more quickly than others. This makes a difference in the dung produced by the same food. Some things are digested, and turned into a state of corruption by some animals, that pass through others sound and undissolved. The matter then in the stomach that digests the food, must be different in the different animals. The dung must partake something of the nature of this, which makes another difference in the dung produced by the same food.

Some writers in agriculture treat of the dung of the different animals separately. But it is needless to do this; for it requires more pains and expence to keep them separate, and use each of them by itself, than all the advantages arising from this way, above the ordinary way, can possibly amount to.

The dung of fowls, particularly of pigeons, is an exception to this. It is commonly used without any mixture, and it can be kept separate from other dung without any trouble or expence. It is observed, with respect to it, that the effects of it are more violent, and sooner over,

than the effects of common dung. The effects of some other kinds of dung would perhaps be the same, if they were used without any mixture. The pigeons dung being thoroughly corrupted, soon dissolves, and becomes vegetable food. But the straw, with which the other kinds of dung are commonly mixed, not being so thoroughly corrupted, prevents the effects of them from being so violent, and so soon over.

The way in which pigeons dung operates, points out the manner in which it should be applied. As it is very rich, and its qualities soon exhausted, a very small quantity should be applied in proportion to the quantity of other dung. If care is not taken of this, the crop will be destroyed by being too luxuriant. Perhaps, mixing it with some other things may have good effects. The strewing small chaff of any kind, from time to time, on the bottom of the pigeon house, is very proper. The chaff sucks up the moisture, and makes it easy to reduce the dung to powder, which is an advantage: for thereby the dung is scattered more equally, and manures a greater quantity of land.

It is a custom in some places, to fold sheep and cattle, for the sake of their dung, which, in this way, is used without any mixture. Some writers on husbandry give particular directions how to do this in the most advantageous manner. But it is needless to consider these. The farmer must consult the advantage of his sheep and cattle, and not to the advantage of the land by the dung; and therefore must fold them in the most convenient manner. A score of sheep, with the best management in folding, will not produce much more than ten shillings worth of dung, in the season, above the expence of folding; a sum soon lost by an injudicious management of them.

Dung is commonly mixed with vegetables, and allowed to lie for some time before it is used.

Straw is thrown below the cattle, and this is carried out along with the dung, and thrown upon the dunghill. On the dunghill is also thrown all the straw that is left after serving other purposes; and all the refuse of vegetables and animals used in the farmer's family.

In the management of dunghills, two things are always to be kept in view: the promoting putrefaction; and the preventing the vegetable food from flying off into the air, or being conveyed away by water. The straw and other parts of uncorrupted vegetables, of which the dunghill is compounded, make it necessary to keep the first in view; and the salts and oils, which by corruption are rendered volatile, and the water, which extracts the virtues of dung, make it necessary to keep the last in view.

To promote putrefaction, the situation of the dunghill should be dry, and the dung laid together as thick as is convenient. Putrefaction, indeed, cannot be promoted without water: but the quantity that falls in rain, with the natural sap of the dung, is sufficient for this purpose. Too much water prevents that fermentation, which carries on the process of putrefaction most quickly. This is confirmed by experience. If there is any part of a dunghill soaked with water, it is observed that the straw is quite sound, while, in other parts, that are dry, it is completely rotten.

To promote putrefaction, the dung should be laid thick together; thereby the heat is the sooner generated, that produces the putrefaction; and thereby the natural sap is the better preserved, which prevents the dung from being burned.

When the natural sap of the dung is exhaled, and the dung afterwards covered, the heat is in danger of rising to such a height as to burn the dung. This must be carefully guarded against: for when the dung is burned, its strength is exhausted, and it is rendered almost useless. Dung, in this situation, is dry and white; the ploughmen call it fire-fanged. When thus burnt, it is found, from experience, that it has lost almost all its virtues. To prevent the dung from being reduced to this situation, when it is carried out of the stable, or byre, particularly if there is much straw in it, it must not be laid in heaps, which makes it dry too fast, but carefully spread thick upon the top of the dunghill. This prevents the sap from being carried off by the wind, and thereby prevents the heat from being raised to such a height as to burn the dung.

It may be observed, that, when grass is cut green, and immediately thrown into a heap, it heats, and this heat soon reduces the grass to a state of putrefaction. But, if the grass is for some time exposed to the air, and then put together without being sufficiently dry, it heats also; but,

instead

Instead of being reduced to a state of putrefaction, is burned. So it is with dung: if, when carried out, it is laid in small heaps, being thereby too much exposed to the air, it loses its sap; and, being afterwards covered, the heat is raised to such a height as to burn it: but if it is spread thick upon the top of the dunghill, it retains the sap, and putrifies.

A distinction is here made betwixt dung putrified and burned; and this distinction is represented as important. We know not if the chemists make any such distinction. A late author says, that the greater part of what remains of dung, after the putrefaction is completed, seems to be earth, and a fixed alkali. These things, we apprehend, make up the greater part of what remains, when dung is what we have called burned; but when it is only putrified, it contains also salts and oils. But though chemists should make no such distinction, it is absolutely necessary that the farmer do it: for, when the dunghill is allowed to heat to such a degree, as to burn the dung, the value of it is thereby greatly lessened.

To prevent the vegetable food from being conveyed away, no foreign water, except what falls in rain, must be allowed to run into the dunghill; and the situation of the dunghill, if possible, should be high at the sides, and hollow in the middle. When foreign water is allowed to run into the dunghill, the fermentation is not only stopped, but, as it is often necessary to allow the water a passage from it, thereby much of the vegetable food is conveyed away. When the bottom of the dunghill is quite level, the rain, which sometimes falls in heavy showers, easily finds its way off; but this is prevented by making it high at the sides, and hollow in the middle.

The only way to prevent the vegetable food from being exhaled by the sun, or carried off by the wind, is to cover the dunghill. The covering the dung would certainly be an advantage, if it could be easily executed. If it was not for the additions that are daily made to it, earth would be very proper for this purpose. Some persons assert, that by covering the dunghill, it would lose the influence of the air; and it is the air alone, they say, that makes it fit nourishment for vegetables; and, therefore, recommend the exposing it, particularly to the north and north-east; because the wind from these points bring along with it more aerial nourishment than from the others. If the dunghill contained no vegetable food but what it received from the air, this direction would be very proper; but as the dunghill contains in itself all the ingredients of the vegetable food, and as its juices, the more it is putrified, become the more volatile, the vegetable food in it, by being exposed to the air, instead of being increased, would be diminished. The covering the dunghill, therefore, would be an advantage. But the difficulty lies in executing this.

Some propose to dig a large pit, lay the bottom with flags, build up the sides with stones, and cover it with a roof. This, it must be owned, will retain the juices, and promote corruption, as well as prevent the vegetable food from being exhaled. But then it must be so expensive, that few will be engaged to make trial, unless the benefits are more obvious than the assertions of the contrivers make them: and, besides the expence, it must likewise be attended with inconveniencies. In some situations, it will be very difficult to prevent too much water from getting into it, and as difficult to get the dung itself carried out.

The method which we proposed for preventing the dung from over-heating, will also, in a great measure, serve this purpose. The dung, when it comes from the stable or byre, is mixed with straw, which absorbs the juices, and prevents them from flying off, till the straw itself begins to putrify. When, in this situation, it is laid thick upon the top of the dunghill, a small surface only being exposed to the air, and being covered before the straw begins to putrify, the juices, in a great measure, are preserved. A person, by the smell, is sensible that the juices of the dung are not so volatile, when first laid upon the dunghill, as after they have been covered for some time, and then exposed to the air.

Dung, exposed to the sun and wind, or washed by rain, loses its vegetable food; it ought, therefore, to be ploughed in as soon as is possible, after it is laid upon land. Some persons assert, that they have found from experience, that dung is nothing worse, though it lie a considerable time spread upon land, in dry weather, before it is ploughed in. This, if true, is contrary to what has been supposed,

that the vegetable food is exhaled by the sun, and carried off by the wind. It is probable, that, after dung is spread upon land, its fermentation ceases, and the salts and oils remaining in it may become fixed, and may continue so till a new fermentation is raised by mixing the dung with the soil; and that, by attracting acids from the air, more salts may be formed. By these its effects will be more sudden and violent, but sooner over.

It may be proper also to observe, that as the juices contained in the dung are washed downwards by the rain, it should be ploughed in with a very shallow furrow; excepting when the dung is not sufficiently rotten. In this case it requires a deeper furrow to cover it.

The better that dung is mixed with soil, the purposes of vegetation are the better answered; all parts of the soil receive equal benefit, the vegetable food is equally distributed, and in all parts the fermentation equally promoted. When dung then is laid on land, it ought to be spread as equally as possible. This likewise prevents the breeding of vermin, which happens in some soils, when the dung is left in too large pieces.

Some are of opinion that lime is only a stimulus, that is, that it promotes vegetation, only by making the soil with which it is mixed, exert itself. Others, that it promotes vegetation by enriching the land, and adding to the quantity of vegetable food.

They first support their opinion by observing, that the crops which lime enables land to produce, exhaust it in a remarkable manner. It is a certain fact, that land thoroughly limed may be reduced to a much poorer condition by cropping than land can be reduced to, that is not limed. It is possible to reduce limed land almost to a *caput mortuum*; and the better and the oftener the land is ploughed, this is done the sooner.

The other opinion is supported by observing, that, in some places, lime is applied regularly once in four or five years: that the land seldom gets any other manure: that it is kept almost constantly in tillage; and with the assistance of fallowing, carries very good crops.

From these observations, one is led to conclude, that lime acts both ways; not only makes land exert itself in the nourishment of vegetables, but also enriches it, and adds to the vegetable food.

An inquiry into the qualities of lime will probably illustrate this.

Chemists tell us, that lime has the following qualities:

It is a great dissolver of all animal and vegetable substances: it is a very heavy body: it is an attracter of acids; with these it raises a fermentation, and produces salt; and it communicates its virtues to water.

When these things are considered, it will appear, that lime promotes vegetation in the ways following.

It communicates to the soil a power of attracting the vegetable food from the air. It attracts the acids from the air and soil; these it converts into a neutral salt, by which oils are attracted from the air. This operation of lime is confirmed by the experience of those who use it as a manure once in four or five years.

Lime enlarges the vegetable pasture. By its weight it penetrates the soil; and, by its fermentation with acids, it separates its particles.

This operation of lime is obvious to every person that views with attention any land that is thoroughly limed. It appears soft and mellow, and obviously in a state of fermentation.

Lime dissolves the vegetable food, and fits it for entering the roots of plants. It dissolves all the animal and vegetable substances which it meets within the soil, and converts them to vegetable food; and, by the salts which it produces, it dissolves all oily substances in the soil, and conveys them into the roots of plants. We find from experience, that lime clears land of root-weeds. This it does by its dissolving power. Root-weeds, when torn up by the plough, have their growth checked, and are for some time in a languishing condition: if lime is applied to their roots while in this situation, by its dissolving power, it is apt to destroy them.

That it is owing to the salt which lime produces by its attracting and fermenting with acids, that it chiefly owes its power of promoting vegetation, is confirmed by this observation. The lime of old walls which has been long exposed to the air, and where the salt is already formed, is much more sudden in its operations, when laid upon land, than quick lime.

It has been observed, that lime promotes vegetation by communicating to the soil a power of attracting the vegetable food from the air, by enlarging the vegetable pasture, and by dissolving the vegetable food, and fitting it for entering the roots of plants. It is probable, that the two last are the ways by which it chiefly operates.

By this it exhausts the land of its vegetable food. For it cannot be supposed to attract from the air a sufficient quantity of food for the nourishment of the crops which it enables the land on which it is laid to carry; and it contains none of this food in itself. This is confirmed by experience. If land upon which lime has been laid, is exhausted by crops, the application of lime a second time has not the same effect as before; unless the vegetable food is supplied by dung, or the land allowed to rest for some years, and have the vegetable food supplied by the air.

Thus it appears, that lime from its nature must act both as a stimulus and a manure; while it makes the earth exert itself in the nourishment of vegetables, in some measure also enriches it, and adds to the vegetable food.

In some lands, the dissolving the vegetable food, and fitting it for entering the roots of plants, may be most beneficial: in others, the communicating the power of attracting the vegetable food from the air, may be most beneficial. It will not be improper, therefore, to point out how lime is to be applied, so that it may chiefly answer the one or the other of these purposes.

In uncultivated land, in which there is a large quantity of vegetable substance, lime ought to be used chiefly as a stimulus: and when improved land needs a recruit of vegetable food, it ought chiefly to be used as a manure.

When lime is intended for a stimulus, a large quantity should be applied at once. For it takes a considerable quantity to dissolve roots, and the other vegetable substances in the land, and to produce a high degree of fermentation.

When lime is intended for a manure, a small quantity applied at a time is sufficient. It is probable, that it requires only a small quantity of lime to impregnate a large quantity of earth, and to communicate it to an absorbent quality, in as high a degree as it is capable of receiving: and it is certain, that it is in proportion to the absorbent quality which it communicates, that the soil is enriched by it. This is not a mere conjecture. It is certain that a small quantity of lime will impregnate a large quantity of water, and communicate to it all its virtues, and these in as high a degree too as it is capable of receiving: it is not improbable, that it may operate in the same manner upon earth. If a small quantity of lime communicates an absorbent quality to a large quantity of earth, but has not such influence in dissolving vegetable substances, or in producing fermentation, it follows, that the smaller the quantity is which is applied, it will operate the more as a manure; and the greater the quantity applied, it will operate the more as a stimulus.

It is proper to observe likewise, that when lime is applied in small quantities as a manure, it is necessary to repeat the application frequently; for it is probable, that the soil by action loses the absorbent quality which the lime communicates.

These things which we have observed, concerning the operation of lime in smaller and larger quantities, are, in some measure, confirmed by experience. They are agreeable to the practice in those parts where lime is most used. When barren land is to be improved, it is laid on in large quantities; and when it is applied to land already improved, it is laid on in small quantities, and frequently once in three or four years.

As lime operates by attracting acids from the air, the longer that it is exposed to the air before it is ploughed in, it will exert itself the more quickly, and with the greater violence. Some alledge, that this should not be done in summer. For they say, that the sun acts contrary to the air; as the air supplies the salt, the sun exhales it, and communicates it again to the air.

As lime, when laid on in large quantities, exhausts land of its vegetable food, it is necessary to supply this food by dung, or such other manures as have it in great plenty; or the land should be managed in such a manner, as to prevent, as much as possible, the vegetable food from being exhausted. Laying off land, after a very few crops of corn, into grass for pasture, is the most proper way of doing this. Land, when pastured, has not its vegetable food so much exhausted, as when it carries corn. The quantity

of vegetable food carried off in flesh, by the cattle, or conveyed to the air by their perspiration, bears but a small proportion to the quantity carried off by a crop of corn and straw.

It is necessary further to observe, that as lime communicates its virtues to water, land inclining to be wet, and from which the water has free access away, is not proper for it: for the water, in running off, carries along with it the virtues of the lime.

There are a variety of marles, which are commonly reduced to three sorts: the clay, the stone, and the shell.

The first has its name from its similitude, in appearance, to clay; the second from its hardness, and similitude to stone; and the third from the shells, with which it is mixed, or rather of which it is compounded.

The clay and stone marles are of the same nature; the shell marle is very different from both. This makes it necessary to treat of them separately.

Marle of the stone and clay kinds promotes vegetation in a surprising manner. It is probable, however, that it contains in itself few of the principles of which the vegetable food is compounded. Plants are not able to find their food in it. When in a bed below the surface, it resists the entrance of water, like till or clay. When near the surface, and turned up by the plough in great quantities, the soil is little better than till, almost quite barren. The method of its operation will be best known by inquiring into its qualities.

It is observed, that both the clay and stone marles have the following qualities.

When long exposed to the air, or put into water, they fall down into a powder: they are very heavy bodies: the earth of which they are compounded, is of the absorbent kind: they are attractors of acids; with them they raise a fermentation, and produce salts.

The only difference betwixt them is this: the clay marle is sooner dissolved than the stone marle; and commonly has a stronger power of destroying acids, and producing salts. Dr. Home says, that the clay marle, which he tried, destroyed a third more of acids than the stone marle.

These marles seem to have much the same qualities with lime; and, therefore, must operate in the same manner.

They communicate to the soil a power of attracting the vegetable food from the air, they enlarge the vegetable pasture; and they dissolve the vegetable food that is in the soil, and prepare it for entering the roots of plants.

These marles communicate to the soil a power of attracting the vegetable food from the air. The absorbent earth which they contain, and the salts which they produce, are strong attractors of oils.

It is observed, that they attract oils so strongly, that they are used by some to extract greasy spots from cloaths. When laid upon land, they will therefore attract oil from the air, which is the ingredient of the vegetable food most wanted.

These marles enlarge the pasture of plants. They ferment with acids, and fall down into powder, when exposed to the air, or put into water. These things make them operate in separating the particles of the soil with which they are mixed.

These marles also prepare the vegetable food for being nourishment to plants. The salts which they produce, not only attract oils from the air, but also from the soil, dissolve these oils, and render them capable of being mixed with water, and of being conveyed by it into the roots of plants.

According to some, these marles contain some oily matter. This, if true, would make them operate in a manner different from lime. But this is uncertain. The earth of which these marles are compounded, is of the absorbent kind; it cannot be long exposed to the air, without attracting oils; and therefore, though they contain none in their original composition, yet some marks of them may appear upon trial.

These marles are long in dissolving. Large pieces of the stone marle are seen sometimes undissolved, six or seven years after it has been laid upon land. This makes it necessary to apply a very large quantity of them, otherwise their effects will not be known.

As the quantity of marles applied is very great in proportion to the quantity of lime; land, when manured with marle, must have a stronger power of attracting the vegetable

table food from the air; and therefore the marle should be preferred, when it can be as easily obtained.

As the earth of these marles is of the absorbent kind, as a great quantity of it is applied at one time, and as it is long in dissolving, it must be many years before its operation ceases; and, if the land is barren, the nature of it will be changed, and ever after, by the same kind of dressings it received before, will continue to carry better crops. In this respect also it is preferable to lime. This advantage however, depends, in a great measure, upon the nature of the soil. If the soil is soft and spongy, and has not a firm bottom, the marle, by its weight, will, by degrees, penetrate, like lime, beyond the reach of the plough; and therefore must leave the soil no better than it found it.

Although, in some respects, these marles seem preferable to lime, yet we are to consider, that their principal operation is the same with that of lime; which is enlarging the pasture of plants, and fitting the vegetable food for entering their roots. When land, therefore, manured with them, is exhausted by crops, it cannot receive much benefit from them a second time, if immediately applied. This is confirmed, it is said, by experience. It is observed, that marle, when applied a second time to land exhausted by crops, has not the same effect as when first applied.

As marle operates in the same manner as lime, it follows likewise, that limed land exhausted by crops, can receive little benefit from the application of marle; and that marled land, exhausted by crops can receive little benefit from the application of lime, as it exhausts the vegetable food, the proper manure after it is dung, which contains this food in the greatest plenty.

It was observed, that marle operates chiefly by attracting oils and acids from the air; the longer, therefore, that it lies upon land, exposed to the influence of the air, the more quickly it will operate.

The difference betwixt the clay and stone marles was said to consist in this; that the clay marle dissolves sooner, and has a stronger power to destroy acids and produce salts. This kind is therefore preferable, as a less quantity will produce the same effects. If Dr. Home's experiments are to be depended upon, or rather, if all clay and stone marles have the same powers with those which he made his experiments with, then four cart-load of the clay marle is equal to five of the stone.

What was said of lime, with respect to the application of it in smaller and larger quantities, may likewise be said of marle. When barren land is to be improved, the marle should be laid on in large quantities: but when land is in good order, the applying a fifth or sixth part of the quantity commonly used, once in six or seven years, may have very good effects.

Shell marle is very different in its nature from the other two. It is commonly classed among the animal manures.

It does not dissolve with water, as the other marles do. It sucks it up, and swells with it, like a sponge. It is a much stronger attractor of acids than they. Dr. Home says, that it takes six times more of acids to saturate it than any of the other marles which he had met with. But the greatest difference betwixt the shell marle and the other marles consists in this; the shell marle contains oils. It is uncertain whether the other marles contain any oils; but this kind, it is said, contains them in great plenty.

This marle, it would seem, from the qualities which it possesses, promotes vegetation in all the different ways. It increases the food of plants; it communicates to the soil a power of attracting this food from the air; it enlarges the pasture of plants; and it prepares the vegetable food for entering their roots.

It increases the food of plants by the oils which it contains, and the salts which it produces: by these salts, and by the absorbent quality which it possesses, it communicates to the soil a power of attracting this food from the air. It enlarges the pasture of plants, by its swelling with water, and the fermentation which it occasions; and it prepares the vegetable food for entering the roots of plants, by the salts it produces in fermentation.

It will not be improper to attend the effects of these different operations. The communicating vegetable food immediately to the soil, and communicating to it a power of attracting this food from the air, have the same effects. By both these operations the vegetable food is increased.

The enlarging the pasture of plants, and fitting the vegetable food for entering their roots, have also the same effects. By both the vegetable food is diminished. It is

obvious, that, by these operations, plants are assisted in extracting this food from the soil.

The oils which it contains, it is probable, are soon exhausted: having a strong power of attracting acids, and forming salts, it is natural to suppose that these salts do more than work upon its own oils: they will also attract and dissolve the oils which they meet with in the soil; and would exhaust it of the vegetable food which it contains, was it not for the strong absorbent quality which it communicates. This quality, it is probable, remains after the operation of the salts is over; and thus, upon the whole, the soil is rather bettered by it.

We had occasion to show, that the difference betwixt poor and rich soil consisteth in the different powers of attraction. As this marle has so strong an absorbent quality, if it is applied in large quantities, and frequently repeated, it is possible that it may communicate such an attractive power to the soil, as to enrich it in a very high degree, so as to need no further manuring, but by proper tillage may be made to attract from the air in the winter season such a quantity of vegetable food as is sufficient to nourish a crop in summer.

As this kind of marle does not exhaust land of its vegetable food, as the other marles, or as lime does, it may be applied to land exhausted by them, or it may be repeated. As it dissolves sooner than the other marles, its effects will be more sudden; and as it does not dissolve so soon as dung, its effects will not be so soon over.

A late author supposes, that the marle found below moss is compounded of earth and the alkaline salts of rotten wood. He explains in what manner he imagines it is formed. If there is a marle compounded of these ingredients, it is different from any of the marles that have been mentioned. However, it will operate much in the same manner. It will communicate a power to the soil of attracting the vegetable food from the air; it will enlarge the pasture of plants, and it will prepare the vegetable food for entering their roots.

As it contains a large proportion of salt, its effects will be sudden and violent. It is not proper therefore that a great quantity of it should be applied.

As its effects are sudden and violent, it cannot be expected that they will last long. It is probable that they will be soon over after it is entirely dissolved.

The salts which it contains, will make it operate chiefly in dissolving the vegetable food in the soil, and fitting it for entering the roots of plants. By this it will exhaust the soil, if care is not taken to prevent it, by the application of dung, or turning the land from tillage into grass for pasture.

There is another kind of marle that goes under the name of shell marle, and in some parts of the country is found in great plenty. It seems to be almost wholly lime, and it operates in the same manner.

Ashes contain a large proportion of salt; they attract acids more violently than any other thing as yet known, but they soon lose their virtue.

The effects of ashes will then be of the same kind with lime. But as ashes contain salt, their operation will be more sudden; as they attract acids with greater violence, and sooner lose their virtue, their operation will be more violent, and sooner over. This is confirmed by experience. The first crop after land is manured with ashes is commonly very luxuriant, and the second crop exhausts almost the whole of their virtues.

As the effects of ashes are sudden and violent, they should be applied in very small quantities; and as they operate in the same way with lime, they should not be applied to land exhausted by lime or marle; should not be followed by these, nor repeated.

Turf is composed chiefly of vegetables; that which remains then after burning, must be of the same nature with ashes. To these the fertility communicated to the soil is chiefly owing. It is found from experience, that in proportion to the number of roots contained in the turf, the burning turns out to advantage; and therefore land, with a tough sward of grass upon it, is recommended as the kind most proper for being improved in this manner.

The heat which part of the soil receives from burning the heaps of turf is supposed to contribute to its fertility: but this can have little influence, except to destroy any seeds or roots of weeds that may be in the land.

In burning the turf, care must be taken to cover the heaps in such a manner as to prevent the fire from breaking

ing out into flame. Where this happens, it is observed, that the ashes lose part of their virtue, and that the parts of the field manured by them are not so much enriched as the other parts are by the heaps of turf that are burned without flame. It is natural to think, that the earth of the turf, when properly piled up, will retain the oils of the vegetables, and prevent them from ascending into the air in smoke and flame.

This makes some difference betwixt the manuring by burning, and the manuring by ashes. However, as the oils contained in burnt turf are in very small quantities, we may well suppose that they will soon be exhausted by the salts; and therefore, though the effects of burning may be more violent, yet they will be equally sudden; and as soon over.

To prevent burnt land from being exhausted, one crop only, or two at most, should be taken, and then turned into grass for pasture. If a little dung is added after the first crop, its fertility will be the longer preserved.

Soot cannot be procured in such large quantities as to be used by itself, excepting in the neighbourhood of large cities; it is needless therefore to insist upon it.

It contains oil, salt, and earth. These, it seems, are compounded in such a manner as to be ready to be conveyed into the roots of plants by water. For the effects of soot, when spread upon the surface, are discovered immediately after the first rain. It promotes vegetation in the same manner as dung, or shell marle. It increases the food of plants by the ingredients of the vegetable food which it contains. It enlarges the pasture of plants, enables the soil to attract the vegetable food from the air, and prepares it for entering the roots of plants by the salt that it contains, which is of the alkaline kind, attracts and ferments with acids, and attracts and dissolves oils.

As it contains great plenty of vegetable food, and as its effects are sudden, it must be laid on in very small quantities. Sowing it in the spring on winter corn or grass, seems to be the most proper way of using it.

When the quantity laid on it is but small, and its effects sudden, it cannot be supposed to last long. Its virtues are commonly exhausted by one crop.

When its effects are over, the soil is left in the same situation as before it was laid on, not exhausted of its vegetable food, as by lime or ashes; and therefore it may be repeated; or it may be followed by these manures, as it is very proper to be applied to land that is exhausted by them.

All the plants that grow upon the rocks within reach of the sea, are good manures. Those that grow upon the rocks that are almost always covered by the water, are the richest.

Some kinds of sea-weed are burnt for kelp. This it is thought, turns out to greater advantage than using them as manures. The best kinds for manures cannot be reached, as their roots are almost always below water; but they are frequently driven on the shore by the sea. A considerable quantity of them may always be expected on the shore in the neighbourhood of the rocks, where they grow, when a spring tide, heavy rain, and a high swelling sea all happen at the same time. The spring tide exposes their roots to the air, the fresh water falling in rain loosens the roots, and the high swelling sea tears them up. Sometimes the tide carries them to a considerable distance.

They are of a soft pulpy nature, easily dissolved, and soon putrify; and they contain oil, salt, and, earth. They must promote vegetation, therefore in the same manner as dung or soot.

Their effects are sooner over than those of dung mixed with vegetables from a dunghill; for they sooner dissolve and sooner putrify.

They may be applied to soil in any situation, and are very proper for land exhausted by lime or ashes.

When their effects are over, the land is in no worse a situation than before they were applied, and any kind of manure may be applied after them.

The oftener they are applied, the land becomes the richer; for the earth of which they are compounded is of the absorbent kind. This is confirmed by experience. The land near the shores, where these sea-weeds are in greatest plenty, and have been long used as manures, are amongst the richest in Scotland, and have been kept almost constantly in tillage.

They are preferable to dung, in this respect, that they do not produce such a quantity of weeds. Every person that has used these manures, knows, that weeds do not appear in such plenty upon land manured with sea-weed, as upon land manured with dung. This seems to confirm the

opinion of those, who assert, that the great quantity of weeds mixed with the dunged land, are produced by seeds mixed with the dung. But it is submitted, whether this difference is not owing to the great quantity of salts contained in the sea-weed and applied with it, which at first destroys some of the seeds and roots of weeds. Salt, applied in too large a quantity, is undoubtedly a poison to many plants. According to Mr. Tull's experiments, a small quantity of salt water destroyed a plant of mint. It is observed likewise, when any grass upon the shore is overflowed by a spring tide, it withers away in a few days, and does not recover till it gets a plentiful shower. Then indeed, by the freshness of its verdure, it is distinguished from the grass that was not overflowed by the salt water. That it is the salt in the water that destroys the plants, is obvious: for the quantity of fresh water would have had no such effect. And it is probable, that the oils attracted by the salts, and carried down by the rain, are the cause of their recovery.

In many places, particularly near the sea-shore, broken shells are found in beds. These are used by some as a manure.

They ferment with acids, and, like other animal substances, contain oil, salt, and earth. The oil and salt are not in great quantities in proportion to the earth, and they take a long time in dissolving.

Their operation must be of the same kind with that of shell marle, but slower and weaker.

They make some addition to the vegetable food by the ingredients of this food of which they are compounded. They communicate to the soil a power of attracting this food from the air; and they dissolve it by the salt which they contain and produce. And they increase the pasture of plants by the fermentation.

They operate chiefly by enlarging the pasture of plants and preparing the vegetable food for entering the roots. They are so long in dissolving, that the quantity of oil communicated in a season must be small in proportion to the salts which they produce. Though these are their principal operations, yet in them they are inferior to lime, marles, or ashes.

As they take a long time to dissolve, and do not operate quickly, it is necessary to apply them in large quantities. For without this their operations will scarcely be perceptible.

For the same reason it may be expected they will continue for a considerable time. They will continue till the shells are wholly dissolved, and all their oils exhausted in vegetation.

As they operate chiefly by enlarging the pasture of plants, and fitting the vegetable food for entering their roots; they will in some degree exhaust the land of its vegetable food, though not so much as lime or ashes do, as they communicate some oils to it in dissolving. It is not proper therefore to apply them after lime or ashes, to repeat them immediately, or apply lime and ashes after them.

If they are taken up from below the surface, as must happen most commonly, it is proper to allow them to lie some time exposed to the air before they are ploughed down. This will not only assist their fermentation, but will also promote their putrefaction.

As lime, when mixed with them, takes a very strong band, it is probable, that the mixing them together in the application may in some cases produce very good effects.

It is a practice in some places to sow turnep, buck-wheat, pease, &c. on land; and when grown up, to plough them down for manures.

These may be called vegetables in an entire state, to distinguish them from dung made of putrified vegetables; though no vegetables can be a manure till it is putrified.

As these vegetables receive their food from the soil on which they grow, it is natural to think, that when ploughed down, they do no more than restore what they have taken; and therefore, that by this operation land cannot be rendered more fertile than before; at least, cannot communicate such a quantity of vegetable food to it as may be done by frequent ploughings. For the vegetables, though ploughed down, are not all preserved; a part of them being uncovered, is blown away by the winds. Besides, the plants while growing, cover the surface, and prevent the vegetable food in the air from entering the soil; whereas, when land is frequently ploughed, none of its vegetable food is exhausted, and it is exposed to receive all the benefit from the influence of the air. But, notwithstanding this, some assert

assert from experience, that a crop of such vegetables as those mentioned, ploughed down, render land more fertile than frequent ploughings without the application of manure.

To account for this upon the principles established, let the following things be considered.

The soil, manured by ploughing down a crop of vegetables, receives all the vegetable food contained in the seed sown. This quantity in pease and buck-wheat is not very inconsiderable. The quantity in one grain is probably as much as there is in a whole stalk after the seed is fully ripened. It is observed, that plants, when cut green, exhaust land of its vegetable food, but in a very small degree to what they do when allowed to carry seed.

Some of the plants mentioned push down their roots below the reach of the plough, and bring up the vegetable food lodged there to the surface. Pease, turneps, clover, and other plants push down their roots very far; and whatever vegetable food they find, is sucked up; and when they are ploughed down, this vegetable food is lodged near the surface, and thereby the quantity within the pasture of some other plants, such as wheat and barley, is increased. A late author makes a calculation of the quantity of vegetable food which clover in this manner communicates to land, and represents it as very considerable. In few places the soil is so deep as to have the vegetable food in great plenty beyond the reach of the plough; and therefore it is probable, that this author, in his calculation, makes the quantity of this food brought near the surface by clover much greater than it really is. However, it is certain, that as plants push down their roots below the reach of the plough, they there find nourishment, which is communicated to their stems and leaves; and therefore, when these are ploughed down, the quantity of vegetable food near the surface is increased.

The covering of the surface seems to be an advantage; for thereby the air in the soil, not having a free communication with the external air, becomes putrified, by which a fermentation is raised, and the vegetable pasture enlarged. Whatever is the cause of this fermentation, the fact itself is obvious. Every farmer knows, that when the soil has been covered for a considerable time by a strong crop of pease, or any other kind of corn laid down, and what is commonly called flooring, though naturally hard and stiff, becomes mellow, soft, and free, and obviously in a state of fermentation. It is probable, that this is occasioned by the corruption of the air, or of the water, which the covering of the surface prevents from being exhaled.

To these things it may be added, that it is not impossible but the plant, when growing, may suck in the vegetable food from the air in as great plenty as the soil would have done, though there had been no plants growing upon it. If plants have this faculty, considering what an immense surface is exposed by them to the influence of the air, the quantity of vegetable food acquired cannot be inconsiderable.

Having thus considered the effects of ploughing, harrowing, rolling, and manuring land, in order to produce a large crop of wheat, we shall now proceed to the cultivation of this useful species of grain.

It has been very justly observed by the ancients, as well as moderns, that wheat will grow in almost any part of the world, and that, as it is the plant most necessary to mankind, so it is the most general and the most fruitful. It thrives not only in temperate climates, but also in very hot, and very cold regions; and, when sown in places where it never grew spontaneously, succeeds as well as where it has been always common. The success of our crops of wheat in America plainly proves this: and in Peru and Chili in particular, where this grain was not known till the Europeans introduced it there, it now produces, as large crops as in most parts of Europe.

Wheat should be sowed in autumn, and always when the ground is moist. In the downs of Hampshire, Wiltshire, and Dorsetshire, farmers begin to sow their wheat in August, if any rain has fallen, and even employ their people to sow one place whilst they reap another, if wet weather interrupts them in their harvest: for if the corn is not forward in autumn, so as to cover the ground before winter, it seldom does well on those high dry lands, especially if the ensuing spring proves likewise dry. In low strong lands, some husbandmen think they are in good season, if they get their wheat into the ground by the middle of November; nay, it sometimes is Christmas, or even later, before all their wheat is sown. But this late sown wheat, besides being apt to run too much to straw,

especially if the spring be moist, is liable to be thrown out of the ground by frosts.

In general, all wheat succeeds best upon strong soils, especially if they have been well drained, so that the corn lies dry: but as some sorts of this grain thrive better in some soils than in others, it might redound to the public welfare if more particular observations were judiciously made, in regard to each kind, than have hitherto been. The white egg-shell wheat is reckoned best for light lands, and to sow with rye for meslin; because it ripens soonest. It should also be the earliest in the ground. This species is much sown in Essex, upon their hazely brick-earths, or loams; as the red wheat, and the Poland bearded wheat also is there, and in Hertfordshire upon stiff yellow clays. The white Poland, or pole-rivet wheat has not a hollow straw, and therefore is not so subject to lodge as other corn that has. This kind is particularly fit for lands where the crop is apt to run much to straw.

In Oxfordshire they have a sort of wheat which they call long-coned wheat, and reckon the best for rank clays. Its straw not being hollow, it is the less liable to lodge; and farmers observe, that it is the least apt to be mildewed, or be eaten by birds; from which last it is greatly guarded by its long rough awns; but the flour of it is somewhat coarse. Their white kind of red-eared wheat has a white ear and a red grain, and is a very good sort for clayey land. It yields a good crop, and seldom smuts.

In Staffordshire, they reckon the red Lammas or bearded wheat the best for cold lands or stiff clays.

In Berkshire is a wheat called pendulum-wheat, from the hanging of its ear, much like the cone-wheat.

In Northamptonshire, they have a sort of wheat with a white straw and reddish ear and grain; much commended for the plumpness and largeness of the grain, and the strength of the straw, which prevents its being subject to lodge; nor is it apt to be eaten by birds. They have also a red-eared bearded wheat, and a sort of pollard or duck bill wheat, as it is called, known in Sussex by the name of fuller's wheat, which has so close and thick a husk, that the birds never injure it. Mr. Miller observes, that this sort of wheat grows very tall, and, if it be sown too thick, is very apt to be lodged by rain and wind; for that its ears are large and heavy, and incline on one side as the grain increases in weight: but that, if its roots are at a proper distance from each other, it will tiller greatly, and have strong stalks, and that the grain of this wheat yields more flour in proportion than that of any other sort. The awns of this wheat always drop off when the grain is full grown.

Smyrna wheat, commonly called many-eared wheat, because several lesser or collateral ears grow around the bottom of the main ear, which is very large in its state of perfection, requires more nourishment than the common husbandry in a large way can give it, and therefore is not cultivated by our farmers: But it would, probably, do extremely well in the horse-hoeing husbandry, where the quantity of food can be enlarged almost at pleasure. For the same reason maize, commonly called Turkey or Indian corn, is fitted for this last husbandry. See MAIZE.

Some gentlemen have been curious enough to procure their seed wheat from Sicily, and it has succeeded very well as to the growth: but the grain of this species has proved too hard for our English mills to grind.

The best time for sowing wheat is about the beginning of September, especially if any rain has fallen; a circumstance so essential, that, if the earth be very dry, the farmer had better stay till friendly showers have moistened his soil, then put his corn in ground, where it will not grow before it has been wet, let the time be ever so long. Mr. Mortimer says he has known wheat to be so musty and spoiled by laying long in the ground, before rain came, that it has never grown at all: to which he adds, that he has likewise seen very good crops of wheat from seeds sown in July. It is a general practice among farmers, to make choice of a time for sowing their wheat when the earth is moist: and the writers on agriculture have likewise, in general, recommended that practice; but without assigning any reason for it, or such reasons as are by any means satisfactory. This is the more extraordinary, because sowing dry, is almost universally recommended and practised, in sowing other seeds. The ground of this difference appears to be, that wheat being subject to be smutty, the seed is commonly brined and limed, which has been found in a great measure a security from that distemper in the crop.

crop. It is nevertheless true, that sound good seed, from a good change, produces, for the most part, sound crops of wheat, free from smutiness; and when such seed is sown dry, or without steeping, it is most adviseable to sow it when the land is dry. When the seed is steeped, it imbibes moisture, more or less, in proportion to the condition of the seed, and the time it lies in the steep, and a vegetation commences: if the seed in this state is laid in dry earth, and the weather for some time continues dry, the vegetation is checked, which kills or much damages the seed. Another inconveniency also arises from delaying to sow, and waiting for rain; the season for sowing is delayed; and if much rain falls, the earth consolidates, which renders it less proper for receiving and nourishing the seed, it being a general maxim with gardeners, and with husbandmen, in other cases, that seed thrives best upon fresh tilled ground. At all events, the husbandman should certainly have his wheat-sowing finished by the middle of October. Whoever neglects this, shews, in so doing, a want of proper œconomy in his affairs, and will have cause to repent the delay.

Early sowings require less seed than late ones, because the plants then rise better, and acquire strength to resist the winter's cold. More seed should always be allowed for poor lands than for rich, because a greater number of plants will perish on the former. Rich lands, sowed early, require the least seed of any.

Another circumstance which the husbandman should carefully attend to in sowing, is that his estimate of seed be formed, not from the capacity of any particular measure, but from the number of grains which that measure will contain; because the grains of some growths of wheat are much larger than those from off other lands, though of the same species, and perhaps equally good. By not considering this, the ground will of course frequently be sown too thick, or too thin: though I believe farmers are seldom apt to run into this last extreme. That they too often commit the former error, so manifestly contrary to their interest in every respect, is demonstrated by reason and by daily experience: but neither of these is sufficient to make them deviate from the beaten track. Instead of the usual allowance of three bushels of seed-wheat to an acre of land, repeated trials have shewn that half that quantity is generally more than sufficient: consequently a great deal of corn is actually thrown away; for the expence of purchasing seed, which most skilful husbandmen do, at least every other year, amounts to a considerable article in large farms, and in a whole country, merits the attention of the public, especially in scarce years: besides which, the future plants, crowded together by being thus sown too thick, and not having a sufficient space allowed them for their sustenance, cannot yield near so fine and plentiful a crop as they would otherwise produce. A fair trial, made with proper care, would soon convince farmers of their error in this respect; for if they but examine a field of corn sown in the common way, they will find few plants with more than two or three stalks, unless by chance, where some of them stand so as to have room to spread. These will have six, eight, or ten stalks, and frequently many more: but a field of wheat sown with only a bushel of good corn has been known to be well covered with healthy vigorous plants, each of which has had from six to fourteen, or more stalks, covered with long well nourished ears, full of fine plump grain, of which it has yielded a much greater quantity than any of the neighbouring grounds sown with the common allowance. If the land is good, and the plants stand at a proper distance from each other, few of them will produce less than the above number of stalks and ears. But farmers think they shall have no crop if the ground is not covered with the blades of corn by the spring: whereas, if they would have patience to wait till the plants put out all their stems, they would be amply convinced of the contrary. Every one must have observed, in places where foot-paths are made through corn fields, that, by the side of those paths, where the corn is thin, and has been trodden down in the winter and spring, the plants have stood erect, when most of the corn in the same field has been laid flat upon the ground; an advantage which can proceed from no other cause, than that their stalks are stronger from their having more room; for those of the other plants are drawn up tall and slender by being too close together.

More seed is commonly sowed upon new broken up ground, than upon that which has been longer in tillage.

From half an inch to three inches is the usual depth at which wheat is planted, according to the nature of the soil; the stiffest lands requiring the shallowest sowing, as was before observed. The general custom is, to sow it under furrow, which is certainly most adviseable, if the soil be shallow, to prevent the plants being thrown out by the winter's frosts, or their roots being left bare by the drying winds in the spring. Some sow in broad-cast, either with a single cast, or double bout, harrowing once between; after which the ground is again harrowed several times, till the seed is well covered. However, a great deal of it will become the prey of the birds, in this manner of sowing. On the other hand, in planting the corn deep, there is the greater danger of its being eaten off by worms between the grain and the blade.

Great care should be taken to guard against the rooks just at the time when the wheat is shooting up. These mischievous birds perceive its sprouting much sooner than the farmer can, and are led by the shoot to pick it up. They must therefore be carefully kept off the ground for a week or ten days at this season; for at the end of that time the blade will be grown up, and the grain so exhausted of its substance, that they will not give themselves any trouble about stealing it. They never molest the wheat which is sown about Michaelmas; because so much grain of the late harvest then lies scattered about the fields, that they find it easier to pick up that, than to search for corn under ground in the new-sown lands.

No part of husbandry requires the farmer's attention more than keeping his land free from weeds; yet few trouble themselves much about this essential article, are sensible of its importance, or understand the proper method of doing it: nay, many do not even know which weeds are annual, and which perennial; a distinction highly necessary to be made by every person who would keep his ground clean and in good order, and without which the greatest industry will often be baffled. Annual weeds may be soon destroyed, if taken in time; but if they are neglected, their seeds will ripen, and sow themselves in such abundance, that much additional labour and expence will be required to do that which might have been performed with ease at the beginning, without subjecting the corn to be robbed of its nourishment by bad neighbours. The common method of weeding is very absurd: for in that practice the weeds are to grow till the wheat begins to ear and they are in flower; by which means the ground being covered by the corn, all the low weeds are hid, left to ripen, and scatter their seeds: only the tall weeds are taken out; and if the people employed are not careful, many of these will escape them, by being so intermixed with the stalks of the wheat, as not instantly to be distinguished. At the same time, great numbers of the plants of wheat are broken and trod under foot by the weeders.

To obviate these inconveniencies, Mr. Miller recommends the method now practised by good kitchen gardeners, who clear their ground with a small kind of hoe, which, if used among the wheat early in the spring, before the ground is covered by the blades of corn, will effectually eradicate all the weeds, especially if this work be done in dry weather; because being small, they then soon wither and die. If the ground happens to be very full of weeds, it may be necessary to go over it a second time, about a fortnight after the first, to cut up those which may have been too small to be noticed. By this means the corn will be kept clean, freed from robbers, which would deprive it of due nourishment, and there will not be time for new weeds to grow so as afterwards to do it any great prejudice: for the ground will be so much shaded by the corn, that the weeds will thereby be kept down in such manner as not to ripen their seeds before harvest.

If, at the time of this operation, some of the plants of corn are cut up where they grow too close, the rest will be greatly benefited thereby: "but in this," adds Mr. Miller, "I fear that few of the old farmers will ever agree with me, though what I mention is not from theory, but from experiments repeated with great care, and such success, that the produce of twenty rods of ground was much greater both in weight and measure, than that of the same extent in the very best part of the field, where this was not practised; and the stalks of the corn thus thinned stood upright, when a great part of the crop in the same field was lodged."

Both the advantage of having the plants of corn at proper

per distance from each other, and that of keeping them quite free from weeds, too difficult, not to say almost impracticable tasks, to be completely effected in the common method of sowing, are fully obtained in the New Husbandry, as will soon be evidently shewn.

M. Duhamel and Mr. Miller justly blame the practice of those who either turn hogs in among their wheat, to destroy part of it when it grows too thick; or sheep to eat it down, when they think it too rank. The absurdity of the former is self-evident: and in regard to the latter, it is well known, from long experience, that the leaves, or blades of corn, are necessary to draw in nourishment from the air and dews, for the increase of the stalk and ear. To be thoroughly satisfied in this, Mr. Miller cut off the leaves of some plants of wheat, alternately, early in the spring, and always found the stalks of these plants much smaller, the ears shorter, and the grain poorer, than those of the intermediate plants whose blades were not cut. Several experiments made by M. Duhamel have proved, not only that all plants are impeded in their growth, and rendered less perfect in their productions, but often even killed, by stripping them of their leaves: and this is confirmed by Mr. Miller, who adds, that he has frequently observed in gardens, that plants divested only of their lower leaves, plucked off by ignorant persons upon a supposition of their drawing the nourishment from the head, have been greatly weakened thereby. The same will undoubtedly hold good with respect to corn: besides which, cattle, and particularly sheep, will often bite so close as to destroy the crown of the plant from whence its future growth should proceed.

Wheat is ripe when its straw is turned yellow, its ears hang, no greenness appears in the middle of them, and the grain is hard when bitten.

It was formerly a custom among farmers, to delay reaping their wheat till it was very ripe, except in the neighbourhood of London, where their land was sown early, warmed with good manure, well tilled and kept clean from weeds; in these circumstances, and their reaping before the wheat was very ripe, their harvest was much earlier than in remote countries, particularly westward: for this reason, some industrious reapers began wheat harvest near London, and from thence they proceeded westward, reaping still as they went on towards Wiltshire, where they came in time for the harvest, and all the way thither; by this means, they had a long harvest, and earned much more money than those who reaped in only one part of the country.

But many of the west country farmers do now reap their wheat, almost as early as about London: for they do not let it stand to be so ripe as they did formerly, and find their account in cutting it greener; for such wheat has a better colour than the thorough ripe, and sells for more money at market; and one skilful farmer, who cuts his wheat very early, and generally sells it at a high price, assured me that he found upon trial, his wheat reaped early, was heavier in the bushel, than the same wheat, when it stood till thoroughly ripe: the reason of which appears to be, that wheat cut before it is quite ripe, handles best, being smoother, and more slippery, than the very ripe, which contracts a roughness that prevents its lying so close in the bushel as the smoother early reaped wheat.

Hence it appears, that the greater weight of this grain, cut green, is not in consequence of the grain filling and ripening in the straw, after it is cut (for this farmer's wheat was commonly among the first at market), but because, the wheat that is cut early is a smaller grained corn, and lies closer in the bushel, which, in that respect, is no advantage to the farmer; and he is also liable to some loss in threshing, it requiring more labour to thresh it clean, than thorough ripe wheat, and more of it is usually left in the straw: but the advantages of reaping it early, more than balances these inconveniencies; as such corn sells at a better price, and there is a greater chance of good weather to harvest it.

Good weather in harvest is of great importance to the farmer, and to the public: and the delay of but a few days is sometimes attended with very bad consequences. In the year 1757, much of the wheat being ripe, or so near ripe, that it might have been harvested; but many farmers being willing to have it thoroughly ripe, and depending too much on a continuance of fair weather, delayed reaping a few days. In the mean time the

weather altered, from fair to a small driving rain, which continued so long with very little intermission, that the ripest corn, though not lodged, sprouted as it stood upon the stem to a very uncommon degree. The unripe corn escaped much better, and did not much of it sprout, but continued to vegetate, fill and ripen, till the return of fair weather. The damage, however, was very great, and the price rose in proportion: for much of the corn that had not sprouted, so as to be visible, had begun to vegetate, and this being ground, together with the sprouted and sound corn, damaged the whole to such a degree, that the bakers could not make good bread of them; and the bad effects were severely felt that year and for a considerable time afterwards.

From four to five quarters an acre is reckoned a good crop: but some would hardly credit how much beyond this the produce of good ground, thoroughly well cultivated, may be increased. Those who are sensible of the vast advantages of a perfect culture will not be surprised at Mr. Miller's assuring us that he has known eight and ten quarters, and sometimes more, reaped from an acre, over the whole field, where the corn has stood thin upon the ground; and that he has been informed by persons of great credit, that even twelve quarters have been reaped from an acre of land drilled and managed with the horse-hoe.

Both wheat and rye may be cut somewhat before they are thoroughly ripe, especially if they be lodged; for if the straw be broken, it will no longer convey any nourishment to the grain. M. Duhamel seems to think this is even the most eligible way for wheat, because the grain will harden afterwards in the sheaf; whereas, if it be let stand till it is too ripe, it will shed greatly in cutting, binding, and carrying home. It is partly to prevent this inconvenience, that good husbandmen tie it in the evening, and carry it off early the next morning. The ancients reaped their corn before it was full ripe, as Pliny informs us. And indeed it must be allowed that very great disadvantages necessarily attend the letting of some sorts of corn stand till their grains have acquired their utmost maturity. Both the chaff and the fodder are the worse for it; and, if such ripe corn takes wet, the increase in malt is lost, if it be barley, it having already spent itself; and if it be wheat, the quality of the flour is greatly impaired, as well as the quantity considerably lessened. But if corn be cut greenish, it will bear a pretty deal of wet without damage; for it will not imbibe the water like full ripe corn, but only take in so much as to be kindly fed thereby. Again, if any sort of corn be blighted, the sooner it is cut down, though but half ripe, the better it will be; for nourishment can no longer be conveyed to it by the straw; but it will be fed by lying in the ear. The straw would become more and more brittle, by standing till the corn is ripe; and the grain comes the clearer from the husk, when threshed, if this blighted sort be cut early.

One man, with a binder, may reap an acre of wheat, and somewhat more of rye, in a day, if the corn stand well; he will also clear about an acre of peas, vetches, &c. in the same space of time.

The medium price of wheat, in this country, is about five shillings the bushel. If it be much under four shillings, the farmer cannot pay his rent and live; and if it exceeds six shillings, the poor sort of people cannot afford to purchase wheaten bread. A bushel of wheat weighs from fifty-six to sixty pounds; a bushel of barley, from forty-four to forty-seven pounds; and a bushel of peas, from sixty-three to sixty-six pounds.

"The husbandman, says Mr. Duhamel, cannot have a more favourable season to get in his harvest, than that which is afforded him by hot and dry weather; for the quality of the corn is improved, and the grain is rendered much fitter to keep, by the sun's having acted powerfully upon it, either towards the latter part of its standing, or just after it has been cut: though it is true, on the other hand, that this very circumstance renders the ears more apt to shed their grain, and that the value of a sowing is often lost thereby. To prevent this, as much as possible, the corn is first laid in grips, and then tied up in sheaves, in the cool of the evening, or early in the morning before the heat comes on; and the mowers of oats frequently work during part of the night, to avoid the excessively fatiguing sultriness of the noon. These poor people, whose task is infinitely laborious, are liable to many grievous disorders; especially the reapers, who, being obliged to stoop to their work,

work, almost to the very point where the rays of the sun are most violently reflected by the earth, breathe a perfectly burning air. This forces them to drink copiously of liquors, which, being heated by the sun, allay their thirst only for a few moments, and I strongly suspect, often occasion severe illnesses: the inventing of a machine, engine, or instrument, by which the hardness of this labour might be mitigated, would therefore be a truly useful discovery, and I most heartily exhort all ingenious persons who have a mechanical turn, seriously to think of it.

"The two usual ways of cutting corn, are either with the scythe or with the sickle. The former is commonly used for oats and barley, or, sometimes, for very thin, short wheat; and the sickle is generally appropriated to the reaping of tall and thick wheat and rye. The scythe dispatches so much more work than the sickle, that the difference of expence between reaping an acre, and mowing it, is nearly in proportion of five to two.

"Every part of the mower's body labours and fatigues, and his work requires greater dexterity than that of the reaper: but as the mower is always in a kind of standing posture, he has the advantage of being refreshed by every breeze of air; which the reaper, for the reasons before mentioned, has not.

"I do not despair but that some engine may, one time or other, be found out, to ease these very hard labourers, and expedite their work. In the mean while, I am persuaded that M. de Lille's following account of what he himself has practised on his own estate, will afford satisfaction to all my readers, who will be pleased to observe, that he does not relate matters of mere speculation, but real facts: things actually executed by him, and which I should certainly have tried, if I could possibly have been in the country when our harvests were got in.

M. de Lille's Account of his Method of mowing Wheat.

"When I first put a scythe into the corn, I was of course laughed at by some of my neighbours, because they had never seen any such thing. I let them enjoy their jokes; but persevered in my undertaking, which I have now practised sufficiently to be able to point out minutely its advantages, and its inconveniencies; for I allow that, though the former are very great and numerous, it is also attended with some of the latter.

"The year 1751 was very rainy; our grass rotted upon the ground, our corn was poor and infested with weeds, and the weather continued extremely bad during all the harvest season. One of my fields of wheat, containing about fifteen acres, was, in particular, in such wretched plight, that I did not think the crop worth taking off. However, after walking over it, and viewing it on every side, I found that the quantity of grass and other growths upon it, might, if mowed, afford a great deal of fodder, which would make me some amends for the total loss of my lucerne. I therefore determined to let my horses have it all, with the little wheat which appeared here and there. This first made me think of mowing a field of wheat; though I soon recollected that I had met with the hint before, in some writings. Accordingly I set my mowers to work: my field yielded a great quantity of fodder; the grass, mowed within two inches of the ground, shot up anew, and afforded excellent pasture; and lastly, my bailiff, more saving than I had been, ordered the trusses to be thrashed, and got out of them as much wheat as was yielded by other grounds.

"Whilst I was congratulating myself upon the success of my operation, by which my horses and cattle were provided with plenty of fodder for the next winter, I learnt that the husbandmen in Hainault, Flanders, Artois, and other adjacent parts, never cut their corn down otherwise than with a scythe; but at the same time I was informed that they do not mow wheat in the same manner as oats: that the scythes are not made alike for both these works, and that there are some other essential differences.

"These observations were a sort of proof that the practice had been found to answer, since it was still continued; and I concluded, that if my operation, imperfect as it was, had succeeded so well, I might expect far greater advantages when it should be performed regularly: but, not to be too strongly prejudiced in its favour, I resolved to make a trial upon about thirty acres only.

"By dint of enquiry, I found within a few miles of me a husbandman who came from the province of Artois, and

had been used to this very business. I talked with him; he told me how the work ought to be done, pointed out its advantages, and I retained him for my intended next year's mowing of wheat: but as the season was pretty far advanced, and there was not time to procure from his country other people equally well acquainted with the practice, to follow the scythe, and do the whole completely in every respect, he instructed two young lads, as well as he could. In short, nothing was wanting but a mere matter of form, by the neglecting of which some of the lifts of the cut corn were misplaced, so that there were ears at both ends of the sheaf.

"I ought not here to forget the clamour raised by this novelty. I made the experiment upon the finest wheat; because my new workman had told me, that the stronger the corn was, the better and more regularly the mowing would be performed. My neighbouring husbandmen, and all the reapers employed by them, thought me out of my senses, and some of them even came to reason the matter with me. They meant well, and I took it kindly; but desired them carefully to notice the event.

"My experiment was made upon three pieces of wheat, of ten acres each, situated in a much more extensive field of the same corn; so that there was the fairest room to make a just comparison between the operation of the scythe and that of the sickle.

"Some of the neighbouring husbandmen had the curiosity to see the work performed, and were surprised to find that less corn was shed in this way, than in the common practice of reaping with the sickle. They thought the method good; but made a few objections to some particular circumstances, in which the experience of subsequent years shewed them that they were wrong. Their entire approbation then followed; and their mowers finding that they should be able by this means to cut down all their corn without the assistance of strolling strangers who often do their work very badly, gladly learnt the new method, and commended it to others.

"This work required a precaution which has been duly attended to ever since: it is, to pick all the stones from off the land every year, as carefully as possible. The expence of doing so is a very trifle, when compared to the advantages attending it. All the roads around my land, which were formerly impassable in winter, are now firm and good, fit for any carriage. We no longer hear of horses lamed, or waggons overturned by them; and which is equally true, I find that my ground now requires a less quantity of seed.

"I have now practised this method, in an extensive manner, during five successive years, in the course of which I have had opportunities of experiencing every circumstance necessary to be considered in order to determine its real merit; I mean, mowing in rainy weather, and cutting of corn either bent, laid flat, totally lodged, or lodged only in particular places, and in various directions. I shall first describe the mechanism of this mowing, and then point out its advantages, with the objections of my neighbours, which will shew the only inconveniences I have met with.

"The Flemish mowers whom I employed in the year 1753, brought with them scythes exactly like ours. I saw no sort of difference in their size, make, manner of being mounted, or even in the hooks they were trimmed with; so that I found I had been misinformed by those who told me in 1751, that this work required an instrument different from that which is used for mowing oats. It was not till the year 1755, that the ingenious workman pointed out some very proper alterations, which have since been made.

"This intelligent mower observed, that the common scythe cannot suit any ground but such as have been ploughed flat; that it therefore was least of all proper for our lands, which are ploughed in ridges of ten or twelve furrows, raised very high in the middle; and that its hooks broke the straw, plucked off numbers of ears, and did not lay hold of many short plants which grow in the bottom of the furrows, whereby a loss was occasioned, or take up the intermixed grass and weeds so exactly as might be wished. To remedy this, he took a scythe at least six inches shorter than those which are commonly used, and, instead of the hooks, substituted what he calls the bender, consisting of two shoots of willow, or other green wood, placed semicircularly upon the handle of the scythe, where the hooks are commonly set. To this end there must be four holes

in the handle, so that the end of one twig may be put into the lowermost hole, and its other end into the third, and the two ends of the other twig into the second and fourth holes. The scythe thus trimmed is to be used in the manner shall now explain.

"When a mower sets about cutting down a crop of oats, he places himself so that the corn is at his right-hand, from whence the action of the scythe throws the waving towards his left. The mower of wheat, on the contrary, proceeds from outside to inside, so that the corn which he is next to cut is always at his left-hand; and that which he has just cut, being collected by the bender, is rested, inclining a little against the adjoining uncut part.

"A helper, which may be a boy of twelve or fifteen years of age, or an elderly woman, follows the mower at the distance of four or five feet, with a reaping hook, or a stick about a foot and a half or two feet long, and by putting that through the interval between the sloping late cut wheat, and the standing corn against which it rests, takes up the former, gives the straw ends a gentle stroke or two upon the ground, to form that parcel into a grip, and lays it down at his right-hand. This should be done very expeditiously, because the picker-up, as this person is called, is followed by another mower; and it should also be done dexterously, because the greater or less quantity of gleanings depends thereon. There should be as many pickers-up (we call them binders,) as there are mowers.

"The posture of the mower is a circumstance of such importance, that I think myself happy in having taken particular notice of it in 1754. In cutting grass, and oats, the mower goes in such manner, that his feet, which are moved alternately at each stroke of the scythe, describe two parallel lines. But in the mowing of wheat, the mower's track should be upon a single line, so that his right foot, which should be foremost, be driven forward by the left, at each cut of the scythe; not unlike the attitude of a fencer when he advances.

"An accident which had like to have over-set my whole operation in the year 1754, demonstrated to me the necessity of this different posture. I employed for mowing my wheat, men who used to come yearly to cut down my oats: they were seven in number. On the third day of their labour, five of them fell ill; upon which I set three others to work: but the consequence was, that I had ten sick people to take care of at the end of the week. I visited them, inquired into their ailments, and found that some of them had a fever, but that all of them complained of violent pains and soreness under their left ribs. At first, I was inclined to think them pleuritic; but, upon a close examination, and upon considering the nature of the work they had been at, I saw that their illness proceeded from badly managed hard labour, the stress of which had been made chiefly on the left side. I therefore ordered them to take their rest.

"The next day, upon visiting my infirmary, I found that two of the mowers were returned to their work. I went out to them, and saw, even at some distance, that their posture in this work was the same as if they had been mowing of oats. This immediately shewed me the cause of their pains. The scythes which they then used had the common sort of hooks, and were much heavier than those with only wicker benders. I took up one of them, put myself in the posture of a mower of oats, and shewed them, that as a much greater weight rested upon the hooks of the scythe when they mowed wheat, than when they cut oats, it was not possible for them, in the posture they had chosen, to move that increased load to the left, without an irksome twist of the body. Then, putting myself in the posture of a fencer, as I had seen my plentiful mowers do the year before, I demonstrated to them, that the body was thereby placed in such an attitude as enabled it to exert the greatest strength, when, by the motion from right to left, it had the greatest load to support, and that, by the same means, this load was carried round without fatiguing the ribs of either side. My man took back his scythe, tried as I directed, was convinced of the truth of my demonstration, taught his companions the same method, and they have done their business easily ever since. I thought it necessary to relate the circumstance of this accident, because I am satisfied that even the strongest men would sink under the labour of mowing wheat, if they were to stand in the same posture as the mowers of oats.

"Such is the manner in which this operation should be performed, when the corn stands upright, that is to say, in the most favourable years. I ought too add, that the

mower should take care to place himself, for his work, in such manner that his left hand may be toward the wind. The corn is then naturally inclined over the scythe, and is the more easily cut closer to the ground. The resistance of the wind, be it ever so little, helps to keep the corn which is cut steady upon the benders of the scythe, and facilitates the motion which rests it against the uncut corn, where the binder takes it.

"The mower is not hindered from mowing close, by the wind's blowing at his back; but the corn which he cuts will not be so exactly collected by the bender: some of the ears will be a little scattered: but the greatest inconvenience is, that it does not rest so well against the standing corn, but is often blown down; which renders the binder's work slower, and more troublesome, and occasions greater gleanings.

"The wind is in a bad corner for the mower when it blows in his face. It then occasions a loss of stubble, and a great dispersion of the ears.

"But the worst of all winds for this work, is that which blows upon the right hand of the mower. The stubble then remains long, and so great a quantity of ears lies scattered about, that one would hardly think the ground had been harvested. My mowers did not place themselves in this manner of their own accord: but I made them do it for a quarter of an hour, to try the effect, of which I am fully convinced.

"When the corn is inclined, or bent, the mower takes it in the direction of its bending from left to right: which has the same effect in calm weather, as if the wind blew towards his left.

"Corn which is lodged cannot be easily mowed inward, because the binder would be incessantly impeded by the intangling of his grip with the uncut corn. A good mower judges by his eye, which part it is most proper to begin at, and takes advantage of the wind when it can be of service to him. The method which I have seen most commonly practised, has been by taking the corn in the direction of its bending, and throwing it in waves. The work thus done, is neatly performed: no remains of stubble are seen after the mowing: but the field looks like a meadow.

"Corn laid absolutely flat, and intangled, is the most difficult to cut well. I have seen a mower take it in every various direction in which it was beaten down, as if the wind had been constantly at his back, and by this means he has cut as close as if it had been only lodged. My wheat was in this condition in the year 1757, and was mowed very regularly: only the work was somewhat longer about, than generally is in other cases.

"I shall not speak of rainy seasons till I come to the objections against this method of cutting corn; because they have nothing to do with our mowing, and the only thing requisite in such cases is to keep the corn from sprouting in the ear: but I shall here relate the advancement which I find in this practice.

"The preservation of my fellow creatures is so dear to me, that I look upon the means of lessening their excessive hard labour at a time when the heat alone is enough to over-power them, as the first and greatest advantage resulting from this method. Now I see that a good reaper, with his sickle, can scarcely cut an acre of wheat in a day, let him toil ever so much; whilst the mower will dispatch from an acre and a half upwards of two acres, according to his skill and dexterity. I have, indeed, met with but few able to exceed two acres, when they have done their business well: but we may reckon that a good mower, taking them one with another, and the corn as it runs, upright, lodged, intangled, &c. will clear an acre and a half, or perhaps an acre and three quarters, in a day, neatly, and without wasting any of it. This mower does then three fifths more work than a reaper can. It is true, he has not the grips to tye up, because the person, who follows him does that part: but he is obliged to whet his scythe when he comes to the end of the field, and still oftener when the corn does not grow thick; besides which, notwithstanding all the care that can be taken to clear the ground of stones, not a day will pass without his meeting some which will oblige him to have his scythe new hammered; and lastly, when he has finished a row, he must go back to the other end of the field before he can begin another. All this takes up at least as much time as the reaper's binding up what he has cut: and in regard to the hardness of labour on each side, I believe that every one who rightly considers the nature of their respective

works, and their postures in working, will allow, that the mower's toil and fatigue is three fifths less than that of the reaper.

" Another circumstance, well worth attending to, in this method is, that the mower is not exposed to those injuries from thistles, thorns, and other noxious plants; which often prove fatal to the reaper.

" From the first of these advantages result several benefits: 1. A greater celerity of the necessary work. Not a year passes without the husbandman's experiencing that some part or other of his corn ripens too suddenly; and this unexpected maturity, being exceedingly heightened by the least delay, occasions a great waste by the shedding of the grain, both when the crop is reaped with the sickle; and in loading and unloading it when carried home: whereas the scythe, by clearing in two days a field which could not be reaped in less than five, in the common way, guards against that excessive ripeness.

" 2. This method of cutting down the corn requires fewer workmen. I must here explain myself; because the fact would contradict me, if it be objected that a mower and a binder are necessary in this way, for what the reaper alone does in the other. But I consider, that to harvest ninety acres, for example, of wheat, I must employ ten men at least twenty days, with their sickle; whilst seven mowers, and their binders, (fourteen people) easily do my business in ten days. The difference then is equal to sixty days work of one man: and if I do not intend to get my harvest in quicker with the scythe than with the sickle, I take but four mowers and four binders, eight persons, of which the four last stand me in less expence than three reapers; because I employ for this business young people who would not be strong enough to reap with the sickle. Consequently I have two workmen the less, and some advantage in the comparison between the grown-up man, who has a higher price, and the lad who answers my purpose.

" 3. The thus employing of children, old women, and men whose constitution is not robust, would be an advantage to the inhabitants of the place. It would afford the means of subsistence to a greater number of people, and prevent idleness and beggary; an important object upon many accounts. Almost every parish would find within itself hands enough to get in its harvest, without being obliged to have recourse to accidental passengers, who often work badly, require exorbitant wages, and sometimes leave their master in the middle of the harvest, if they do not submit to their unconscionable demands.

" Let us leave speculation, and notice some advantages which are evident beyond contradiction. 1. It is not a small one to have a greater quantity of straw, and that straw intermixed with more grass and other fodder, than when the corn is reaped in the usual way. This does not need any proof; for every one knows, that the scythe cuts as close to the ground as the mower pleases. Experience has shewn me, that the stubble has not been left two inches long upon our mowed fields, where the stones had been carefully picked off; whilst the sickle generally leaves it eight or nine inches long, and sometimes much more when the ground is infested with thistles and other stubborn growths, which make the reaper lift up his hand to avoid them. The straw is therefore plainly six inches longer when cut with the scythe, than with the sickle; a difference which may be valued at a sixth part more than that which is usually reaped in the common way.

" 2. The green fodder in the mowed fields shoots up anew when cut, and affords excellent pasture after the corn is taken off. The same demonstrative evidence as before, will again take place here with those who but consider, that the reaper, leaving the stubble either eight or nine inches long, takes off only the very tips of the grass which chance to be within his grip; so that being then near its time of maturity, it ripens its seeds, sows them, and withers away: whereas, when the scythe cuts it within two inches of the ground, in its greenest and most un-ripe part, the yet remaining eyes, and the crowns of the roots, send forth new shoots, which form a good after crop for cattle.

" 3. The pasture upon fields mowed with the scythe, is attended with an advantage, in regard to cows, which may perhaps be peculiar to my country. I know not whether it be the same elsewhere. We find every year, and I have always taken particular notice of it, that our cows cease to yield milk during the first week of their feeding among the wheat stubble. I take the reason of this to be, that the stubble gets into their nostrils, pricks them, hinders them

from feeding, and makes them range the whole field over in quest of grass unattended with this irksome inconvenience; so that they spend their time in running about, without grazing. I do find that this accident happens to cows which are turned in among the short stubble left by the scythe: the grass there soon shoots up a-new, and yields me plenty of pasture, especially if a little rain happens to fall after harvest.

" It results from hence, that the husbandman is enabled to feed more cattle than he could otherwise do, to save his saintfoin or lucerne, and to have a greater quantity of dung; as I have experienced with almost incredible success.

" I now proceed to the objection, which I shall state in the same order as they were made; that is to say, as each year gave room for one or other of them.

" The first was that the scythe must make the corn shed very much by shaking it considerably. To affirm the contrary may seem paradoxical; though the assertion will be proved from manifest principles; and by facts. To judge rightly of my proposition, it will be necessary to compare the operation of the scythe with that of the sickle; both of which I have examined very attentively.

" The reaper presents his hand to the corn, and with wide extended fingers, grasps as much as he possibly can; after which to bring the lower part of the stalks so close together that the sickle may encompass the whole of his grip, and at the same time to give it a tension which renders the action of the sickle more certain, he gives it a violent shake and at that instant cuts it. The grip thus cut is generally entangled with the standing corn; or the reaper, when going to lay it down, finds that he has missed cutting a stalk, or perhaps more, which he then breaks with a jerk of his hand. Thus several shakes precede that which the corn receives afterwards when it is tied up.

" The scythe has not these effects. I have already explained the mechanism of its operation, and shewn that the corn cut without any violent shake, is carried gently by the bender (or cradle, as we more commonly call it) upon the scythe, to the standing corn, against which it rests inclined till the binder takes it away to tie it up.

" To prove my proposition by facts, I instance the following. After my wheat was mowed in the year 1752, in the manner before related, upon the three several spots of ten acres each, which were parts of much larger fields, I went, with four other persons, purposely to examine with all the care we could, what quantity of grain might have been shed by the mowing. We found none at all in the two first mowed pieces; but a great deal in the other parts of the same fields which had been reaped with the sickle. In the last piece, which was not cut till the corn was riper, we found little grain in the mowed part, but incomparably more in the other. I did not repeat this search every year with the same care, because I had not always the same conveniences of making a comparison: but I have seen enough to be certain that no grain is shed unless the corn be exceeding ripe, and that much less is then lost by the scythe, than by the sickle.

" The following more important objection was afterward made by a sensible husbandman, who observed to me, that, in a rainy year, the corn cut after this manner must be more liable to grow in the ear, than that which is reaped in the common way, because the heads of the grips not being supported here by a pretty high stubble, the wet cannot well drain off; and that the grain will imbibe a great deal of moisture from the grass underneath, when the ear is beaten down upon it by rain, which will render it very apt to sprout as soon as the sun shines upon it. I had been told how to guard against this accident, but did not try the method till the year 1756, when it answered perfectly well.

" This method consists in laying the grips in a triangular form, so that the head of one rests upon the foot of another. This operation is neither long nor fatiguing: nor does it require, in order to do it quick, anything more than a little dexterity in closing the triangle, by making the foot of the third grip support the ears of the first. The rains which fell during the harvest of 1756, rendering the getting in of that year's crops extremely troublesome, my neighbours had a great deal of sprouted corn, but mine escaped by this method; and what little I had, proceeded from that which remained unmowed when the rain became incessant.

" With regard to the sheaves, when bound, my Flemish mowers

mowers informed me, in 1753, of their practice when they are overtaken by lasting rains. It is, to heap upon one another, ends to ends, as many sheaves as they can possibly cover with one, which is then opened and laid over them. My people did not practice this method, which I believe the best; but they secured my corn by other means; which answer extremely well, and are generally known.

"From the above objection my husbandman derived another, relative to the difficulty of drying the grass and weeds intermixed with the corn, in rainy years, and the danger of housing the sheaves when full of that trash; which may ferment and be the occasion of the rotting of a whole pile of wheat. I cannot answer this objection otherwise than by experience. The harvests of 1756, and 1757, were certainly not favoured by the weather: yet all the wild growths which were cut down with, and bound up among my sheaves, were well withered when they were housed. No sort of smell which indicated the least fermentation was perceived in any of my barns; the threshers did not find any thing that looked like it: and the straw which is taken from those barns to feed my horses, attests that there was not any.

"I now come to the last objection; by so much the more serious, as it is one of those inconveniencies which I cannot remedy but to which I readily submit. The ears of the corn, says the objector, do not lie so even in your grips, as in those which are reaped with the sickle: some of them are in the middle, and others at the very bottom of the sheaf; so that your corn is not threshed so well or so regularly, and you thereby lose perhaps a considerable part of it. 2. All the grass and weeds contained in your sheaves are threshed with the wheat, and their seeds are mingled with the corn when the thresher measures it out: consequently you pay him for threshing his trash, which again increases the labour and pay of the winnower.

"All this is true: but let us discuss the matter a little more thoroughly. There are ears in the middle and at the bottom of my sheaves; but they seldom are of any other kind than those which we call backward or late ears; the weak productions of sickly plants, or of seeds not perfectly sound. Repeated examinations have convinced me, that very few others are in this case; and these ears hardly part with their grain at any time, in whatever manner they are threshed; for though the grains be torn from of them by the action of the flail, the inmost husk still adheres to the corn. These diminutive imperfect grains are so great a detriment to the fine plump, well nourished corn, that they lessen its value if not carefully separated by winnowing; after which they serve to feed poultry. If these ears escape the flail, the straw is so much the better. Our horses and other cattle reap therefrom a benefit which we ought not to grudge, because, I think it turns to our advantage.

"The threshed grass and other wild productions, do indeed yield a considerable quantity of what are commonly called bad or useless seeds, for the beating out of which I pay the thresher. But the grass which occasions this expence, saves me that of a great deal of sainfoin and lucerne which my cattle would consume; and it would be unjust in me to complain of the additional charge in the winnowing, since my manager has thought of applying those seeds to domestic purposes, such as feeding fowls, &c. which prove more profitable to me than an equal quantity of the finest corn.

"A real increase of expence, is what I pay the thresher beyond the common price of the country. This difference, which consists in two-pence or three-pence for a quarter of wheat, is but a just compensation for his extraordinary trouble in unbinding and binding up again perhaps an hundred and fifty sheaves, and sometimes more, for what an hundred sheaves generally yield, when reaped in the common way. But this expence is so amply repaid by the extraordinary quantity of straw obtained by my method, that I rate the difference at more than the value of five quarters of corn, which, to silence contradiction, I will suppose to be otherwise lost in my practice. Still my crop is cut down and housed with far less toil and expence, than if it was reaped."

"They begin ploughing in the Isle of Thanet, says a correspondent of the editors of the *Museum Rusticum*, about the first week in November, contriving so that the wheat season may be over by the end of the month.

"In the spring, if the wheat is ranks and the weather dry, they feed it down with their sheep, which they think

makes the wheat branch more, and settles the earth about the roots of the plants. Experience has convinced them, that this method of sowing wheat after trefoil, is better than sowing it on a fallow; for the land hereabout is naturally very light and hover, and the wheat on that account very much subject to be root-fallen. To prevent this, it is no uncommon thing for them, as soon as they have sown their wheat, to drive a flock of sheep over the land, to settle the earth close to the seed.

"Their crops of wheat here are generally three, four, and five quarters on an acre; which last is, indeed, a very large crop, when it is considered, that the land is in general, by nature, poor and barren, and that it is almost entirely owing to the industry and good husbandry of the farmers that it is at all brought to bear wheat: in fact, they are an assiduous people, and spare neither costs nor labour to improve their land.

"On the light land here they for the most part sow about fourteen pecks on an acre, but on the richer lands they allow four bushels.

"The farmers here never sow the seed produced by their own land; they find their wheat succeed much better by change; for which reason the seed which they sow on the light hover-land they chuse to procure from a gravel or deep cledge, or clay land, taking care that the soil on which the seed has grown should be as different as possible from that on which it is to be sown.

"Instead of making artificial steepes with great parade, they make use of that which providence has put in their way, wetting their seed with salt water, which they fetch from the sea: and they afterwards sprinkle it with lime, to prevent the smut: they are also particularly careful to clear their seed from wild oats, cockle, &c.

"I know no part of England where there are better farmers; for though they keep their lands constantly cropped without fallow, which they call sowing a round tilth, yet do they so manage matters, as to keep them still in good heart.

"They reap their wheat very high here, leaving as much straw as possible in the field: this they say they do to save barn-room. Some farmers here have a practice of sowing rye to make bands for their sheaves, the straw being longer, and as they think tougher, than that of wheat. The reaper makes the bands, which he cuts as low as he well can, and binds the sheaves.

"The wheat stubble, which, as I said before, is left very long, is generally mown for the maltsters, as they burn it in their kilns to dry their pale malts for the London market. The greatest part of this island is a light chalky soil, so that wet summers in general agree best with it; and it is by this means the farmers here get so much money: for when the crops fail in other parts of the kingdom, they are almost sure here to be very large; and they have the great convenience, besides, of water carriage to the London markets. It is extremely pleasant, towards the latter end of the summer, before harvest, to ride over this little island: I do not imagine there is a more improved spot in the kingdom; the fields are all kept so clear from weeds, that they resemble a well kept garden; they grudge no expence in hoeing, weeding, ploughing, or manuring: and experience has long ago convinced them that they pursue a right method. Their practices are many of them good and worthy imitation; it would therefore be great pity if they were not made known, by some means or other, to the rest of the kingdom." *Museum Rusticum*, vol. I. p. 3.

"It is now upwards of seven years that I have been tenant of a considerable farm in Essex; but as there are some particular circumstances attending this farm, I must beg leave to say a few words on the subject:

"The soil, which is, for the most part, a fine mellow loam, or what is in general called a good wheat soil, was in very good heart, and not impoverished; yet the last tenant broke on this farm, and the landlord lost by him near two years rent; for his crops of wheat were continually damaged by smut, let him take what care he would of the seed, and were besides often laid, and the land got very foul, though he was not sparing of his fallows:

"On the contrary, since I have occupied this land, it has borne large crops of good sound wheat, with very little smutty corn, and barley, oats, peas, beans, and other things in proportion. What will appear still more surprising is, that I do not lay on half so much dung as he did.

"It will now, perhaps, be necessary to explain this seeming paradox. At no great distance from the farm lives the landlord, who is a man of fortune, and drives a set of horses. This gentleman keeps no land in his own hands, so that he was for many years obliged to buy all the straw used for the litter of his stables, which amounted to a very considerable quantity: however, when the last tenant of this farm came into it, having been a servant in the family, he offered to supply the squire with straw for his stables, provided he might have all the dung except what the gardener had occasion for. The squire thought this a good proposal, and the farmer imagined he had the best of the bargain; so the matter was soon settled.

"Now, you are to understand, that the squire kept, besides seven coach-horses, a stable of hunters, a number of road-horses, and a pack of hounds; so that there was made on his premises, in a year, an incredible quantity of rich dung.

"The farmer imagined he was now in a fair way of making his fortune; for his father had taught him, that the man who can command dung is always sure of large crops: but this did not prove true in the present case.

"To proceed; my predecessor went on ploughing his land, got his fallows in good order, dressed them largely with dung, and always sowed them with wheat.

"His crops of this noble grain, however, by no means answered his expectations: his wheat constantly looked well and promising in the winter and the early part of the spring of the year; but as it advanced, it grew rank, and at harvest was either run all to straw, and was besides very smutty, or else, if a heavy shower of rain happened to fall, it was lodged, matted, and grew. This was indeed a very mortifying circumstance, but our farmer could find no remedy for it. He several times, without success, tried folding some sheep on his wheat; but this part of husbandry, for want of skill, he managed so badly, that he lost two entire crops, for he had scarcely the return of his seed at harvest. This could never hold long; so that in the end he was, as I said before, broke and ruined.

"This man never could be persuaded that any part of his loss was to be attributed to the dung he laid on his land, though he constantly manured it with the horse-dung before it was half rotten, and without any mixture to allay its great heat; this kept the soil in a constant state of fermentation, and stocked it with weeds, insomuch that, when I took possession of the farm, some of the soil was absolutely mouldy, and stunk again, it was so rank.

"I will now inform you of my method of management, that you may be enabled to judge how far I was benefited by the errors of my predecessor.

"I found sixty acres of fallow ready for sowing with wheat: these, as the land was rank, I sowed with the winter tare, which I knew, by experience, would choke the weeds, and abate the rankness of the soil. In some parts, where the soil was not so rank, I ploughed in the tares in order to sow wheat over them; in other parts I suffered the tares to stand for a crop, which, however, was not considerable, they ran so much to straw or haulm.

"When the tares were off, I got the land instantly in order and sowed the whole with wheat, of which I had a better and cleaner crop than had been known upon the land for upwards of seven years before: this all my neighbours acknowledged: however, it was neither clean enough, nor considerable enough, to satisfy me. Some of your readers may perhaps wonder what I did with my tares, as but few are sold at the country markets; but I must inform them, that I live within ten miles of a sea-port town, whither I sent them at various times, in order to their being carried by sea to London.

"I am to observe to you, that I continued the agreement of giving the squire straw for his dung; but I made a use of it very different from my predecessor.

"I make it a rule never to manure for wheat, or sow wheat on a fallow. I do not indeed allow many fallows on my land; and when I do, I generally sow my fallow with barley, to which I allow four or five ploughings. This commonly yields me a large return, and I have a good crop of wheat after it.

"This, however, is not my general method; for I am very fond of the hoeing husbandry, to practise which, in some degree, is the only infallible way of keeping land clean. To begin then with my method, I never lay dung alone on my land, let it be ever so rotten; but as soon as I get any long dung from the squire's, I carry it to my compost-heap, where it is mixed in alternate layers of

beds, with fresh virgin earth, (if I can get it) lime, or chalk, lime-rubbish, scorings of ditches and ponds, turf, leaves of trees, and all the dung and offal of my family, of the hog-yard, the poultry-yard, and the dog-kennel. As to my pigeons dung, I always preserve it to mix with foot, and use the mixture as a top-dressing for my wheat, whenever it happens to be too backward in the spring.

"But to return to my compost: I have always several distinct heaps of different ages, and I sometimes leave it three years before I use it, and never lay on any under two years old.

"When I have got a plot of ground in order, I give it a thorough good dressing of this compost, which I immediately plough in. I then sow it with some crop that requires hoeing; such as horse-beans, broad-beans, or white or grey peas. During the whole summer, I take care to keep these crops very clean by hoeing, especially if the season is rainy; and I am particularly cautious in preventing any of the weeds from perfecting their seeds.

"When my hoeing-crop, which generally more than pays me all my expences, is off the land, I immediately get it into as fine tilth as I possibly can, by repeated ploughings, and then sow it with either wheat or barley, whichever is likely to pay me best; for little as some of your readers may think of it, barley, when it is sown on good land well prepared, is very frequently as profitable a crop as wheat.

"By thus sowing my wheat after a hoeing-crop with dung, I have always a good return of clean corn, often five quarters on an acre; and my land will still be in heart enough to give me a reasonable crop of oats; after which, without any fallow, comes my hoeing-crop, &c.

"When I sow barley after the hoeing-crop, I suffer wheat to follow it; and then it is that, if I find it necessary, I give the wheat in the spring a top-dressing or foot mixed with pigeon's dung.

"I sometimes allow only six pecks of wheat-seed to an acre: this is when I sow over it, in the spring of the year, eighteen pounds of broad clover-seed, which I harrow in with a pair of very light harrows; and it does not in the least damage my wheat-plants. I leave the clover only two years on the land; for the second year, after I have mown the first crop for hay, I suffer the second to grow very rank, (having given my land a slight dressing from my compost dung-hill the preceding year) which I plough in, and over it sow wheat, to be harrowed in on once ploughing.

"These crops of wheat are smaller in quantity than any others I get, but the grain is finer, plumper, brighter, and heavier, generally selling for more at market, as being always very clean and clear from seeds of weeds.

"In my method of farming, some particulars are to be noted. In the first place, as my crops succeed one the other very quick, I am under a necessity of having all my stubble extirpated before I give the land the first ploughing after the crop is off. If it is a wheat or bean-stubble, I generally have it all pulled up by hand by women and children; barley and oat-stubbles I have torn up by a pair of loaded drags, and afterwards gathered into heaps and carted to the compost heap. This I do to prevent the stubble from being buried by the plough, and from growing mouldy in the land; from which mouldiness I have great reason to think smut often proceeds.

"Another thing to be noted is, that I allow less seeds to my land than most of my neighbours, my quantity being from seven to nine pecks of wheat, from nine to twelve of barley, and about twelve of oats to an acre of land; but it is always to be presumed that the seed I sow is good. If any farmer should imagine that these quantities are too small, let him suppose every wheat plant to occupy a space of six inches square, which is small enough: let him then calculate how many such spaces there are in a square acre. When he has done this, let him proceed to count how many grains of wheat there are in a pint, which multiply by the number of pints in nine pecks, and he will find by the result that I, in fact, allow too much seed." *Museum Rusticum, vol. V. p. 104.*

"I have, for some years last past, held a considerable farm in the county of Leicesters, and have, thank God, met with some success in my practice.

"My methods of farming are thought by many to have something peculiar in them; yet, as I do not often miscarry, no one has a right to find fault with me.

"Great part of my farm is very good wheat land, the soil being a substantial loam.

"I frequently

"I frequently, as well as the rest of my neighbours, make use of lime as manure; but then I use it differently from what they do.

"The common practice is, to lay about forty bushels of unslaked lime on an acre, which makes a peck on every square perch, (half a bushel when it is slaked.) On wheat land they spread the lime at the same time they sow the seed; but this is a way I do not much approve, and for this reason I vary my practice: The method I use is as follows: I sow my wheat without laying on my manure; but in the beginning of the month of February I get, for every acre of land I intend to lime, twenty bushels of that manure, unslaked, and forty bushels of sand, or the rubbish of a brick kiln.

"Towards the latter end of the month I cause the lime to be slaked, which doubles its measure, and very well mixed with the sand; immediately after which, in the last week of the month, I have it scattered by way of top-dressing over the green wheat; and as rain generally succeeds, it is soon washed down to the roots of the plants, and gives them a vigour and strength of growth that is really astonishing to a person who had never seen this method practised.

"This is my way, if I see the weather is inclinable to be wet; but if it is dry, and not likely to rain, I double the quantity of sand, in order to take away all danger of the wheat-plants being burnt, or hurt, by the strongly corrosive power of the lime.

"The above method I would willingly recommend to the attention of your readers; and though I have benefited greatly by it, yet need they not take my word, as it is so very easy to make a small trial, and form a judgment from the success they may have.

"I must observe, that I look upon it to be almost a matter of indifference what kind of sand I use, except that I prefer lime-stone sand to the crystal sand, as being most absorbent, and in truth prefer the rubbish of broken bricks to either.

"It will perhaps be unnecessary to tell your readers my motive for this preference; yet that I may not be thought obscure, I shall do it.

"When lime is slaked, it crumbles and falls into very minute particles: the smallest of these particles are, together with the moisture that adheres to them, absorbed by the large open pores of the brick rubbish, which afterwards disposes them by slow degrees to the soil on which it is laid, for the support of the crop: this occasions the operation of the lime to be more equal; the parts which were not absorbed, are first attracted by the earth; these nourish the young plants, which, in time growing stronger, have power to draw from the absorbent the particles it had reserved for their use." *Museum Rusticum*, vol. III. p. 366.

"Almost every part of this kingdom has a method of farming peculiar to itself; and this I have often found to be true, in the many journies I have made through various parts of the island.

"A short time since, my occasions calling me down into the west, I stopped for a few days in Wiltshire, where I could not help observing, that the wheat-corn was remarkably backward, though it in general promised to be a good crop.

"I thought it worth my while to ask some of the neighbouring farmers the reason of this appearance, when I was informed that most of the wheat was sown late, owing to a wet autumn, which prevented them from giving their land the necessary ploughing for that crop sooner than November, December, and even January.

"The soil is a pretty good loam, on a chalky bottom: and I found they often sow late; but whenever they do it, they take care to allow an additional quantity of seed, generally one fourth, or a third more than they use when they sow early.

"I was also told, that many benefits often resulted from such late sowing; particularly, the crop is generally clearer from weeds; for in early-sown wheat, poppies, and other noxious weeds, are very apt to get a-head, and injure the corn. I even saw in my walks many early-sown fields, which rather seemed to be under poppies than wheat, as the poppies were in full bloom, and made a glaring appearance.

"The Wiltshire farmers, the best of them I mean, often give their land four ploughings for wheat; and they find their advantage, as it is by such means brought to a fine tilth, and yields a good crop.

"Another advantage they told me they had from sowing

their wheat late, was, that in the blooming season the weather was generally fine; whereas in a wet summer, the bloom is often washed off from the forward-sown wheat.

"But it must not be imagined this method of sowing wheat late is indiscriminately pursued: in many circumstances it would be very imprudent to do it.

"This method of husbandry must, to meet with success, be chiefly practised on fallows, where the land is good, and has been well dressed.

"Every crop, and method, has dangers to encounter; and the chief danger of sowing late is, that a frost may come on just as the seed begins to sprout; but then good land, well dressed, is not so subject to this misfortune as poor, unmanured land, that has, perhaps, been not half ploughed.

"I find, from enquiry, also, that it is dangerous sowing wheat on clover lays on one ploughing only, unless it is done sooner than the middle of November; for the turf or grass-lay forms a crust immediately under the seed corn; and this not only prevents its taking a firm rooting, but also exposes it to the ravages of the field fowls, which are, at this season, particularly voracious, as having a scarcity of food; and the infant plant is, besides, liable to be killed by the frost, just as it is about sprouting and shooting out its first leaf. It stands, therefore, to reason, and is warranted by experience, that wheat should not be harrowed in on a clover lay, on one ploughing, so late after the middle of November, as the danger is great, though the loss may not always be certain." *Museum Rusticum*, vol. III. p. 1.

"As I have been many years a farmer, it is not to be wondered at that I should know something of husbandry.

"Experience, which is an excellent mistress, has, in fact, bestowed on me most of the knowledge I have acquired. I imagine, therefore, that an account of the result of this experience will not be unacceptable to your readers.

"Most farmers chuse to sow wheat on a fallow; we, in Essex, on the contrary, often, not without good reason, avoid it. Every fallow designed for wheat requires a good dressing of rotten dung, or some other manure; and this dressing, we imagine, often is the cause of a smutty crop, if laid on uncompounded; therefore, whenever I sow my wheat on a fallow, instead of laying on my muck-heap unmixed, I make it into a compost in the preceding spring: this compost consists, according to the nature of the soil it is to be laid on, either of chalk, light earth, and rotten dung, or of lime, clay, and dung, laid in a heap, in alternate layers, or beds.

"This compost-heap I cause to be frequently turned during the course of the summer, till it is thoroughly mixed, and forms one united mass of manure, rather crumbly than otherwise.

"With this manure I dress my fallows in the same manner farmers lay on their rotten dung alone; and I find, by experience, it is less apt to heat and canker the wheat-seed, and it is also much less inclined to mould and burn the seed.

"This, I say, is my method of management when I sow my fallows with wheat as a first crop; but I more generally approve of making wheat the second crop after barley, oats, beans, or peas.

"I am sensible many of your readers will be surprised at this method, and exclaim, that it is impossible to get a good crop of wheat but after a good fallow; yet I know the contrary: it is from experience I know it; may I not therefore venture to assert it?

"When I intend to sow wheat as a second crop, I lay my due quantity of compost on the land some time before I sow it with barley, oats, beans, or peas.

"When this crop is off, the following year I sow wheat. You may suppose the land to be duly prepared by well-timed and careful ploughings; but I am to premise, that after beans and peas, being hoeing crops, the land is much sooner brought into good tilth, than after oats or barley.

"The wheat sowed the second year of the fallow is, with me, generally a good crop, and almost always clear from smut and pepper-wheat.

"If, by any accident, the wheat should be sickly, or pining, after Christmas, I bestow on it a top-dressing of wood-ashes, soot, if I can get it, or coal-ashes, if the soil happens to be strong: this seldom fails answering my expectation; checking the growth of the weeds, and forwarding that of the corn.

"It is very frequently that I sow wheat in this manner

for a second crop; but when I have an opportunity of chusing, which I cannot always do, as I must suit my crop to my wants; I prefer, for the first crop, beans or peas, either of which I take to do the land nearly as much good as a fallow.

"Neither peas nor beans are, in my opinion, great impoverishers; and the frequent hoeing which they both require, if they are properly cultivated during their growth, brings the land into finer order than the best regulated course of husbandry with the common implements could effect.

"Wheat succeeds particularly well after either of these two last-mentioned crops; and I have found, by experience, that if peas or beans are made intermediate crops, and are well and properly hoed during their growth, land of a moderate quality may, without being impoverished or hurt, be made to bear a continued succession of crops for many years; but it must be understood that it should, from time to time, be refreshed with proper dressings of well-prepared compost.

"I know many farmers think there is no such thing as carrying on a course of husbandry without allowing, once in three or four years, a year of fallow; but such are little acquainted with the benefit resulting from hoeing crops: and it is this benefit that has of late induced farmers to sow such immense quantities of turneps in the counties of Norfolk, Suffolk, Essex, and other counties adjacent.

"Many of the advocates for intermediate fallows think that the earth requires rest; but this is a great mistake; for I could easily make it appear that, with a proper method of husbandry, land might be almost continually cropped, without being impoverished or worn out.

The real benefit accruing from frequent fallows is, that they allow the husbandman time and opportunity to bring, by good tillage, his land into proper order for the reception of the seed; but in the method of husbandry I would recommend, the land would always be kept, by frequent stirring, in such good tilth, that the time betwixt gathering the crops, and sowing the next succeeding seed, would be abundantly sufficient for any preparation it might require; for it is a well known fact among husbandmen, that when land is well tilled, and kept in good order, one ploughing will go much further than three where the land has been neglected, is rough, and grown hard and cloddy, through inattention or laziness." *Museum Rusticum*, vol. III. p. 3.

"A wet harvest, says an old husbandman, is what a farmer dreads more than almost any thing, as it hurts the quality of his corn, increases his expences, and greatly lessens his profits.

"So much depends on the well getting-in of our bread-corn, that every man, who knows any thing, that can forward so good a purpose, is, I think, in duty bound to communicate it for the benefit of the public.

"It is a well-known maxim that wheat should be left for some days in the field, after it is cut, before it is inched: this, the farmers think, and not without reason, improves its quality; the dews plump the kernels, and the sun brings it to a proper and perfect state of maturity.

"These then are the benefits that result from leaving the sheaves some time abroad; but it is necessary the weather should be fine, or great losses are often the consequence of this practice.

"Sometimes, when the farmer least expects it, the weather sets in foul, and it rains for several weeks successively: it is then very difficult to preserve the wheat from being greatly damaged, notwithstanding the many contrivances that have been thought of for this purpose.

"Some shock their sheaves, setting them up in thraves of six sheaves of a side and two to cap them; but this is a very dangerous method, and never to be practised after much rain has fallen: if the sheaves were dry when the thraves were set up, from an expectation of its raining, it is of great service; but if the sheaves are first suffered to be wet, ten to one but the corn sweats, sprouts, and rots, by being so close confined from the action of the air.

"After all, I am apt to think that it is full as well not to cap the shocks; for if the rain is not very heavy and constant indeed, the ears, provided they do not touch the ground, will dry nearly as fast as they are wetted.

"In Middlesex, Kent, and some parts of Essex, they generally bind their wheat as they reap; but then it must be supposed that their crops are, for the most part, pretty clear from green weeds, which would otherwise cause the sheaves to sweat violently in the mow, and greatly damage the corn.

"When a farmer is so unfortunate as to have his wheat sheaves thoroughly wetted, if fine weather ensues, I would by all means advise him to unbind them, and afterwards spread them out to be dried by the sun. This simple method will often prevent great losses, and the wheat may at last be got in, in tolerable good order.

"If the rain, however, should continue long, and there should be danger of the kernels growing, which by observation he may easily judge of, I would advise the thinking farmer instantly to carry it home, wet as it is, and afterwards manage it as I shall direct from my own frequent experience.

"When the waggon, or cart, comes home loaded with sheaves, let them be thrown promiscuously into the bay of the barn, and not regularly moved; for it is necessary they should lie hollow, that the air may get into the vacuities, and prevent the sheaves from heating during the little time they are to continue in the situation above described.

"Let our farmer next prepare some cutting-boxes, such as horse meat is cut in, in Kent, and some other counties. The number of these boxes should be according to the quantity of wheat he has wet; but three or four constantly kept going will do a great deal of work.

"With these cutters, let the ears be cut off from the wet sheaves; and when a sufficient quantity is collected from all the boxes, let them be put loosely up in sacks, and carried to a malt-kiln, there to be regularly and gradually dried; and when the first parcel is done, another is to succeed, and so on till the whole work is completed.

"This method I can from my own experience recommend to your readers; and it is less expence than would at first thought be imagined. The heat of the kiln may be kept up higher than when malt is drying, as the chaff of the ear will prevent the kernel of the wheat from being damaged by the fire, unless the heat is very intense indeed: but it will, however, be proper to keep the ears gently stirred with a fork, or rake, during the time they are drying.

"In this management the farmer will find great advantages; and his wheat will, with a very inconsiderable additional expence, be nearly, and sometimes quite as good in a wet harvest, as if it was housed in ever so good order, in fine sun-shining weather.

"If, by chance, after you have cut off the ears from the sheaves, the weather should change and become fine, you may often dry them without the assistance of the kiln, by spreading them thin on a large threshing-cloth, and turning them frequently with a wooden rake; and even, if by this method you should not entirely dry them, it will still bring them so forward that the kiln will easily complete the cure.

"I must, however, before I conclude, caution the farmer not to suffer the kiln to be much heated, unless the ears are kept constantly stirring during the time they are drying." *Museum Rusticum*, vol. II. p. 106.

"Give me leave, says a practical farmer in Warwickshire, to mention to you a practice which, however, I do not absolutely recommend, though with me it succeeded, and, as I have been informed, has done so with several other farmers who have ventured to make the experiment.

"A few years ago, after what I thought a good fallow, I sowed a field containing five acres, with wheat. The soil was a good loam, but rather light than stiff, and inclined to be stony. The wheat-plants looked healthy during the whole winter and promised fair to yield me a plentiful crop; but in the spring, warm rains coming on, brought such store of weeds, that my wheat was in danger of being choked.

"I was for some time puzzled what to do; for it being now the latter end of May, and the wheat being on the spindle, and some even in the ear, to weed it with hooks would have been endless, not to mention the damage that would have been done to the plants by the weeders feet.

"I had at one time thoughts of mowing wheat and weeds all together, and drying them to make fodder for my cattle: intending, if I had done this, to have got the land as fast as possible in order, and sown it again with wheat the succeeding autumn.

"However, in looking over the field, I found no great deficiency of wheat plants; but they were in most places so over-topped by the weeds, as to be scarcely visible, and in the furrows, in particular, not a blade of wheat was to be seen.

" My method of ploughing for wheat seed in this land is, to make narrow fitches, but wider than a ridge, and more rounding, being not so sharp on the back.

" Whilst I was meditating what to do in this matter, a gap was by some accident made in the hedge, and a parcel of my sheep got into the wheat field.

" As soon as I saw where they were, apprehending great damage, I ordered them to be immediately driven out, and the gap mended.

" On taking a survey, I was not a little surprised to find that the sheep, instead of doing any damage to the wheat, had done it great deal of good, for they had eat up almost every weed which grew in that part of the field next to the pasture.

" Encouraged by this accidental discovery of a propensity in sheep to eat weeds rather than wheat, I turned a hundred of my flock into the field, two or three hours in the morning and the evening, for several days together, till all the weeds were nearly consumed.

" On inspecting my field afterwards, I found the sheep had done very inconsiderable damage to the wheat, but the weeds were eat down so close that they could never again get a-head; the wheat going on prosperously, and yielding me at harvest a plentiful crop of clean, good corn, which was more than any of my neighbours could that year boast of.

" Whilst the sheep were eating the weeds, I found they mostly walked in the furrows, as being easier to their tread than the sloping sides of the narrow fitches; and this might be one reason of their doing the wheat so little damage by their treading.

" In this new method of husbandry I took, however, one precaution, which I am apt to think greatly contributed to my success.

" The precaution I mean is, that I never let them lie in the field at night, as the weight of their bodies when they lay down to sleep could not have failed doing great damage to the plants." *Museum Rusticum*, vol. III. p. 31.

" Permit me, says another experienced farmer, to communicate to your readers, for their benefit, I hope, a little of the experience I have in many years acquired.

" Being now grown old, and retired to spend the remainder of my days in this city, I trouble myself but little about the practical part of farming; yet did I some years ago occupy a considerable tract of ground in Norfolk.

" I shall, for this time, confine myself to the propriety and impropriety of feeding wheat down with sheep in the spring; a practice which has by many been hitherto but little understood.

" This practice, when prudently adopted, is replete with many and great advantages; but if indiscriminately adopted, nothing would sooner ruin a farmer.

" The advantages to be derived from it are, that it affords feed for your wethers and ewes after the turneps are consumed, and before the spring feed comes in; it causes the wheat to tiller and branch more than it would otherwise have done, and of course produce a larger and better crop; it brings, by the rich manure it affords the land, the crop forward, and makes it heavier in the scale, as well as plumper in the bushel.

" The disadvantages attending this practice are, that, in certain circumstances, it checks the growth of the corn, and makes the second shoot diminutive and small; of course the ears are lean and poor, and the crop in proportion. It gives the weeds an opportunity of getting a-head, and ruining the crop, to the farmer's great loss and disappointment.

" I shall, to be better understood, relate some cases which happened to myself, as I find them noted in my journal, for I always kept one.

" In the year 1742, I had ten acres of wheat, which after Christmas, seemed proud. The soil was a loose loam, and I had, when I fallowed, laid on plenty of dung.

" I turned into this field a parcel of sheep on the twenty-second of January, in order to feed it down, which they did; but the weather coming in milder than I expected, the weeds which had been brought in with the dung, got such a head, that I was above twenty pounds loser by feeding it.

" In 1744, I fed, very indiscreetly indeed, another piece of wheat of fifteen acres. The land was poor, and had not been well dressed, so that about the 10th of March, the

wheat plant stood very thin. I turned in some sheep, thinking it would afterwards branch more, and produce a better crop; but I was disappointed, for the sheep bit off the knot of the plant, and I had, I think, the worst crop I ever reaped.

" The next year, 1745, I had another thin crop of wheat on much the same land as the last: I turned in some sheep the 6th of February, before the knot was above the ground within reach, and it succeeded; for, as I gave it a good top-dressing within a fortnight, it tillered and branched so well, as to produce a much better crop than I expected.

" I could relate to you many other circumstances of this nature, but it would take up too much room; I shall therefore proceed to make some observations on my general experience in this matter.

" I find wheat should never have any sheep turned on it, unless it is forward in January, and likely to be lodged at harvest, except now and then, with great precaution, when you want to thicken a crop.

" Such wheat only should be fed down as was as early sown: and I hold it a bad practice if the land is rich with dung.

" Wheat should not be fed down, unless the land is pretty clear of weeds, and has strength and substance enough to afford the wheat nourishment in plenty, that it may get in-to ear at the proper season, notwithstanding the growth was so checked.

" There is in every plant of wheat a certain knot, or crown of the root, as I call it, from which all the branches issue; now if this crown is nipped off by the sheep, a dwindled production is the certain consequence; for this reason, sheep should never, (unless it is in a very backward season, and then it will not be prudent to feed wheat down at all); I say sheep should never be turned on it after the middle of February: the best time in general, is the latter end of January, or even the middle of that month.

" If seasonable rains follow, provided the ground is clear of weeds, it will be greatly to the advantage of the farmer.

" If the farmer has the least doubt of the strength of his land, towards giving the checked plant nourishment, I would by all means have him afford his wheat a top-dressing of foot, ashes, malt-dust, or whatever other proper manure he may have at hand, provided he is sure it is quite clear of weeds.

" Let not the industrious farmer be at all uneasy if, after feeding down his wheat, he perceives the plants stand at a distance one from the other; for if he has practised this piece of husbandry, with the precautions above noted, he may depend upon it, that every plant will throw out a number of branches, and that he will have a field full of stalks at harvest, and a crop that will surprise him.

" I am very fond of recommending wheat crops to the farmer's attention, not only because it is the most noble of grains, but also because, if well managed, it is the most profitable.

" We must not always judge the farmer's profits by the produce of his land; which some of our readers may think odd; but I will make it appear by an example from my own practice.

" In the year 1743, I had two fields of twenty acres each, in wheat; one of which yielded me, at harvest, at the rate of four quarters an acre throughout; the other yielded me only twenty bushels, one acre with another; yet I got more by the last than the first. The case was thus; falling short of dung, I was obliged to buy; but it was so dear, that I only bought enough for the first field, giving the other two ploughings extraordinary, instead of manuring it; and these ploughings I reckon at a mere trifle, as my horses would otherwise have stood still." *Museum Rusticum*, vol. III. p. 151.

" I have often thought that it would be of great service to the public, if, by any method there could be determined a mean weight for any given quantity of corn, and likewise what number of grains, upon an average, ought to be contained in each ear, and the proportional weight between the ear, with the grains in it, and when taken out; and likewise the proportional difference between the weight of the whole stalk, including the ear and the grain.

" But in order to settle this medium, under our present consideration, it will be absolutely necessary, in the first place, to make accurate and impartial experiments for a number of years, and then, by comparing the produce and

and the weight, &c. of the whole, both separately and together, we may come pretty near the mark in view:

"In order therefore to pursue the plan I had laid down, in the beginning of the harvest of the year 1757, I got three acres of common red Lammas wheat out of ——— field, August 26th. I then cut of the stalk close to the ear, which I weighed with the corn in it: I then weighed the grains when rubbed out of the ear, and cleared from the chaff: in the next place I compared the difference, and then counted the number of grains in each ear respectively; and at the end of every year set down the weight of a cubical inch of the product of that harvest.

"But in order to give a clearer idea of my method of proceeding, I will set down the weight, &c. of the corn which was gathered from the first field, in columns, in the manner I entered it in a book kept for that purpose, which will be sufficient to explain the whole without a multiplicity of figures.

Numbers of ears, when and where got.	Weight of the ear with the corn in it.	Weight of the grain when free from the chaff.	Difference.	No. of grains in each ear.
1757.	3 3 gr.	3 3 gr.	3 3 gr.	
Three ears got in ——— field,	1 0 1 5 0 0 19	5 0 0 19	5 0 0 5 5	28
August 26.	2 0 1 2 0 0 17	5 0 0 17	5 0 0 4 5	27
	3 0 1 7 0 1 1	0 0 6		36
Total.	1 0 14 0 2 18	0 0 16		91

"I proceeded in the same method with each of the three ears taken out of fourteen other different fields, during the time of the same harvest; then casting up the sum total of each column, and dividing their products by the number of ears gathered that season, the quotient would give me the mean weight, &c. of an ear of that harvest, and its number of grains, &c. &c.

"I then made a cubical vessel containing exactly a square inch; and having mixed all the corn together, I filled the above vessel, and weighed its contents with the greatest accuracy; which weight I set down, repeating the operation seven or eight times, having well mixed the little heap of corn together, after each trial, and then set down the weight of each as before: and as there would sometimes be the difference of a grain or two more or less in each cubical inch, I divided the product of the whole by the number of times the experiment was made, and set down the quotient as the mean weight of a cubical inch of corn for that year, which in 1757 I found to be 3 dr. 12.3 gr. I have persevered in this method every year since: but to avoid troubling you with the particulars of each, I will give you at one view the mean weight, &c. the number of grains in an ear, and the weight of a cubical inch for each of these last seven years past, and after that the medium of all taken together.

"I made use of apothecaries weights, upon account of the smaller subdivisions of the ounce into drachms, scruples, and grains, which I have afterwards, in reckoning up the weight of the bushel, reduced to troy, and averdupois. But we will now give the result of the seven years experiments in the following columns."

A. D.	Mean weight of each ear with the corn in it.	Mean wt. of the grains alone.	Difference.	No. of grains.	Mean weight of a cubical inch.
	3 3 gr.	3 3 gr.	3 3 gr.		3 3 gr.
1757	0 1 10 5	0 1 5	0 0 5 5	38	3 0 12 3
1758	0 1 5	0 1 0 5	0 0 4 5	30 4	3 0 13 3
1759	0 1 8 2	0 1 2 4	0 0 5 8	37 6	3 0 14 5
1760	0 1 14	0 1 4 4	0 0 9 6	36 8	3 1 4 3
1761	0 1 9 5	0 1 4 5	0 0 5	36 6	3 1 4 3
1762	0 1 17 4	0 1 8 3	0 0 9 1	36 5	3 0 16 5
1763	0 1 10 1	0 1 3 3	0 0 6 8	35 5	3 0 17
Total	3 1 14 7	2 2 8 4	0 2 6 4	251 4	23 0 2 2
Mean wt.	0 1 10 67	0 1 4 5	0 0 6 62	35 9	3 0 17 457

The total divided by seven gives the mean weight, &c. &c. of the whole together, as in the preceding line.

"The first of the above columns (the date of the year not being reckoned) shews us, at one view, what we may

expect a single ear of Lammas wheat, separated from the stalk, to weigh upon an average; and the second what its produce in grain should weigh when separated from the chaff: the next division gives the difference, being the weight of the ear and chaff alone without the grain; the fourth, the number of grains in each ear; and the last, the weight of a cubical inch; which latter we shall further consider, and see what will be the mean weight of a bushel, omitting the odd grains and decimal parts, as immaterial in so large a measure.

"As the standard Winchester bushel contains 2150.4 cubical inches, if the above weight of one, viz. 3 3 17.457 gr. be multiplied by that sum, the product will be 73lb. 8 oz. 12 dwt. troy. But this standard bushel is in fact too small, the real contents of a bushel dry measure being 2178 cubical inches, which, according to that calculation, will give 74lb. 7 oz. 19 dwt. which sums reduced to averdupois weight will stand as follows:

Troy { 73 8 12 } equal to { 60 10 8 6 } averdupois.
 { 74 7 19 } { 61 6 15 9 }

"But it will be proper to take notice that none of this corn was weighed till thoroughly dry, and seldom till the harvest after it was got, and sometimes later; therefore there must be some allowance made for the loss of weight by keeping: which I found upon trial to be about four grains yearly in a cubical inch, and considerably more the first year, especially if the corn happened to be got in a wet harvest: therefore I think we may fairly estimate the mean weight of a bushel of wheat, containing 2178 inches, to be about 62 lb. avoirdupois weight.

"I know that a bushel of good wheat is, by the generality of writers upon agriculture, calculated at about 64 lb.; but our present enquiry is not whether it is good or bad, light or heavy of its kind; but what is the medium betwixt the two extremes, in order the better to judge of its qualities, according as it falls short of, or exceeds, that determined weight.

"The fields out of which the corn was gathered for the above experiments, are mostly situated within a circle of ten or twelve miles round the town of Warwick, and some of them in Northamptonshire; and in soils of different kinds, and such as have been productive of good, bad, and indifferent crops.

"With regard to the observations, which I now offer to the public, they may be assured that they have been made with the greatest accuracy, and, barring any errors in the calculations, without the least deviation from the truth.

"My method of gathering the ears of corn was, to crop them standing during the time of harvest, always endeavouring, as near as I could guess, to take such as were of a middling growth, avoiding the fullest ears, as well as those which were shrivelled or flinted. I therefore generally got them from about the middle space between the ridge and the furrow; I then carefully wrapt up the produce of each field in separate papers, to prevent the corn from shedding, or intermixing.

"The column which shews the difference between the weight of the ear with the corn in it, and that of the grains alone, is meant only as relative to the ear itself, without the stalk added to it, which latter was always separated from it. But I have since made some few experiments with regard to the proportional weight between the whole stalk and ear, and its produce in grain; and I found the former to be to the latter as about sixty-seven to seventy-two. But I cannot depend so much upon the justness of this calculation as of the others, it being only tried upon the produce of one harvest.

"It must be observed that the weight of corn will vary more or less by keeping, according to the nature of the grain itself, the seasons that it has had for its growth and maturity, and the dryness or moisture of it when reaped: for notwithstanding, it was before observed, that there may be an annual loss of about four grains in every cubical inch upon an average, yet it may so happen that the weight of it may even be increased by keeping, as was really the case with regard to the corn which was got in the harvest of the year 1762, after an excessive dry summer; for I found, upon weighing a cubical inch of the same corn, a year after the first trial, that it had actually increased in weight 2.6 grains, which I can by no means account for, but upon a supposition that the corn contained

ed in the ear, having been so thoroughly dried, whilst standing by the preceding heats and great drought, there was no room for any further evaporation of aqueous particles; but that, on the contrary, being laid up in this extreme state of dryness, it must even imbibe moisture afterwards, from the coolness of the place where it was reposit- ed; by which means the grain would become more plump than when fresh gathered, and would consequently increase in weight. From hence the reason is very obvious, why corn that is thoroughly ripe, and well inned, will under- go a much less change by keeping, than that which has been plumped up by preceding rains, though perhaps it may be laid down as a rule, that the more the external coat of the grain is extended by redundant moisture from within, the more will it appear shrivelled and wrinkled, whenever that moisture is evaporated, which it must lose upon being kept for any considerable time in a dry place: therefore it will be most to the advantage of the owner to have such corn spent as soon as it is sufficiently dry for common use, and not to hoard it too long in the granary, as the heap from the above mentioned cause will be daily decreasing.

"If further experiments of this kind were to be tried in other parts of this kingdom, and even in different cli- mates; and if the result of each observation was to be compared with the others, we might probably come still nearer to the medium which we have been aiming at; and the same trials might be made with any sort of grain." *Museum Rusticum, vol. II. p. 175.*

"The experiments made by the above ingenious gen- tleman are very accurate, though, in my opinion, much too small to determine matters of such importance: but he has, I think, fallen into a mistake that I also did in trying some experiments upon wheat, viz. in supposing that a middling ear is a standard for computing the crop. This, indeed would be the right rule, provided there was a regu- lar gradation in the ears above and below the middle size: but, in fact, it is otherwise; there are generally more small ears than large ones, and yet the corn in the large ears may weigh most.

"To explain this, let us suppose a person going to choose some middling ears as they stand in the field: he must do this either guessing by his eye, or by measuring some of the different sizes, and taking those of the middle size as near as he can. The sizes can only be determined by their length and fullness: and if, for example, the longest are five inches, and the shortest one, the medium is three inches. Now, though those of three inches are undoubt- edly the middle size, yet, unless the weight and measure of the corn in the ears below three inches are equal to that of the ears above that size, the calculation of the crop from the three-inch ears will be wrong. This will be seen in the following tables.

"I once took an account of great part of a sheaf of red Lammas-wheat; but having mislaid my notes of it, I shall at present take notice chiefly of an experiment made upon white Lammas wheat, of the crop of 1762. The ears and straw of this crop were in general very short; but the corn was remarkably fine, full, and heavy. The wheat of this experiment was raised upon clover lay, and the crop about twenty bushels upon an acre. A nine gal- lon bushel of this wheat weighed above seventy pounds averdupoise, which is usually reckoned the full weight of good wheat, though some will weigh more, as the best generally did that year.

"In February 1763, I took some of this corn out of a middling sheaf, and, as near as I could, of the middle- sized corn: but it was taken out all together, and with- out separating of it. I sorted what was thus taken out, into four parcels, nearly according to the length of the straw, in order to discover the proportion between the ears and straw of different lengths; but there seems to be little certainty in this.

"These four parcels were weighed separately, ears and straw together; then the ears by themselves; and, last of all, the corn when separated from the chaff.

I weighed twenty of the first parcel by themselves that had the longest straw, and longest and fullest ears: and afterwards weighed them singly, taking the weight and measure of each, as in the table.

"Being desirous to know the weight and produce of the ears of different lengths, I sorted each parcel according to the length of the ears, differing one from another about half an inch; and I weighed these subdivisions separately, noting the length of the ears, and the number of chests and grains in each. The length of the ears was measured from the bottom of the lowest chest that had any corn in it, to the top of the ear. The longest ear was three inches and a half, but there being only one of that length, it is included among those of three inches and a quarter. The twenty ears first weighed are included in the sixty-three large ears in this last weighing.

"Several ears have some very small grains in them: these are set down in the table, but not reckoned in the weight, because I supposed them not marketable, and that they would go to the tailing, or off-fall corn. Of these small grains two thousand one hundred and eighty-seven weighed an ounce averdupoise. The rest were weighed by troy weight, as below.

The weight of the four parcels.

		oz.	dw.	gr.
250 of the longest (the straw 28 to 36 inch)		18	18	4
500 of the second size	24 to 32	26	17	10

333.684 = 34.2 grains in each ear upon a medium.

"In the first of the following tables are inserted the assortments of the four parcels, by the length of the ears, with the number of chests and grains in each, and the se- parate weight of the ears, grain, and chaff. I must ob- serve, that by accident I missed taking the distinct weight of the two hundred and fifty smallest ears: they are set down in the table as I computed them, in proportion to the third, or preceding parcel, which may differ a little from the real weight; but this cannot be much, for the weight of the whole parcel is right.

"In the second table, the length, weight, &c. of the twenty largest ears, are set down in the first line: in the second line are the sixty-three large ears, including these twenty: and the third line contains the two hundred and eighty-eight smallest ears. They are set thus together to give the more easy comparative view of them. The next three lines of this table shew the weight, &c. of all the middle-sized ears, and of all those above and below the middle-size, brought thus together also by way of compa- rison. To these I have added, in the following columns, a calculation of the number of chests in each assortment of ears, and the mean number of grains in each chest; also, the number of grains, and weight of a mean ear, of each assortment.

"The last table shews the total weight of the corn, chaff, and straw, upon an acre, agreeable to this experiment, reckoning the crop at twenty bushels of nine gallons, or seventy pounds, averdupoise per bushel.

"The very small grains are not reckoned here, for the above reasons; and that the waste, in reaping, carrying, threshing, and some left in the straw, is more than they amount to. But by adding them, and allowing for about seven or eight inches long of stubble, the total weight of the crop may be nearly estimated.

A table of the length, weight, &c. of one thousand two hundred and fifty ears, sorted according to their length.

"Small experiments are not so satisfactory as large ones; and I could wish this had been more extensive, but I had no thoughts of offering it to the public view till I read your correspondent's letter, who has, I apprehend, gone upon a wrong rule in computing a crop, and has also chosen the mean ears too large: for though the ears of red Lammas wheat are usually longer than the white, it cannot be supposed that, upon an average, they are above double, both in weight and number of grains, as we find those were to the mean ears of this experiment. Neither is it at all probable, that the mean ears of the common crops in any part of England, and in the same year, should be heavier, and contain more grains in them than the very largest ears of this experiment.

"The ears of this wheat being from three and a quarter to three quarters of an inch in length, the medium is two inches. I have ranged all these together in the second table. They are a fair medium in regard to length; and they are so also as to the fulness, because they are all included: but, as appears in the table, they are not so in respect to the weight of the grain, which is the rule for the medium of the crop; for the small ears are more than double the number of the large ones, and yet the large ears are the heaviest. If, in order to make the number of ears equal, we choose the mean ears shorter than two inches, the inequality of weight will be greater than before; and if we take our medium higher than two inches, the weight may be made equal, but this will increase the disproportion in the number: and hence I think it is evident, that we cannot fix upon any size of ears that will

give us a just medium of the crop. The same will happen in other crops, for they all vary one from another in the size and number of ears: and, as we cannot be certain of their real proportion as they stand in the field, it is impracticable to calculate a crop from those of any size.

"The calculation of a crop from a mean ear is made by multiplying the weight of grain in that ear by the number of ears upon an acre. A mean ear of this experiment weighed, as in the table, 10.232 grains troy, and the crop was about twenty bushels upon an acre. Your correspondent reckons the weight of the mean ear at 24.05 grains troy, upon an average of seven years; so that, reckoning the same number of ears upon an acre as in this experiment, his crops will amount annually to forty-seven bushels per acre, of seventy pounds, averdupoise, per bushel. These are such crops, as I suppose, no considerable extent of contiguous lands in England produce annually; and are, doubtless, more than double the common crops upon an average.

"The disproportion in the number of small and large ears is very remarkable, and also their disproportion in size: for, if we calculate from the twenty largest, we shall find that forty-three of them weighed as much as all the two hundred and eighty-eight small ones, viz. one large ear produced as much corn as seven small ones, and the grain in them also larger, and consequently more flour in them: for one hundred of the large ears weighed seventy-eight grains troy, and one hundred of the small but sixty grains; so that four grains of the large ears were heavier

heavier than five of the small. This great difference is not from any defect in the rudiments of these small ears, but is occasioned principally from bad culture, and a defective nourishment; because we see that the plants raised from the same seed will have larger or smaller ears, according as they are cultivated. It might, however, be useful to know at what period of their growth those small ears are stunted, and whether they are produced from the original plant, or from the tillers. I am not furnished with experiments to determine these points, but recommend them to the enquiry of your readers.

"It is certain that the ears of wheat, in general, do not arrive to the size that they are naturally capable of: and if it was known at what period they are formed, the stunting of them might, in some degree, be prevented by a dressing, or other culture, at that period. That there is some such period in nature may appear from other circumstances in the growth of this plant. There is a particular season for its tillering, or spreading; another for its upright growth; and one for its blossoming and forming the seed; and probably one also for the ear being formed: and the growth of it, in respect to each of these, may be promoted by culture, or retarded by a defect of nourishment, at these periods.

"When the season of tillering is past, no culture will make this plant throw out more branches; and after the ear is shot out, it is then impracticable to make it larger, viz. to increase the number of chests. Again, when it has blossomed, no art will cause the stem to rise higher. And, last of all, after the time of blossoming, there is no adding of one grain more than is already formed in the ear; though, in all these cases, an addition, or improvement, may be made by culture, if applied at the proper time.

"It is therefore of importance to know the periods of growth of the different parts of the plant, and that if we happen to miss assisting of it in one, we may improve it in another. If the season is lost to increase the number of tillers, we may enlarge the ears: or if that is also omitted, we may increase the number of grains in the ears, and make them larger and fuller of flour.

"To shew this more plainly, with respect to the grain, let us a little consider the structure of an ear of wheat. The grain is placed in a cell, consisting of two valves or leaves; and there is one leaf extraordinary on each outside of the chests, which seems intended as a fence or security against accidents to the outward grains. The chests about the middle of the ear are the largest, and usually consists of four, five, and sometimes six or seven cells: and the number of cells decreases towards the top and bottom of the ear. If the ear is examined when in blossom, we may see what number of grains each chest is formed to produce: or this may be seen afterwards by the number of double valves, which are properly the chaff; for these remain though the grains have proved abortive, and therefore by counting the leaves of chaff, allowing two to each grain, and two extraordinary to each chest, we shall find what number of grains each chest might have produced.

"The outward grains of the chests are commonly the largest, and smaller towards the middle, and often stunted grains, or none at all, in the middle cells; and this, notwithstanding most of these had blossoms in them, and the grains had made some progress, or begun forming. They are later than the outside grains, as if last impregnated.

"The number of these deficient, or missing grains, is greater than might be supposed without examining them. In a favourable season most of the cells have grains in them; and, if examined at the time of blossoming, the grains may be seen in different degrees of maturity; many of them, with the naked eye, and others with a good glass; but though they appear then in general to be fresh and in a growing state, a considerable number of them is afterwards stunted, or die away entirely. In an ear of red Lammas wheat, of six inches long, twenty-five chests, and two hundred and eighty-six leaves of chaff, I have counted seventy-four grains some time after blossoming; by which it appears, that this ear might have produced one hundred and eighteen grains; and yet at harvest I have not commonly found above sixty grains in an ear of that length. I have likewise this season counted fifty-four grains in an ear of white Lammas wheat, of three inches and a quarter long, nineteen chests, and one hundred and

seventy-four leaves of chaff; so that this ear might have yielded sixty-eight grains: but we see in the above tables that the fullest ear, of the same sort of wheat, and the same length, yielded only forty-one grains; and three of the same length yielded but thirty-eight grains and one third each, upon an average.

"The tillage and dressing of land for wheat is done for the most part, before the wheat is sown, and the benefit of these gradually decrease; whereas the wheat requires a gradual increase of nourishment, both in order to form large ears, and afterwards to fill them with large grain. And hence appears the great defect of the common husbandry, and points out the advantages of top-dressing wheat in the spring with foot, or other light manure, which brings the plants a fresh supply of nourishment when they want it most; and hoeing, when it can be performed at the proper times, particularly the deep, or horse-hoeing, has the same effect of producing large ears; and for filling them, the horse-hoeing is the most effectual, as that can be performed at the critical time, and when the plants are large.

"It has been commonly supposed, by those who practise the New Husbandry, that the most important hoeing for the purpose of filling the ears with good grain, is soon after the wheat has blossomed: but this, I believe, is a mistake, and that it should be performed immediately before the wheat blows; for before that is over, the grain is considerably advanced. I have found no less than seventy-seven grains in an ear of red Lammas wheat, of four inches and three quarters long, and at the same time a considerable part of the blossoms still remaining on the outside of the ear.

"This is above one third more than usually comes to maturity in an ear of that length; so that it seems very probable the ears would produce near one third more corn than they commonly do, were they to be assisted at that time with sufficient nourishment. But this would come too late after the blossoming is over; for by that time, some of the weak grains die, and others are stunted, so as not to be recovered again by any future hoeings. A check at this critical time seems to have the same effect as it has upon a grain of corn, or other seed, after it has begun to vegetate: if that is put a stop to, it never recovers.

"From the great number of small ears in a crop, and the deficient grains in all the ears, we may plainly see the advantage of good culture, and of taking the proper seasons to apply it. The New Husbandry is, in this respect, much to be preferred; and also because much fewer plants will produce an equal crop; in which there are several advantages, besides saving above half the seed. This method of culture is, indeed, so much superior to the common husbandry, not only in raising wheat, but plants of almost every kind, that it is to be wished it was more promoted.

"I am sensible that several gentlemen have objections to this husbandry, arising partly from a misinformation of Mr. Tull's practice and success, and partly from the difficulty they apprehend in overcoming the prejudices of the farmers to any new methods.

"That they are very tenacious of old customs, is readily admitted, nor are they to be too much blamed on that account: but that they cannot be prevailed with to alter them, upon rational evidence, and proper encouragement, is, it is apprehended, carrying the argument too far, as this tends to discourage all attempts of improvement.

"One of the reasons assigned, why the farmers cannot be brought to practise the New Husbandry, is the difficulty of managing a drill-plough for sowing corn, which is admitted, though that is not so great as some have supposed; for I have seen a husbandman learn to manage such an instrument, who, after one day's practice, could sow with it four or five acres a day, with the proper quantity of seed, at a less expence than common sowing and harrowing.

"Some have objected farther, that the farmers cannot practise this husbandry, because they are ignorant of its principles: but these principles are not many, nor hard to be understood, so far, at least, as relates to practice; and in fact, the practice of the New Husbandry is easier than the old, because it is founded upon clear principles, which often is not the case in the old husbandry.

"It seems that several gentlemen are not for introducing

eing this new method, because they are not convinced that it is, upon the whole, better than the old. If we may credit those who have gone furthest in the practice of the New Husbandry, those gentlemen abroad in particular, who have published their experiments, there seems to be no doubt of its superiority: but as it is a matter of great importance that this fact should be fully established to the satisfaction of all gentlemen, from whose influence and example the most valuable improvements are to be expected, the trial is not difficult, nor very expensive: a small farm, with some variety of soils in it, cultivated in the several methods by way of comparison, and exact accounts kept of the expence and produce of each, would determine this point without any reasonable doubt.

"In matters of this sort, speculations and reasonings are not to be relied on without experiments; and the larger they are, they will be the more convincing. Whether something, like what is here proposed, might not have the desired effect, and likewise be a means of making useful discoveries in vegetation and the culture of plants, is submitted to the consideration of those who have at heart the improvement of agriculture.

"A more extensive plan is necessary for introducing new methods into common practice, and which might comprehend the farmers, and also the husbandmen, who execute and excel in the performance. It is recommended to your readers to consider and propose what they think the most probable means for attaining these desirable ends." *Museum Rusticum*, vol. III. p. 38.

"It is certain, says another ingenious husbandman, that many strange reports were raised of Mr. Tull, and his husbandry, by prejudiced persons; and his book being printed for the author, some booksellers were much offended, and employed several hands to write against him, which they did in a most scurrilous manner, asserting many things that were false, and misrepresenting others. Some of these he takes notice of himself, in the additional parts of his work. I shall mention only one instance how ready people were to give credit to such false reports. "Last summer," says he, "the vulgar in general believed, in a country but twelve miles distant from me, that I always carried my dung and threw it into a river: now there is no river nearer to the barton where my dung is made, than is the farthest part of my land; so that the expence of losing my dung would be greater than spreading it on any part of my farm. Besides, I live in a country where farmers buy dung at a good price; but it is known that I neither sell nor waste any dung. Against such lying tongues there is no defence."

"But a principal cause, that the reports of his bad success in his wheat crops have gained so much credit, I believe, is, that the additions to his Essay are out of print, and not generally known; and it is chiefly with a view to inform your readers of them that I write this letter.

"Mr. Tull began his scheme of successive wheat crops with four rows. Afterwards he found that three rows were better, and was in that practice, of drilling three rows upon a ridge, when he published his Essay. Upon further experience he found, that two rows produced as good crops as three or four, and were more easily managed. This he recommends as his last and best method; and altered his drill-plough to his practice of planting only two rows upon a ridge, of which he gives a cut and description in his Addenda and Conclusion. By this alteration, his drill is much less complicated, and less difficult to manage, than that for planting three rows, described in his Essay.

"The gentlemen abroad, who are now promoting the New Husbandry, have gone into the practice of planting three rows upon every ridge, supposing that to be the best method; and the drill-ploughs invented by M. Duhamel, and M. de Chateaucieux, are constructed to sow three rows.

"From the practice of the gentlemen abroad, and other instances that might be given at home, it is evident, that they had not seen the additions that Mr. Tull made to his Essay, in which, besides his different method of drilling, there are several very material improvements in the manner of hoeing and cultivating wheat, and other crops; and from these last parts of his work may be also seen, that the reports of his bad success, in repeated wheat crops, are without any just foundation.

"In order to shew this more clearly, it may be proper to premise a short chronology of the progress of his husbandry, collected from his own account of it; in which it

is to be observed, that as the year, at that time, was by some reckoned to commence the first of January, and by others the twenty-fifth of March, and the crops at other periods, it occasions an uncertainty of sometimes a year of this account.

Mr. Tull began his horse-hoeing husbandry about
the year — — — 1723
his successive horse-hoed wheat crops 1726

He published his Specimen — — — 1731
his essay — — — 1733
his Supplement to the Essay — — — 1735
his Addenda — — — 1737 or 1738
His conclusion is dated March 31, — — — 1739
(All these are printed in small folio.)

He died about the year 1741.

"As to his practice of raising successive crops of wheat, he made the experiment first upon part of a field, which had not been dunged for some time, and upon this part he continued to raise wheat for twelve years, without the assistance of any manure. In the Preface to his Essay, he says, "The particular scheme of raising annual crops of wheat, without dung or fallow, is as yet only upon probation; but by the six crops I have had in that manner, I see nothing against their being continued." In the Supplement, page 249, he tells us, "There is now the eleventh crop of wheat on the same field, (except that in the ninth year, by accident, of having contracted to let my farm, it was drilled with white oats) and I do not yet see any reason against its being continued for wheat annually, as long as it is kept in this culture." In the Addenda, page 261, "The field which last year had the eleventh crop of wheat," (as in page 249) "has now the twelfth on it, very likely to be a good one." And in the conclusion, he says, that the twelfth crop of wheat, upon this field, "was the best, I believe, that ever grew on it. It is now the thirteenth crop, likely to be very good, though the land was not ploughed crossways;" which he mentions it was the year before, in order to alter the size of the ridges.

"I have here collected what he says of this field in particular, as it was his field of experiment, upon which he had raised the most crops of wheat, without any manure. Let us next see what crops he had upon his lands in general.

"He begins his Addenda with acquainting the reader that he was desired to take an exact account of the crop of an acre of horse-hoed wheat, part of a field of twenty-five acres, in order to see the difference between that and the crop of a small piece of ground, drilled upon the level, and hand-hoed. This acre being measured, and the crop reaped, and threshed by itself, yielded twenty-nine bushels and three pecks of clean wheat, nine gallon measure. But he observes that great waste was made by the reapers of this acre; and some damage was done to the corn by cattle; for which allowance being made, he reckons the real produce of this acre to have been thirty-two bushels, or four quarters of wheat.

"He then proceeds to give an account of the crops of wheat upon his other fields, which, including the above-mentioned field, were in all one hundred and six acres. The corn was not threshed when he wrote this; but it appears by his account of the crop, as I have computed it, that these one hundred and six acres produced, upon an average, nearly twenty bushels of wheat per acre.

"If the quality of this land is considered, none of it rich, and the greater part light, and of a thin staple, this cannot be called a bad crop. But there was another very important circumstance, which ought to be considered: Mr. Tull was now advanced in years, and in a very bad state of health; was frequently confined to his room, and sometimes to his bed; inasmuch that, as he tells us, he had not seen some of his crops from the time they were sown till the spring following. And in his Supplement he says, page 225, "My agriculture having been carried on by common day-labourers, without any body to inspect them, (except when my diseases suffered me to attend them, which for several years last past has been very seldom) cannot be expected to be all well managed; for though they can do it well when they please, yet their will being above controul, I must be content with their doing some tolerably well every year."

The dust of the master's feet is a kind of manure so necessary in every scheme of husbandry, that no person of experience in such matters; who reflects upon these circumstances, would have reason to be much surprised, if Mr. Tull's crops had really failed as much as has been supposed; and if we also take into the account, that these day-labourers whom he employed, and who had the management of his agriculture at the critical seasons, were then generally, as such men still are, prejudiced against the new husbandry, I think his success, notwithstanding these disadvantages, is a strong argument in favour of this husbandry.

"But let us proceed to what Mr. Tull says further of these successive wheat crops. In the Addenda, page 263, he tells us, "I have now six score acres of wheat, an hundred acres of which are on the stubble of the last year's wheat crop."

And in the Conclusion, p. 273, "The crop of the six score acres of wheat, that was growing at the time of publishing my Addenda, was much greater than the crop the year before it, and would have produced more grain in proportion, if the heavens had been as propitious; but the heavy rains that fell when the first planted was most in blossom, diminished the filling of the ear and its grain, yet not so much as of most sown wheat, especially of the early-sown, which generally escapes the best in this common calamity. The burn-baked wheat, being always early sown, I am informed, had next to no grain in it; and this is the most expensive sort of husbandry, the tenants pay such exorbitant fines for the liberty of ploughing this land."

Again, page 274, "The same six score acres that was wheat the last year, is planted with wheat now, and is all of it as strong and likely for a good crop as in any of the former years, though there is but about one acre of it dunged. The whole is the freest from weeds before hoeing that ever was seen, and the sown wheat in the neighbourhood the fullest of them."

"I can shew, at this instant, one of the experiments I have recommended, which, though it be on less than two perch of ground, must convince every man who sees it (and doth not renounce the evidence of his reason and senses) that pulverization by instruments can vastly exceed the benefit of common manure."

"It is to such experiments that I leave the progress of my horse-hoeing husbandry, assuring the public, that in all my practice, which is now thirteen years, I never have met with one instance that gives me the least suspicion of the truth of the principles I have advanced; and that, I believe, they have nothing to fear from enemies, but the false relation of facts, or fallacious arguments."

"Mr. Tull mentions here, that he intended this to be his last crop. He lived about two years afterwards. Whether he continued to occupy his farm, I am not certain; but if he did, and his crops were worse than the preceding years, that could not be justly attributed to any error in the principles, but to the other causes above mentioned. We see here that he appeals to an experience of thirteen years: nor can it be supposed, or admitted, that a person of Mr. Tull's understanding would go on from year to year to enlarge his plantations of wheat to the extent of one hundred and twenty acres, had he not been fully sensible of the advantage of so doing."

"The repetition of wheat crops upon the same land may, by many persons, be supposed rather a matter of curiosity than of any great use; a change of crops being the general custom, and supposed to be the most profitable: but this is not so clear as some imagine. The custom is founded upon the supposition that change of crops is necessary; which, though it may be true in the old husbandry, is not so in the new: and, without doubt, the change is often hurtful to the farmer; for, not to insist on the extraordinary labour necessary to prepare the land, and the loss of the season, if it cannot be got into proper order in time, or, which is as bad, sowing it, though not in proper tilth to receive the seed, the main point of all is, whether the profit of these several different crops is really more than hoed successive crops of wheat, or other corn commonly propagated? In answer to this, I believe it is not very difficult to shew, by a fair comparison of both, that the hoed crops are the most profitable, even including the clover and turneps in the old husbandry. Nor is a profitable change of the crop, or the advantage of obtaining sometimes three

crops in two years, peculiar to the old husbandry; for the same may be had to greater advantage in the way of hoeing.

"There is another circumstance in the old husbandry, very unfavourable to the farmer. As he is under a necessity of changing his crops, he cannot adapt them to the soil. Most farms have land in them of very different qualities, and these are not equally proper for the production of plants of every kind. The strong land, that is very fit for beans, wheat, and clover, is not equally so for peas, barley, and turneps. But the farmers commonly vary their crops according to the custom of the country; and the consequence is, that most of their lands are planted in their turn with crops not the most suitable to them; which is an inconveniency that may be avoided in the New Husbandry."

"Having pointed out the additional parts of Mr. Tull's work, it is hoped that we shall soon have a new impression; but as it may possibly be some time before the last parts of his work are re-published, I shall, for the benefit of such of your readers as incline to practise the New Husbandry, take notice of one or two important alterations in the horse-hoeing culture."

"In the Essay, Mr. Tull directs, that the hoe-plough should be brought as near as possible to the rows at first, and when the plants are young; but that the subsequent hoeings should be at some distance from the rows, lest the plough should tear off too many of the roots, and destroy the plants; also that the last hoeing should throw the earth of the intervals up to the plants which he thought necessary for their better nourishment, when they were grown large. His last practice was different in both these respects."

"For in the Conclusion, page 272, he says, "At the second hoeing, the plough goes in the furrow of the first, making it deeper and nearer to the wheat: the third hoeing fills up this furrow; and then, at the fourth hoeing, the plough goes in the same place as the second, turning the mould into the intervals. It is remarkable, that though the furrows of the second and fourth hoeings be deep and near to the rows, seeming to deprive the wheat of the mould which should nourish it, whereby one would imagine, that these furrows, lying long open, should weaken or starve it; but it is just the contrary, for it grows the more vigorous: and it is the observation of my ploughmen, that they cannot, at these hoeings, go too near to the rows, unless the plough should tear out the plants."

"If I may presume to assign the cause of this surprising effect, it is, in my opinion, the following, viz. this open furrow has a double surface of earth, which, by the nitre of the contiguous atmosphere, is pulverised to a great degree of minuteness near the row. The roots that the plough cuts off on the perpendicular side of the furrow, send out new fibres to receive the pabulum from this new-made pasture; and also part of this superfine powder is continually falling down into the bottom of the furrow, and there gives a very quick growth to those roots that are next it, and a quick passage through it into the earth of the interval, where they take likewise the benefit of the other side of this pulverised furrow. When it is said that air kills roots, it must not be understood that it kills a plant, unless all, or almost all its root, is exposed to it, as it is not in this case. Some think there are roots that run horizontally below the plough into the interval; but of this I am not convinced."

"It is not often that we plough above four times, and then the furrow is turned towards the row at the third time only."

"Whether these furrows lying long open next the rows, in very hot dry climates, may be prejudicial, cannot be known but by trials."

"The practical hoer will find this method of going close to the rows of wheat and other plants, of great service to him, not only in the vigour of his plants, but also in the more perfect tillage of his land, and a considerable saving in hand-hoeing, weeding, and manure."

"The other circumstance, of a large plant growing more vigorous, and the seed filling better, by ploughing the earth away from one side of it, is so singular, and opposite to the common practice of gardeners, that should it succeed generally, it may lead to something new in the theory of vegetation." *Museum Rusticum*, vol. III. p. 159.

A comparative calculation of expence and profit between the drill and the common husbandry; taken from Mr. Baker's Report to the Dublin Society of his experiments in agriculture, for the year 1765. Published by order of the Society.

An estimate of the expence upon a plantation acre of wheat, in the common husbandry :

	l.	s.	d.
To the first ploughing, commonly called breaking for fallow, eight horses eight shillings; two ploughmen one shilling and four-pence; two drivers one shilling	0	10	4
To the first harrowing, four horses four shillings; a driver six-pence	0	4	6
To the second ploughing, commonly called gau-rowing	0	10	4
To the second harrowing	0	4	6
To the third ploughing, commonly called stretching	0	10	4
To sowing the seed, eight horses eight shillings; two ploughmen one shilling and four-pence; two drivers one shilling; the feed-man eight-pence	0	11	0
To feed wheat, one barrel	1	0	0
To rent for the year of fallow	0	18	0
To ditto, the year the crop is growing	0	18	0
	5	7	0

In this account forty shillings are charged for forty horses, employed in the culture of one acre of wheat, in the common husbandry; a charge which ought to be considered by the farmer, for he actually buys and maintains his horses for this business.

The crop which follows wheat is generally oats; but sometimes peas are sown instead of oats: with some, the practice is to let the peas follow oats, in which case they fallow only every fourth year; but where land receives no other assistance than what arises from fallow, it is a bad practice not to fallow every third year. It is the general practice to plough but once for oats, and therefore it shall be stated so; but it is a much better practice to plough the wheat stubble once before winter, and again in the spring.

An estimate of expence upon an acre of oats :

	l.	s.	d.
To ploughing once	0	10	4
To seed oats, two barrels	0	12	0
To harrowing 4s. 6d. feed-man 4d.	0	4	10
To one year's rent	0	18	0
	2	5	2

These two crops consume three years; after which the farmer is to begin again, and to incur every article of expence stated in the above accounts, in order to obtain two crops more.

An estimate of expence upon a plantation acre of wheat in the drill husbandry, the first year :

	l.	s.	d.
To ploughing 4 times, to prepare the fallow	2	1	4
[This is the same charge as in preparing for the common husbandry.]			
To harrowing twice for ditto	0	9	0
[This is the same also.]			
To rent for the year of fallow	0	18	0
[This charge is saved after the first year.]			
To harrowing with the drill harrows	0	0	6½
[Four acres a-day may be harrowed with one horse.]			
To sowing with the drill plough	0	1	1
[From 3 to 5 acres may be sown in a day.]			

To seed-wheat, generally 5 stone, but suppose 6	0	6	0
To the first or winter hoeing	0	1	7
[Two acres may be hoed in a day, two horses, ploughman and driver; the design of this hoeing is to leave the plants dry, and to meliorate the earth.]			
To the spring hoeing with the cultivator	0	1	1
[To deepen the soil, one horse, ploughman and driver.]			
To the third hoeing, i.e. to return the meliorated earth to the corn	0	1	7
[To make the corn tiller, i.e. to increase its branches.]			
To the fourth and final hoeing	0	1	1
[To fill the grain and render it large.]			
To rent the year the corn is growing	0	18	0
	4	19	3½

N. B. Although the drill culture for the first year is very near as expensive as the common, yet, after taking the first crop, the expence and labour of fallow, and loss of time, is not to be incurred again, as is unavoidable in the common husbandry.

An estimate of expence upon an acre of drilled wheat, after the first crop :

	l.	s.	d.
To ploughing the land once	0	10	4
[One ploughing is all that is necessary.]			
To harrowing with the drill harrow	0	0	6½
To sowing with the drill plough	0	1	1
To feed wheat	0	6	0
[Be it remembered, 5 stone is enough.]			
	0	17	11½
To four times horse-hoeing, as before stated	0	5	4
To one year's rent	0	18	0
	2	1	3½

Thus the land is sown again with wheat every year, and instead of 4l. 9s. which is the farmer's expence in the common husbandry, exclusive of one year's rent of the land: in the drill method it is no more than 17s. 11½d. and the total expence, instead of 5l. 7s. is no more than 2l. 1s. 3½d. rent included; whereby there is a saving of 3l. 5s. 8½d. an acre.

Before the account of profit and loss upon these different methods of culture be stated, it will be necessary to take notice of an objection, which may perhaps be made to the above charge of ploughing in the common husbandry. It is pretended, that three quarters of an acre may be ploughed in a day, with one plough: but can it be done effectually? The land may, indeed, be scratched, but cannot really be ploughed as it ought to be. The farmer ought to be cautioned against a trick too frequently practised in ploughing. When a ploughman enters his plough, and passes across the field, he turns a sod about a foot broad: when he is to return, he enters his plough about four feet distance from the outside of the former furrow, and so turns another sod of the same breadth, which, when turned, just meets the former sod; thus four feet of the land appear to be ploughed, whereas the fact is, that the two feet lying under the sods is not touched with the plough at all. This deception, added to the practice of just skimming the ground, enables hirelings to undertake ploughing at 6 and 7s. an acre. But if a plantation acre of land be well and effectually ploughed, 10s. 4d. as charged above, will not appear too much; and it is, in fact, supported by the common course of business. When wheat is to be sown, it is the general custom to send a barrel of seed into the field with two ploughs, which is to sow an acre of land, and that is the usual day's work for two ploughs in the general course of business. Let us see then, what the expence will amount to. Eight cattle will be 8s. two ploughmen 1s. 4d. two drivers 1s. and the seedman 8d. which in all makes 11s. and corresponds with the above charge.

To clear profit arising upon an acre of land in fifteen years in the common husbandry	52	3	11
To clear profit arising upon an acre of land in fifteen years in the common husbandry	27	19	2
Greater profit on the drilled acre, in fifteen years	24	4	9

which amounts to 1l. 12s. 3½d. per annum, for fifteen years, on the acre, more than by the common husbandry.

In the drill husbandry the crops are stated at three barrels of wheat less upon an acre than in the common husbandry, that it may not be supposed to be over-rated; but in the common husbandry, the crops are rated at the highest; fourteen barrels of oats an acre, are also allowed in the common husbandry, which every farmer must admit to be a great allowance upon the general produce.

That the drill culture will produce six barrels an acre, is fully proved in Mr. Baker's Report at large, which will be shortly published, where it will be shewn, that much more has been produced.

Doubtless it will be observed, that in fifteen years, fourteen wheat crops are obtained in the drill husbandry; in the common husbandry only five wheat and five oat crops: the five other years are not only lost, but are an heavy expence to the farmer.

A farmer having forty acres of tillage, supposing him to direct his attention to bringing it to the drill culture, would make in fifteen years 969l. 10s. more than he can in the common husbandry; which is such an advantage, that the greater profit in the drilled acre in fifteen years will purchase the fee-simple of that in the common husbandry, at twenty-seven purchase, valuing the land at 18s. an acre.

Thus it appears, that in every fifteen years the fee-simple of all the tillage lands of the kingdom is lost to the community by the common course of tillage.

In stating these accounts, no mention is made of fences, water, cutting the land, weeding and reaping, as these articles of expence depend on a variety of circumstances, but, in general, will be more on the common husbandry than on the drill.

Mr. Baker began the horse-hoeing culture of wheat before he was fully master of the practice, as appeared by the event: for his crops, during the three years that he practised this culture, declined every year, and for that reason he gave it up as unprofitable; which, without doubt, discouraged many from engaging in it, particularly in Ireland. His ill success was not, however, from any error in the principles, which is evident from Mr. Tull's own success, and of others since, who have practised this husbandry on wheat much longer than he did; and it appears from the account given by Mr. Baker, that he deviated from the methods necessary in this cultivation of wheat.

1. In the horse-hoeings from the wheat, his hoe-plough was not brought so near the rows as Mr. Tull directs, and as he himself and others since have practised.

2. He gave his wheat but four horse-hoeings, which were not enough; for though Mr. Tull, when he became perfect in this culture, gave commonly but four hoeings, Mr. Baker's land required more to keep it in that state of tilth and pulverization that is necessary in such strong, stiff, churlish land, as Mr. Baker describes his to be.

3. Two of Mr. Baker's four hoeings were performed with M. de Chateauvieux's cultivators, which have no earth-board, and do not turn the furrows; which the hoe plough does, and is necessary in hoeing wheat. By turning the furrows frequently, a new surface of earth is every time exposed

exposed to the action of the atmosphere : and to this we must ascribe the increased fertility of the land, whereby it is enabled to nourish the crops of wheat repeated every year ; for it has no manure, nor any assistance but from tillage : if that is abridged, and it has not due exposure, the crops must decline, as Mr. Baker's did, partly from this defect in the manner of hoeing.

4. In horse-hoeing wheat, if the crops are found to decline, there are two remedies directed by Mr. Tull, and practised by skilful cultivators, viz. to give the land more hoeing in the proper season, which increases its fertility ; or to sprinkle a little soot, malt-dust, coal-ashes, or other fine manure, upon the rows of wheat in the spring, about the beginning of February ; one or both of these will, without doubt, restore the land, and improve the crop. Had Mr. Baker done so, when he perceived his crops were declining, he might have gone on with success, as some others have done, from eight to ten, to near thirty years.

Though we, happily, in this kingdom, are not under the same necessity as some foreign countries of building large edifices for public granaries, because our harvests are much less apt to fail us ; yet as this work is perhaps too presumptuously intended for general use, it is incumbent on me to speak of those effectual, though expensive means, of guarding against dearth, or even famine, as well as of the cheaper and easier methods, by which every farmer may be enabled to enjoy the advantage of preserving a large quantity of corn in a small space, without danger of its heating and fermenting, of its being preyed upon by destructive animals and insects, or of its being spoiled through the ignorance or want of judgment, of inattentive servants.

Corn reaped in a dry year, and especially that of the growth of a hot country, is well known to be the most perfect, and the fittest for keeping ; as, on the contrary, experience has proved that the softer and less ripened grains of wet years and rainy harvests should always be disposed of for more immediate use, though their too great humidity, which would infallibly occasion a putrefaction, if not remedied in time, may be exhaled, and they may then be preserved a long while in very good condition, as will be shewn from repeated facts and proper experiments.

The ancient Romans imported annually vast quantities of corn from Egypt, a very hot and dry country, scarcely ever watered but by the periodical overflowings of the fruitful Nile ; and they found this grain answer much better than any of their own growth, both for yielding plentiful crops, when sown in Italy, and for keeping in their public granaries, where they frequently preserved it many years perfectly sound. Pliny tells us, that, in his time, they kept corn a long while in subterranean caverns, made in a dry soil, and so closely stopped that not a breath of air could enter. They then covered the bottom with straw, and laid upon that the corn in the ear. We have the concurrent testimony both of the ancients and moderns, that it will keep thus perfectly well for at least six or seven years ; and an accident, not long ago, discovered a parcel of corn thus preserved at Amiens, where, though it had been laid up during a great number of years, it was found to be fresh and good, neither worm-eaten, rotten, nor mouldy. This was certainly owing to the moist air having been kept out, and with it the eggs of animals, and seeds of those minute vegetables which we see in form of mouldiness on such corn as has been less carefully defended from their access. In effect, experimental philosophy has proved that the air is the great source of corruption ; for even the most corruptible substance, such as meal, butter, milk, and the like, have been preserved fresh four months in the exhausted receiver of an air-pump.

There still is, near grand Cairo, a vast subterranean magazine of corn, defended with good walls, and called Joseph's granaries. It is hardly to be supposed that they are quite so old as the days of that patriarch ; but they abundantly prove the utility of such places of store, by the vast quantities of grain annually preserved in them.

Many parts of Africa, the corn of which country, and particularly that about Algiers and Tunis, will keep much longer than the growth of any other place, abound with granaries of this kind. They are deep pits made in the solid rock, but just wide enough at their top for a man to go down into them, but they grow larger immediately after, and are usually squares of from thirty to forty feet in diameter. In these the great men of the country preserve their corn. They first cover the floor with straw, then

spread upon that a layer of corn, upon this another, but thin bed of straw ; then another couch of corn ; and so on, till the whole cavity is filled ; observing all the while, as the heap rises, to place straw between the corn and the sides of the walls. When this is finished, they cover the mouth of the entrance with a sort of hurdle, over which they lay about two feet thick of sand, and over this they raise a ridge of earth, well beaten together, in order to throw off the rain both ways, that none may settle there on the place and soak into the magazine. The corn thus stored up always keeps three, four, or more years, very sound ; and not unfrequently the proprietor being taken off by the cruel despotism of the Eastern governments, the magazine is forgotten, some accident discovers it many years afterwards, and the corn is almost always found perfectly good in it. All the care they take, by way of preparing the grain, is to expose it two or three days to the heat of the sun, to dry it thoroughly before they carry it into the magazine.

In the duchy of Lithuania, and in the Ukraine, the people always preserve their corn in nearly the same manner, in wells or pits made in dry places : but great care must be taken there in the opening of these stores ; for people who have descended into them, before they had sufficient communication with the fresh air, have been killed by the damps.

The Russians too preserve their corn under ground in deep pits of almost the figure of a sugar-loaf, wide below, and narrow at top. The sides are well plastered, and the top is covered with stones. They are very careful to dry their corn well, generally by means of ovens, kilns, or stoves, for their summer is too short to effect it sufficiently, before it is laid into these repositories.

The same thing is practised with unvaried success in the island of Malta : and also in Gascony, the Vivarais, and other southern parts of France, the corn of which is remarkable for keeping many years longer than that of any other province in the same kingdom. M. Duhamel tried this method in the Gatinois : but his corn was so spoiled there by its humidity when laid up ; that country being subject to wet and moisture, and his grain, in this trial, not having been previously dried in an oven or stove.

Upon the whole, it is evident from these, and from many more instances, which might be alledged, of the practice of other countries, that subterraneous granaries, properly made, in a thoroughly dry soil, are the best of all repositories for keeping of the corn ; but, at the same time, experience shews that this method will not succeed in our climate, the sun here not having power to exhale the moisture from the corn, sufficiently to prevent its fermenting when laid in a large heap. I must likewise add, that when one of these subterranean magazines is opened and exposed to the air, it must be emptied immediately, and the corn taken out of it must be thoroughly sifted and screened, or it will soon corrupt. Some think it more nourishing, when it has been well preserved, than that which has been kept in granaries above ground.

The marquis of Santa Cruz, author of many excellent remarks on the political and military state of different nations, observes, that the corn of Galicia and the Asturias will hardly keep from one year to another, because of the humidity it contains, which rots and decays it : but that the corn brought thither from Castile will keep good many years. This last is therefore the only kind that the Spaniards ever venture to lay up in their public granaries : and the sole difference, in M. Des Landes's opinion, between it and their other sorts is, that it is grown in a country where there is less rain in summer. They might indeed, if their religion and policy did not forbid their having intercourse with the Moors of Barbary, once their conquerors, easily import from Africa plenty of some of the best corn that the world affords, perfectly ripened, thoroughly dried, and, in all respects, fit for keeping many years.

The great objections to public granaries, even in countries where the uncertainty of the climate, the indolence of the people, the ill-judged form of government, and various other causes frequently combine to render them highly necessary, is the expence attending such establishments ; generally so great, that none but a monarch can, or a state, properly undertake them : and they, most certainly, cannot do any thing more laudable, more truly noble, in countries whose misfortune it is to be exposed to the dreadful calamities of want and famine, or to depend upon the precarious assistance of their neighbours.

Though

Though subterranean repositories for the keeping of corn are preferable to all others in countries proper for them; yet, even the common granaries may, with due care, and perhaps some few alterations, be rendered much more serviceable than they generally are. The principal cautions necessary to this purpose are, 1. To guard against the too great humidity which always prevails in places where there are many doors and windows: 2. To prevent a too free access of the external air, because this brings in with it the eggs of a vast number of different insects, which prey upon and destroy the corn: and, 3. To take care that the corn be thoroughly dry, and as clean as possible, when it is laid up. These are the three general rules to prevent its corrupting.

The chief cautions to be observed in the erecting of granaries are, to make them sufficiently strong, and to expose them to the most drying winds. Sir Henry Wotton and Mr. Worlidge agree particularly in these; both judiciously advising a northern aspect for these buildings, because that quarter is coolest and most temperate; and the latter rightly observing, in general, that the best granaries are those built of brick, with quarters of timber wrought in the inside, whereto to nail well joined boards so closely to the wall, that there be no room for vermin to shelter themselves. Floors of plaster are reckoned the best, because they are cool in summer, and, if well made, do not retain dampness in the winter. There may be several stories one above the other; for the shallower the corn lieth, the better it will keep, and the more easily it is turned. Some have a small hole in the floor of their upper granary, through which the corn descends into the lower one, like the sand of an hour-glass; and after it is all come down into the lowest granary, it is conveyed back into the upper one; so that it is kept in continual motion, which is a great means of preserving corn.

The granary in the city of Schönbauk, in the vale of Parinburg upon the river Elbe, which is a store-house for the wheat of which the mum is made at Brunswick, is built nearly in this manner. It is three hundred feet long, eighteen feet wide within, has seven stories, each of which is seven feet high, and large windows all around to open and shut close according as the wind fits. By this means, the dross and dust are carried off as the corn is turned; for which a west wind is always preferred, because it is the driest. At each end of this granary, and in the middle, are stoves for fire, in damp weather, and at the going away of great frosts and snows, to prevent moisture. There are also on each side of this building three long troughs or spouts, in the upper loft; and in fair weather men throw the corn out of this loft into those spouts, through which it falls into others, about ten feet wide at the top, and eight or ten inches at the bottom, by which it is conveyed into the lower story, from whence it is wound up again by a crane fixed in the upper loft. By thus falling from one story to another, the corn is cleansed by the wind from all dust and chaff, and receives the benefit of the air, &c. These troughs or spouts are put on and taken off as occasion requires, to any of the windows; that when vessels come to lade corn, it may be conveyed, through them, into the proper barges, without being carried thither by men, or cattle. The wall of the two first stories is two bricks and a half thick, that of the three next is two bricks thick, and the thickness of the two uppermost is a brick and a half. Fourteen thousand quarters of corn may be kept in this granary.

Mr. Mortimer, who gives us this account, which is taken originally from captain Andrew Yarranton's *England's Improvement by Sea and Land*, adds, that the ears of corn, cut off from their stalks, and packed up close in a tight cask, will keep very well, and that this is the best, he indeed says, the only way of carrying any sort of corn over the sea, in order to sow it in a foreign country.

The public granaries at Dantzick are seven, eight, or nine stories high, and have a funnel in the middle of every floor, to let down the corn from one to another. They are built so securely, that the corn does not contract any damp, though they are surrounded with water on every side, in such manner that vessels come up to the very walls for their lading, which is let down into them, likewise through pipes or funnels, with very little labour and charge. No houses are suffered to be built near them, for fear of accidents by fire.

At Zurich, in Switzerland, corn is kept eighty years, or more, in the public granaries, which are very spacious, and

well aired by means of many square wooden pipes which pass through them.

The twelve companies of London, with some other companies and private persons, had formerly their granaries at the bridge-house in Southwark, under the superintendence of a justice of the peace, a steward, and two masters. These granaries were built on two sides of an oblong square (now used for a wharf) one of which stood north and south, and was near an hundred yards long. Along this side were lattice windows which faced the north-east; and on the other side, which was about fifty yards long, the windows looked to the north. The opposite sides had no apertures. All the windows were about a yard high, without any shutters, and ran on in a continued series, with very small partitions, sufficient only to nail the lattices to. Each of these granaries was three or four stories high; but the lowest, or ground story, which was twelve feet high, was used only for a ware house.

In Kent, two square holes are made at the end of the floor, and a round one in the middle, by means of which the corn is thrown from the upper into the lower rooms, and back again, the better to turn and air it. The screens used on this occasion are made with two partitions to separate the dust from the corn. The dust falls into a bag, and when it is sufficiently full, it is thrown away, the pure and good corn remaining behind. By these means corn has been kept thirty years in this country: and it is observed that the longer it is kept, the more flour it yields in proportion, and the purer and whiter the bread is; only the superfluous humidity evaporating in the keeping: for grain does not diminish in weight or bulk, after the first year.

The usual way of preserving it in our common granaries is, after it has been well sifted and screened, to spread it upon the floor about six inches thick, to turn it twice in a week, and to repeat the screening of it once a week during the first two months. It is then laid a foot thick, for two months more; and in this time it is turned once a week, or twice if the season be damp, and now and then it is screened again. At the end of five or six months, it is raised to the thickness of two feet, turned once a fortnight, and screened once a month, or as occasion requires. After a year, it is laid two feet and a half or three feet deep, turned once in three weeks or a month and screened in proportion. When it has lain two years, or more, it is turned once in two months, and screened once in three, and how long soever it is kept, the oftener it is turned and screened, the better the grain will be preserved. An empty space, about two feet or a yard wide, is always left on each side of the corn, to prevent its running down holes or chinks at the edges of the floor, and to remove it from all moisture that may proceed from the sweating of the walls, or from any defect in the roof; and another space is commonly left along the middle of the heap, if it be a wide one, to facilitate the turning of it as often as is needful. This is the general custom; and experience has shewn it to be necessary in the usual manner of keeping grain.

But all the foregoing methods of preserving corn in granaries above ground are attended with very great expence, by reason of the vast buildings which they require, and the many servants necessary to be employed to take care of these stores: besides which, too much depends here upon the assiduity, skill, and probity of those servants; and the grain is still liable to be preyed upon, wasted, and spoiled, by vermin and insects.

"It is commonly said that a farmer cannot thrive, who, for want of money, is obliged to sell his wheat under five shillings a bushel; but if he will sell it dear, he must keep it when it is cheap; and his way of keeping it is in the straw, using his best contrivance to preserve it from the mice.

"The most secure way of keeping a great quantity of wheat that ever I heard of, is by drying it. When I lived in Oxfordshire, one of my nearest neighbours was very expert in this, having practised it for great part of his life. When wheat was under three shillings a bushel, he bought in the markets as much of the middle sort of wheat as his money would reach to purchase. He has often told me, that his method was to dry it upon a hair cloth, in a malt kiln, with no other fuel than clean wheat straw, never suffering it to have any stronger heat than that of the sun. The longest time he ever let it remain in this heat was twelve hours, and the shortest about four hours. The damper the wheat was, and the longer intended to be kept, the more drying it requires: but how

to distinguish nicely the degrees of dampness, and the number of hours proper for its continuance upon the kiln, he said, was an art impossible to be learnt by any other means than by practice. About three or four and twenty years ago, wheat being at twelve shillings a bushel, he had in his granaries, as I was informed, five thousand quarters of dried wheat, none of which cost him above three shillings a bushel.

"This dry wheat was esteemed by the London bakers to work better than any new wheat the markets afforded. His speculation, which put him upon this project was, that it was only the superfluous moisture of the grain, that caused its corruption, and made it liable to be eaten by the weevil; and that when this moisture was dried out, it might be kept sweet and good for many years; and that the effect of all heat, of the same degree, was the same whether of the straw or of the sun. As a proof, he would shew, that every grain of his wheat would grow after being kept seven years.

[This is an excellent, safe, and cheap method of keeping wheat; and with regard to the difficulty of judging the proper degree of heat, that is easily determined by the thermometer—And the length of time it ought to be dried, may be known by those who are judges of wheat in the same manner as they judge of the quality of it at market.]

"He was a most sincere, honest yeoman, who from a small substance he began with, left behind him about forty thousand pounds; the greatest part whereof was acquired by this drying method." *Tull's Husbandry*, p. 65.

To obviate the inconveniences, and to point out an easier, cheaper, and surer way of keeping all sorts of grain, in granaries, in the other methods before mentioned, is the principal design of M. Duhamel's excellent Treatise on the Preservation of Corn: in which, after rightly noticing the several disadvantages attending the common practice, he proposes a method founded in reason, and on his own repeated experience, as well as that of others, whereby a large quantity of corn may be preserved in a small space, during a number of years, without danger of its heating, fermenting, or contracting a bad smell or taste, and secure from the spoil of animals and insects, at a trifling expence, and with very little trouble. All these desirable ends may be obtained, in some cases, by ventilation only; in others, by drying the corn in a kiln over a stove; and in others again by both these methods. See the article VENTILATION.

A Letter to Dr. Templeman, Secretary to the Society for the Encouragement of Arts, Manufactures, and Commerce, describing a new invented Granary for preserving Grain.

"S I R,

"Where public utility is in question, a private apology becomes unnecessary: accept, therefore, without ceremony, the following hints to be laid before the Society.

"I have long been of opinion, that a method of preserving grain from decay is much wanting; but it must be, to answer any good purpose, easy in its execution, and cheap in its process.

"The method now practised, of laying wheat in a room or a granary, and turning it frequently with shovels, and sometimes screening it, is subject to many inconveniences: it must be laid very thin, or it is apt to ferment; and by being laid thin it takes up so much space, that to lay up and keep five hundred quarters for three years only, would be considerably expensive.

"Could we preserve our corn for a number of years, it would not only be of great service to the public, but of no small benefit to the farmers. For want of doing this, we find a great, and often a sudden, variation in the price of bread corn; wheat will one year sell for five pounds a load (that is five quarters), and the next year it will rise to fourteen or fifteen pounds, or even higher.

"The rents of lands are of late greatly risen, owing to the increase of our trade; so is the price of all kinds of labour, insomuch that when wheat is low in price, the great farmers are considerable losers, and the poor ones are ruined: this is one reason why our lands are so much monopolised as they are in some counties. The great farmers, being rich, can afford to be losers for several successive years, as they are sure that once in a while the markets will rise, and not only repay all their losses, but secure them

a large profit. The poor farmers are under a necessity of selling their corn before the winter is passed: if the markets are low, they fail in the payment of their Michaelmas rent; their stock is in consequence seized, and some over-grown monopolizer in the neighbourhood adds their little plot to the many formerly separate farms he already holds.

"Were the interest of the community to be consulted, no man should be allowed to rent above three hundred acres of land: the profits of such a farm will, with proper regulations, maintain a family decently and well; and it is not requisite, or even salutary, that farmers should acquire large fortunes.

"But to return to my subject. Were a proper method projected for keeping wheat good for a number of years at a small expence, all this would be remedied, our lands would no longer be monopolized, and corn would from year to year vary very little in price. This stands to reason; for in a very plentiful year a farmer would not sell his corn too cheap, if he had the power in his hands to lay it up without great charges; and when the crops by any accident failed, the price of corn would not greatly rise upon the poor manufacturer and labourer, as what had been some years before laid up would now of course be sold at a reasonable price, and make up the deficiency, and this without loss to the farmer, and with great benefit to the community in general.

"This interesting subject has for many years employed my thoughts and attention; and I have in consequence imagined, and even executed in miniature, or rather in small dimensions, a plan, which will, I have reason to think, answer the important purposes above mentioned: my whole plan consists in building a proper granary, (the construction of which will not cost much, which will keep corn for any number of years sound, sweet, and good, and that with very little annual expence.

"I imagine the following postulata will be allowed.

"If we can preserve corn from fermentation, it will be in a way of keeping.

"To keep it from damp and moisture, is the best means of preserving it from fermenting.

"To move it frequently, give it air at proper times, and separate the dust and other extraneous matter, is certainly the best way to keep it from being moist and damp.

"Destructive insects are to be kept from it, which by frequent stirring is best effected.

"I imagine there are few, who have made this part of nature their study, but will allow the above positions: I shall therefore, without farther prelude, inform you in what manner I effect this at a small expence.

"The granary I would recommend consists of seven stories of floors, and may be built in any dimensions, provided proper proportions are adhered to.

"The form of it is square; and I shall at present suppose it to be fourteen feet square within the rooms or cells; the distance of the floor from one cell to the floor of that above it, is to be five feet: and the whole building should stand on strong posts, more or less in number, according to its dimensions, at the distance of six feet from the ground: the small stairs, or rather ladder, to go to the several cells, must be fixed to the outside of the building side-ways, with a leading rail or rope to prevent falling.

"The whole granary is to be built of what is generally called brick-noggin; that is, the whole is first framed in strong timber-work, and the interstices filled up with brick-work: the floors, beams, and joists, must be made strong to bear the weight of the corn; the inside of the cells must be well lined with dry oak-boards, close jointed, so as to leave no cracks; and the outside must be weather-boarded, the boards being strongly nailed to the timber-work of the frame, and afterwards payed over with pitch. The floors of the cells must be so contrived as to shelve towards the middle, in which part is to be an aperture six inches square, to be opened or closed by means of a sliding shutter, which must have a long handle reaching in a groove without the granary.

"On three sides of the rooms there must be a window, strongly latticed, covered with wire to keep out larger insects and birds, and with strong shutters to defend the corn from the weather; on the fourth side is a door to each room to open from without: the windows are to be small, and as close as possible to the ceiling: over the upper room or cell for the corn is a loft, on the outside of the door of which is fixed a crane to be worked within, by a winch and flyers.

"The use of the windows in the sides of the rooms, is to

to give the corn all the benefit it can receive from the wind and fresh air: the door, when the cell is empty, gives the workmen entry to sweep, dust, and clean it:

"My method of managing my corn in this granary is as follows:

"When my wheat is thrashed and cleaned, it is put up into sacks and carried to the granary: the apertures I mentioned above to have been contrived in the floor of the cells are then opened, except two, viz. one in the floor of the undermost cell, and that in the floor of the second cell, reckoning from the bottom.

"The sacks are then craned up into the loft, and emptied, through a hole made for the purpose, into the uppermost cell, whence it falls through the apertures till it reaches the floor of the undermost cell but one, where it is stopped by that aperture being shut.

"When this cell is filled to the height of about two feet from the floor, which may be seen through the lattices, the aperture in the floor of the third cell is shut by means of the slider: the workmen then continue craning up the sacks till all the cells are filled in the like proportion, except the undermost, observing the proper opportunities of shutting the apertures.

"In this condition the corn is left for a week, or somewhat longer, if it was got in very dry.

"The first stirring it receives, occasions very little trouble: when it has been in the granary about a week, a workman, after having swept and cleaned the undermost cell, which was left empty, opens the aperture in the floor of the second cell, by drawing the slider back: this lets the corn fall from the second into the undermost cell, the windows of which being open, the corn receives great benefit, as it falls, by the current of air that passes through the cell.

"When the second cell is empty, the aperture in the floor of it is shut, and the workman, going in at the door, by means of the stairs on the outside of the granary, sweeps and cleans it from all impurities, in order to prepare it for receiving the corn of the third cell, the aperture of which is next opened, and the floors being all made shelving towards the middle, the corn falls gradually through, in the same manner it did from the second to the undermost cell.

"In this manner they are all managed, till at last the uppermost cell remains empty.

"It is then left for another week, when two workmen must for a small space of time be employed: one of them goes up into the loft at the top of the granary, to work the crane, and the other takes his station on the ground under the floor of the undermost cell: under the aperture in this floor he first fixes a screen, upon which the corn falls, and then by means of a conductor at the foot of the screen, drops into the mouth of a sack which hangs to it, the bottom of the sack resting on a miller's hand-barrow: when all is prepared, he draws away the slider and lets the corn fall on the screen.

"When the sack is full, the slider is for a moment closed, till another sack on another barrow, is put under the conductor: the workman then wheels the first sack to the outside of the granary, and fastening the crane rope to it, makes the signal for the other to draw it up. Whilst this is doing, the second sack is filled, which is wheeled and drawn up in the same manner; and this method is pursued till the undermost cell is empty.

"If it is necessary to screen all the corn at this time, a small screen is fixed under the aperture of the second cell, so contrived as to have a box at the back of it, which receives all the dust, trash, off-corn, and seeds of weeds that pass through the wires: and this screen is successively fixed under every aperture, as the cells are successively emptied.

"After the first month the corn need be stirred in this manner only once a fortnight, and after the first six months, only once a month, unless the weather should prove, in autumn, very hot and damp.

"This then, Sir, is the manner in which I have for some years managed my wheat, and find it answers very well, the vegetative quality of the corn being preserved in full vigour, and no signs being discoverable in it of a tendency to fermentation.

"My country hovel is at some distance from London, in a retired quarter, consequently unnoticed; and there being but little probability of this easy method's being sufficiently known by my practising it, is the reason of my

troubling you with this long letter, flattering myself that by your means it may make a proper appearance in public: Had vanity been my predominant passion, I might have presented it to the Society in person, which, as a member, I had an undoubted right to do; but this would have been encroaching on my beloved obscurity: to you therefore, Sir, do I trust this child of my invention; and if in your hands he can be trained so as to be of public utility to my country, my every purpose is fully answered."

This gentleman's method is much the same as at Dantzick, and other places abroad, where they have public granaries for the preservation of corn; and is not necessary nor advisable to be practised in England. — Not necessary, because our harvests are, in general, more plentiful than in those countries where they have such repositories for corn. — And not advisable, on account of the prodigious expence of erecting and repairing those granaries throughout England; the continual expence of men to store, move, and deliver the corn, and the waste in long keeping. But admitting that the ends proposed by those granaries were obtained, viz. reducing the price of corn, and keeping it constantly at a more moderate price than it is now, after bad harvests, what would be the consequence? Not a regular uniform lowering of the price: for in that case, the farmers would have no expectation of making any considerable advantage by cultivating corn, which would be a certain means of discouraging the culture of it, and the cause of a real scarcity, and then the public granaries could not be supplied at a price so low, as would be of any advantage to the manufacturer and labourer. In most of those states, where public granaries are in use, they do not raise corn sufficient for the people, their dependance, in a great measure, being upon their hoarded corn. But in England, corn is an article of commerce, and a very valuable one, amounting in the century last past, to a clear profit of many millions sterling; besides the invaluable advantage of the surprising advance of agriculture, consequent upon the encouragement given to the farmers, by the exportation of corn: a measure whereof the good effects are evident, enriching the kingdom, and at the same time supplying the inhabitants with bread, in a cheaper and more plentiful manner than those of other countries, who have neglected agriculture, and depended upon public granaries.

The scheme above proposed of granaries, fourteen feet square, and seven stories of floors, would keep but a small quantity of wheat, and be attended with an expence as great, or greater, in proportion, than the large public granaries, both in their first erection, and in the expence of men and waste of corn; and, so far as they are similar to the larger, would in general be attended with the like bad consequences to the community: or if not altogether so hurtful, at whose expence are they to be erected? Few landlords would be at that expence, and few farmers could afford it. And such farmers as could afford to erect them, would hardly be persuaded to lay out so much money upon so uncertain a prospect, especially as the farmer cannot have any benefit from his money thus laid out, upon quitting the farm: for the landlord will not allow him to take away the granary, and if he was allowed that liberty, it would then be of little advantage to him to carry away the old materials: so that upon the whole, it is not probable that this scheme will ever be adopted to any general benefit.

It is therefore apparent that where corn can be kept by the farmers, they are the properest persons to keep it: for the removal of it from them, and laying of it up in any manner, will always be attended with a greater expence, and for that reason will come dearer to the consumer, than if it remained in the farmer's possession.

When the price of corn advances pretty high, and they see several stacks of corn in the yards of some of the wealthiest farmers, the lower class of people becomes extremely clamorous, charging the farmers with extortion and combination. That they endeavour to keep up the price cannot be doubted, as they look upon corn to be an article of merchandize, and are too often prompted by a covetous disposition, to keep up the price as high as they can: but in regard to a general combination among farmers, it is impracticable, for obvious reasons; and the poor should look upon such farmers who keep stocks of corn as their best friends: for should they sell all, as the little farmers are obliged to do, where else could the poor be supplied with bread, so cheap as from the farmers? If they

they have it from the dealers in corn, who hoard it, in expectation of profit by the price advancing, the poor must in that case pay the advanced price, which includes not only the prime cost paid to the farmer, but likewise all the subsequent advances upon it, of commission, carriage, warehouse-room, and the corn-dealers profit. Or if the corn is imported, the additional expences will be still greater to the consumer. Hence it is evident, that the poor cannot have bread in any way so cheap as from the farmers; and that it is the interest of the community to encourage and assist them to keep stocks of corn.

If corn is kept some years in stacks, it is liable to several casualties; the thatch is apt to be blown off, and let in the rain, and to sink down at the tops of the stack; in both which cases, which are very common, the corn will be damaged there, and to a considerable depth, unless great care is taken, and often examined, to prevent the damage. The straw is lost, or fit for nothing but dung, which, in most situations, is a considerable loss to the farmer. Another, and still greater loss, is by the mice and rats eating and wasting the corn, which is often difficult to prevent; for even the method of setting corn stacks upon saddles, which is a very good way, is not only attended with expence, but is sometimes ineffectual; because these vermin lodge in the sheaves, and in them are carried from the field into the stacks, or then get into them, by climbing up ladders, &c. that happen to be set against the stacks; and when this happens, and the corn is kept in the stacks for some years, they multiply incredibly; insomuch that often a very large proportion of the corn is destroyed by them; and there have been instances of their destroying all the corn in a stack.

Preserving corn in the grain, after it has been thrashed out, is, in many respects, preferable to keeping it in the straw; and the method of doing it, related by Mr. Tull, appears to be very ready and cheap, and may be practised by every farmer, especially with the assistance of a thermometer. The method also of keeping corn in granaries of preservation, is a very good one, and the above objections to it are fully obviated by what has been said on that head, confirmed by the experiments of Dr. Hales, M. Duhamel, and others before mentioned. That wheat may be preserved perfectly sweet for many years, by the assistance of kiln-drying and ventilation united, is undeniable, nor is there any doubt of ventilation alone being quite sufficient in general; and in very unfavourable seasons, the wheat may, for the greater safety, be first kiln-dried. And perhaps the effect of the kiln-drying may be assisted by ventilating it with warm or hot air at first, and till the moisture is discharged from it.—Upon the whole, the preservation of corn by the farmers is a matter of such importance and general concern to the community, that every person should endeavour to contribute all they can to the success of it.

A method of preserving corn, different from the others above-mentioned, has been practised with success by M. Marcel de Meziers, of Switzerland, which he relates as follows:

“As soon as the harvest is got in, I give the corn in the barn as much air as possible, to hasten the drying of the sheaves, which I find to be a matter of some importance.

About the middle of August, I get my wheat thrashed out. It costs me indeed something extraordinary; but I have ample amends made me, as it threshes, dresses, and dries better; is no longer subject to the depredations of the rats and mice; to the thefts of servants and labourers; to receiving damage by damps and hard rains; or to shedding in the barn, great part of which sheddings is generally lost. When the farmer, with the view of saving a trifle, puts off the threshing of his wheat till the winter, most of those losses are felt.

After the first day, I cause all they have threshed to be brought into a large room, the windows of which to the east and south are opened, and the floor being made very clean is covered two inches thick with the corn. As soon as it is dry enough, which may be known by its rattling when you pour it out of one hand into the other, I have it screened, which separates from it all the under corn, seeds of weeds, and dust.

I have ready some sacks, made very narrow, of coarse cloth, which have been dipped in a strong lixivium, several handfuls of green oziers having been put in-

to the ley, and into the copper cauldron where the ley was boiled. The reason of doing this will presently appear.

The sacks being well filled and fast tied, hold about three bushels (English) each. When all my sacks are filled, two tressels, about three feet high, with the backs rounded, and about eight inches wide, are set one beside the other. Upon these tressels, six sacks are laid, at six inches distance one from the other: on the intervals, five more are laid, then four, three, two, and one; so that the whole number seems to form a pyramid, consisting of twenty-one sacks. Other tressels of the same kind are used, for what remain to be piled.

When this work is completed, and the sacks are all placed in proper order, I cause the shutters and casements to be closed, and the double curtains of the windows to be drawn: the double doors are also shut, and I keep the keys in my bureau. I never touch this store but for the use of the family, and for sale; and it is very easy for me to distinguish which part is to be applied to those several uses, as I always have the precaution to pile them on different tressels.

Experience having convinced me, that every body, whether liquid or solid, which contains in itself any principle of fermentation, is most inclined to have that principle set in motion when it is long left in one situation without being moved: I never fail, towards the latter end of the month of March following, of having all the corn in my sacks again screened, observing when they are filled, to make them the same weight they were before; when they are once more laid on the tressels in the former order. About the end of June, I think it enough to empty the sacks, one into another, and replace them.

When I want my room for the new corn, I cause that of the last harvest to be carried to my town-house, where it is placed in the same order as it was in the country. In the month of October, the corn which was carried to town, is all screened, and sifted in a wire sieve, after which it is in order to go to the mill. This corn is intended for the consumption of the following year; so that the wheat which I grew in 1761, serves me for the year 1763.

As I always send to town more than I have occasion for, to supply the wants of my family, particularly when it is good in quality and low in price, I have preserved wheat in the manner above related for five years and upwards, without there being any visible difference, betwixt the grain so kept and that only one year old. I have purposely made bread of both sorts, at the same time, and diligently comparing one with the other, there appeared not to be the least advantage in point of goodness on either side.

It is true, that apprehending the dryness of the corn might occasion some inconvenience in the grinding, I caused the old wheat to be washed in several waters, till the water came away pure and unfulled; for the first water was dirty, and of a brownish colour: the wheat being afterwards dried, grinds very well. By this operation, the bread becomes whiter and sweeter, and I have experienced the same with regard to new wheat.

I may then safely conclude that in this manner corn may be preserved much longer than the time I have mentioned above to have experienced, without suffering any sensible damage; particularly, as all the damage to be apprehended, must proceed from the inward moisture of the grain, which moisture must doubtless be insensibly dissipated in the space of five years. If I mistake not, the following inferences may be drawn from the facts above-mentioned.

1. That threshing out wheat as soon as possible after harvest, preserves it from the damage and waste which must necessarily be the consequences of keeping it too long unthreshed in the barn.

2. That by putting it up in sacks when it is sufficiently dried, we guard against a winter's fermentation.

3. That the tressels keep it out of the way of rats and mice, and prevent its being damaged by any moisture, which might proceed from the floor.

4. That the sacks being impregnated with the powerful bitterness of the ozier, kept it from being attacked by any kind of insects, even flies; so much do they avoid this bitterness.

5. That the room being close shut, prevents the alterations

terations from the exterior air from having any sudden effect; on which account these alterations are to be less apprehended, and indeed scarcely at all.

6. That in case any sudden tempests of wind and rain should damage the room; and expose the corn to be wetted, it will be a very easy task to remove the sacks from the round surface of which the water will run off without soaking in; and if any should by chance be wetted, it will be easy to discover where the damage is done.

7. That every room which can be close shut, is fit for this purpose; as a shed built of timber frame-work, and lathed and plastered within, will be as fit for this use, as the most elegant granary built of free-stone. This is no small advantage.

8. That lastly, this method is neither troublesome, expensive, nor requires much attendance; the several operations being very easy, and to be done at several distant times.

The owner has it in his power, at the slightest view, to know what quantity of corn he is possessed of, and as he keeps himself the keys of his store room, it is as safe as the money in his chest.

In my method I guard as much as possible against the entrance of the air and light.

This way of preserving wheat in some sort answers the end that is proposed by kiln-drying it, which consists of drying corn in order to promote its preservation: all the difference is, that one operation is quick and forced, and the other requires more care and time.

The question may be reduced to this single point, which of the two methods with the most certainty preserves the corn without diminishing its natural substance; and with making the least alteration with respect to its nutritive and salubrious qualities.

I think myself obliged to acknowledge, that the kilns will most probably contribute to the longer preservation of the grain; but then I cannot hesitate asserting, that the other method will promote most the preservation of those qualities in the corn, which are so essential to the uses for which it is intended. The uses of wheat are, to make good bread, and for seed. In the above instance quoted from Mr. Tull, the kiln-dried wheat was very proper for seed, seven years after it was so dried; and was by the London bakers preferred to other wheat, not kiln-dried, for making bread.

Let as now, as opposed to the method I propose, make a few remarks on the preservation of wheat, in magazines of granaries, where it is laid in heaps.

It cannot but be acknowledged, that it is in this manner much more exposed to be injured by the alterations in the air, particularly in damp weather the moisture soon penetrates the floors, and the corn suffers accordingly.

It is besides very rare to find any corn, after being twelve or fifteen months in the granary, but what is attacked by weevils, and other pernicious insects. In case the roof should not happen to be weather proof, the least cracks are most dangerous. Let a single quart of water be, in summer time, poured into the middle of a large heap of wheat, and it is incredible to think what damage will be done in a short space of time.

It is needless to enlarge on the infinite number of inconveniencies which are known to attend this method of preserving grain, and by which such heavy losses have been frequently sustained.

It may perhaps be objected that this method, though very proper to be adopted by a private person, would be too expensive for a considerable magazine of corn, on account of the number of sacks which would be required.

I acknowledge that a considerable number of sacks will be necessary; yet is not this so expensive an article as may be imagined. If the sacks are bought at the first hand, they will cost less than a shilling a-piece; and with care, they will last long enough amply to repay their first cost.

The sacks certainly contribute to preserve the corn in good order, prevent waste, and are a security against private embezzlements. Lastly, as they are very easily removed, the corn may more certainly be saved, in cases of sudden fire or inundations. On the contrary, in these cases, how many difficulties are there to surmount when the corn is kept in large heaps in a granary.

Having no desire to form a scheme of a public nature, I have been content honestly, and in plain terms, to relate

what I have come to the knowledge of, by many years experience, and to lay open the inconveniencies which may attend the laying up of wheat, in the methods hitherto practised. This object is of too great importance for me to be under any apprehension that any one will think meanly of me for writing on this subject.

I have omitted all along disquisition, lest I should have extended this paper to too great a length: for instance, if we exclude the air and light, no insects will annoy the corn: but can we at the same time be secure that the wheat will not ferment, grow musty, and suffer some alteration for the worse? By guarding against the action of the air we do not exclude the air itself, which it is too ready to enter at every crack. When air is not in motion, it contracts a kind of corruption: is it not then natural that it should then communicate this corruption to bodies containing air? Let a dungeon, which has been long closely shut, be opened, and a disagreeable strong smell will surely issue from it; we must then conclude that a circulation of the air is necessary. The only question remaining is, how far this circulation may be permitted to take place, so that the alterations may not be too sudden.

"This method of preserving wheat was not published, as the author takes notice, as a scheme of a public nature, which does not lessen the value of this, or any scheme calculated to render the preservation of corn easily practised by private persons; but, on the contrary, is a great recommendation of them, the principal point in view being, to have a stock of sound corn in hand, sufficient to answer the general consumption, which cannot in any other way be obtained, and so cheap to the consumer, as in the hands of private persons, of small or moderate capitals, particularly the farmer or growers of corn; for every step it is removed from them inevitably loads it with an additional expence, which falls upon the consumer. For this reason we have enlarged upon this head, as it is of great importance to the community, and have exhibited the several and most approved practical methods of preserving corn with the greatest certainty, and at the smallest expence.

"And here, as objects of consequence, and nearly connected with the subject, we would recommend to farmers to keep their corn lands in particular as clean and free from weeds as possible, and to bind up their corn in small sheaves; both these will contribute to their getting in the corn in good order, in catching harvests, and render it the fitter for preservation."

"I forgot to observe, that I have lately seen Mons. du Hamel's methods of preserving grain, by means of chests with false bottoms and ventilators.

"This method may in some cases be of service, I allow; but I am nevertheless of opinion, that corn cannot be properly preserved, unless the whole bulk of it be frequently stirred, which by du Hamel's method is not done: could the current of air be equally distributed over the whole chests, and in due proportion, I should still think it sufficient to preserve the corn; and if corn has been kept for some time in that manner, I should rather be apt to attribute it to Mons. du Hamel's first drying it on a kiln, before he puts it into the chests, than to any regular effect of the ventilators.

"Were I acquainted with this gentleman, I would recommend it to him, to make an experiment of his method in the following manner:

"Let him first fill a chest with dry corn that has not been on the kiln: another chest should be filled with some that had been well dried; and a third with the same dried corn: let the first and second chests, at proper intervals, be ventilated, and the third be kept without ventilating, in a dry place. Were this done, I am apt to think, that after six months, or a longer time, there would not be found so great a difference as some may imagine, betwixt the corn which was and that which was not ventilated.

"In my method, the expence, as well as hazard of drying, is avoided, it being never necessary, unless when corn is got in very soft, in a wet harvest; and then a common malt-kiln answers the purpose very well.

"I should have mentioned, that in my method of preserving corn, when by frequent stirrings it is become hard and brittle, it may be laid to the height of three feet, on the floors of the cells, without any danger of damage ensuing; for when it is hard, it is not subject

to heat and ferment; neither are insects so fond of attacking it.

"I have by this time, perhaps, tired your attention, and to be plain, am not unwearied myself; shall therefore conclude with assuring you that I am, Sir,

Your very humble servant,

A MEMBER of the SOCIETY."

Mr. Marshall, in his Rural Economy of Gloucester, says, "If wheat get rank in autumn, it is esteemed good management to eat it down with sheep: not however by a few kept long upon it; but by a large flock at once.

"This is a new idea. The practice may be good. The great complaint against the early sowing of wheat is that of its being liable to get winter-proud. Eating it off, in autumn, may give it a check, and prevent that evil consequence. Eating it in spring is here considered as pernicious.

"Wheat is usually weeded with spud-hooks; not hoed, as in the Vale. One instance, however, in which a thin crop, full of seed weeds, was hoed in autumn with uncommon success, occurred in the practice of a superior manager, in this district: and others, in which wheat have been weeded in autumn, with great advantage. Where wheat is sown very early, as in this district, and the land at the same time full of seed weeds, one or other of these operations seems to be in a degree requisite."

WHEE, or WHEY: a heifer.

WHEY and WHEY BUTTER. See DAIRY.

WHINS, the same with furze. See the article FURZE.

WHISKET, a basket.

WHITE-CLOVER, a well known plant, and reckoned the sweetest feed of any of the sown grasses; and it is of most advantage to the farmer, because it is perennial, or lasts a great number of years on the land.

This plant sends forth roots at every joint, so that it thickens, and soon makes a thick sward. When land is to be laid down for pasture, the farmers will reap great profit, if, with about four bushels of clean sifted hayseed to an acre, he sows eight pounds of this clover; but it is to be remarked, that it is never to be sown with corn.

It may be sown either in spring or autumn; if in spring, it may be cut about the latter end of July; if sown in autumn, the crop will be much earlier. As soon as ever the hay is off the land, it should be rolled with a heavy roller. In laying down land with these grasses, it will be proper for the farmer to be very careful that he cleans the land of all sorts of seeds; and the hayseeds are to be sown first, immediately after which the clover is to be regularly scattered. After sowing, the land should be lightly harrowed, with a short tined harrow, to bury the seed; and a few days afterwards, if the weather is dry, it should be rolled, to break the clods and loosen it.

It will be good husbandry, if, after the plants are come up, the farmer should send in some weeders, to pull up all the tall rampant weeds which might injure the crop, for, if they are suffered to seed, they will soon stock the land.

It will be proper to take the advantage of dry weather, and roll the land three or four times, after the plants have attained some size; for the clover, as is already observed, taking root at every joint, the sward will thereby be greatly thickened.

If a farmer knows his own interest, he will sow some of this white clover-seed by itself, in order to supply himself with what seed he may want, for sometimes it is very dear. The best season for sowing is autumn, upon dry lands, about the beginning or middle of September; but in open, cold lands, much exposed, a month sooner is better: all the caution required in this autumnal sowing is to let the land be very well rolled in the month of October, before the frosts come on, and again in March.

WHITE-SCOUR, a disease with which sheep are too often affected, and by which great numbers of them die.

The following medicine has been often given with success, provided the sheep are at the same time removed into a dry pasture.

Take a pint of old verjuice, half a pound of common or bay salt, dried well before the fire, pounded, and sifted through a sieve. Then mix the verjuice with the salt by degrees; and add half a pint of common gin, and bottle it up for use. When any of your sheep are seized with this disorder, separate them from the flock, and give each of them three large table spoonfuls of the mixture for a dose, repeating it two days after, if they are not better.

WHITE-LANDS; chalky lands.

WILD OATS. See OATS.

WILDS, a term used by our farmers to express that part of a plough by which the whole is drawn forward.

WILLOW, the name of a well-known tree, of which there are several species, some of which may be propagated to great advantage, particularly that known by the name of the Norfolk willow, as demonstrated by the late Mr. North, in an Appendix to a little Treatise on Grasses, published by him some years ago. As this pamphlet may have reached the hands of but few of our readers, and will, now the author is dead, be scarcely ever re-published; we were persuaded it merited a place in our work, especially as it may serve as an example of a profitable method of cultivating trees of this kind, that may be applied to several others, only observing a due regard to the difference of circumstances.

Directions for propagating the sound-growing Norfolk Willow.

"This willow (I dare affirm) will prove very profitable to the planter, and of great utility to the kingdom in general. It will grow taller and larger in twenty or thirty years, than most other sorts of trees will in sixty or seventy. It grows very kindly, and great quantities may be propagated at a small expence. A very considerable profit from it will come to the planter in five or six years after planting: in eight or ten years more another profit will arise much larger than the first; and at last, which will be in about twenty or thirty years after planting, the profit will be surprising, as I will make it appear in the subsequent account.

"In order to begin with this willow-plantation, the land must be securely fenced from all kinds of cattle, and must be well ploughed or dug in winter, to make the surface loose, and to kill the grass and weeds. The season for planting is from November to April, and sometimes later. The driest land should be planted first.

"One year's shoots are best for sets when they are designed to make large trees. The sets should be cut to eighteen or twenty inches long; about eight or nine inches of the thick or lower ends must be thrust into the ground. A strong shoot of one year's growth will frequently make three or four good sets, but I would not advise cutting any sets from the very tops of the rods, because they will be too weak to make strong shoots the first year.

"The proper distance these sets should be planted, is about three feet promiscuously. An acre will require about five thousand. In June, after planting, the sets should be all looked carefully over: and such as have more than one shoot, should be reduced to one, and it should be minded, to leave the uppermost and strongest. The superfluous shoots should be cut off close to the set, that the bark may sooner cover the wound.

"At the same time the ground should be hoed over to kill the weeds, and to loosen the surface, in order to sow turneps, which will no ways hurt the sets, but rather be of service, provided they are properly hoed, and set out at good distances, and not suffered to grow within a foot of the sets. The winter following, when the turneps are gone, the ground should be dug all over, and, the summer after, the weeds cut down with hooks; which is the last, and all the labour of cleaning they will ever want. The best instrument to dig these plantations with, is the sort of broad-tined fork they use in Kent to dig their hop-grounds. The price, by the acre, is twelve shillings for once digging.

"When these sets have grown four or five years, about three-fourths of them must be dug up, in order to leave space for the others to thrive. If they have thrived well, in five years they will be above a foot in circumference,

and twenty or thirty feet high. These young trees will be very proper for many uses, as for chair-makers, hoops, gates, hop-poles, &c. and will surely be worth three-pence a piece upon an average.

"From five thousand sets which are planted upon an acre, at about three feet apart, certainly three thousand may be very properly taken away, and the remaining ones will not be left quite six feet apart. If these young trees are valued at but three-pence a piece, they will be worth thirty-seven pounds, but I rather believe they will be worth more. Eight or ten years after the first thinning, three parts in four should again be took up, which will be about one thousand five hundred; and five hundred or more will be left at about twelve feet apart, which should grow twelve or fifteen years longer, when they will be in fine maturity. The second thinning will be of much more value than the first; upon an average, no doubt but they will be worth half a crown a tree at least, as they will be tall and large, and may be put to divers uses. Many of them will be very proper for masts for small vessels, as the wood is light and tough.

"In twelve or fifteen years more, the remaining five hundred trees will be very tall and large, perhaps above sixty feet high, and five or six feet in circumference. The least value one may conceive must be twenty shillings a tree; so that, at the lowest profit one can set upon the produce of an acre of land, planted with this noble willow, in about thirty years at most, it will be worth six hundred pounds, and all the rent, &c. paid at the rate of twenty shillings a year. I really think I have allowed too low prices for the growth, and that it is very probable they will be worth more. The wood of this tree is very white and tough, and without pith or sap; so must be very proper for carvers, turners, &c. Boards of this wood are as good for floors, or wainscoting common rooms, as any other. I am told, by a man of great veracity and judgment, that posts of this wood, set in the ground, will outlast all other sorts, except yew, or heart of oak. He also affirms, that there is no tree upon the earth so proper for ships masts as this, as it is light and tough, and will not splinter, as fir does.

"This tree has oblong, pointed, saw-edged leaves of a most refreshing light green; at the bottom of each foot-stalk grow two small wings, which almost environ the young shoots.

"This willow will thrive upon almost any soil, so it be not too dry.

"It is also the best kind to plant, in large sets, by the sides of rills, &c. where they will produce larger lopping, and in less time than any other sort of willow will do.

"If any gentleman, &c. have a mind to make plantations of this profitable tree, it would be well worth their while to lay out the ground in some gentle meander walks; which will be but little extraordinary expence, and in a few years will give both shade and shelter.

"This willow will make the most profitable coppice woods, to cut every six or eight years, for hop-holes, and many other very useful purposes.

"They should at first be planted about two feet and a half apart; and, after five or six years, three parts in four should be dug up, and the remainder cut down within six or eight inches of the ground, to remain for stubs.

"This is also one of the best sorts of willow for basket-makers, as it grows freely, and is very tough.

"In many countries, where firing is scarce, this willow would turn to great advantage, merely for fuel; as it will grow into large billets in three or four years, and will burn very well both green and dry.

"Since I wrote this, a gentleman told me, that he knew of three willow trees being sold for fifteen pounds; but he could not inform me what kind they were; I fancy them to be the bright swallow-tail willow; for, next to the Norfolk kind, it is the largest growing sort, and best for most uses."

Mr. North calls this the Norfolk willow; but that is only a local name for this tree. It is by some called the Hertfordshire willow, and has had various other names in different places. The description he has given of the leaves, and the firm sound texture of the wood, without pith or sap, will, however, sufficiently ascertain the species to those who may not before know it. When he published this account, he advertised, that he would

furnish sets to any who might want them. As he is very lately dead, who may be his successors in his business, or whether they will continue to provide for the demand of sets, we are at present ignorant: but it would be a matter of regret, that the difficulty of procuring them should be any discouragement to those who may be disposed to make plantations of this tree.

There is an addition, which might be made to Mr. North's plan of deriving an intermediate profit from a plantation of these trees, while the principal of them are growing to due maturity. It is this; to leave at the second thinning one tree in the middle of every four, that are intended to grow to maturity; which middle tree will consequently be at more than six feet distance from any other, being in the diagonal line of the four. The trees so left should be then cut down, within six or eight inches of the ground, and suffered to shoot afterwards as stubs or pollards. In which state they will afford hop-holes, billets, twigs, for basket-work, &c. if cut at proper periods, from seven years to every other year, respectively to the purposes, for which the shoots may be wanted. This kind of plantation of pollards, with tall trees, is not so proper in a dry, as in a moist situation; because the crowding the roots may, in dry seasons, injure the growth of the trees intended to stand for wood, where there is a want of moisture in the ground. But in a wet soil, it will rather assist than retard them; and will be a constant source of profit during the whole continuance of the plantation.

Other trees may be treated in the same manner, allowing for the respective differences of each, with very great advantage, in swampy and marshy ground, as in the low parts of meadows, or the waste of manors: and the plantations will often prove a beauty and convenience in other respects. In such cases the twenty shillings per year allowed for rent in Mr. North's account may be wholly or mostly saved.

WIND-GALL, a flatulent swelling which yields to the pressure of the finger, and recovers its shape on the removal thereof: the tumor is visible to the eye, and often seated on both sides of the back sinew, above the fetlocks, on the fore legs; but most frequently on the hind legs; though they are met with in various parts of the body, wherever membranes can be so separated, that a quantity of air and ferocities may be included within their duplicatures.

When they appear near the joints and tendons, they are generally caused by strains, or bruises on the sinews, or the sheath that covers them; which by being overstretched, have some of their fibres ruptured; whence probably may ooze out that fluid which is commonly found with the included air: though where these swellings shew themselves in the interstices of large muscles, which appear blown up like bladders, air alone is the chief fluid; and these may safely be opened, and treated as a common wound.

On the first appearance of wind-galls, their cure should be attempted by restrainers and bandage; for which purpose let the swelling be bathed twice a day with vinegar, or verjuice alone, or let the part be fomented with a decoction of oak-bark, pomegranate, and allum boiled in verjuice, binding over it, with a roller, a woollen cloth soaked in the same. Some for this purpose use red wine lees, others carriers shavings wetted with the same, or vinegar, bracing the part up with a firm bandage.

If this method, after a proper trial, should not be found to succeed, authors have advised the swelling to be pierced with an awl, or opened with a knife; but mild blistering has in general the preference given to these methods; the including fluids being thereby drawn off, the impacted air dispersed, and the tumour gradually diminished. A little of the blistering ointment should be laid on every other day for a week, which brings on a plentiful discharge, but generally in a few days is dried up, when the horse may be put to his usual work, and the blistering ointment renewed in that manner once a month or oftener, as the horse can be spared from business, till the cure is completed. This is the only method to prevent scars, which firing of course leaves behind, and unless skilfully executed, too often likewise a fullness of the joint, with stiffness; the mild blistering ointment, where the sublimate is left out, is the properest for this purpose. *Bartlett's Farriery*, p. 276.

WIND-ROW, the green parts, or borders of a field, dug up, in order to carry the earth on the land to mend it; so called because it is laid in rows, and exposed to the wind.

WINE,

WINE, a general name given to any brisk, agreeable, cordial liquor drawn from vegetable bodies and fermented, particularly that procured from the juice of the grape. See the article FERMENTATION.

One and the same kind of grape proves greatly different in taste and flavour, according to the climate and exposure to the sun. In cold countries the vine, if it grows at all, never ripens its fruit; and even in France and Italy, it is constantly observed, that the grapes produced on the south sides of hills are notably sweeter than those which grow on plain grounds. Among the Tokay wine-hills, there is but one which directly fronts the south, and the advantage of its situation is not a little remarkable: from the extraordinary sweetness of its grapes, it is called the sugar hill. It affords the most delicious of all the Hungarian wines, and is appropriated to the use of the imperial family.

In very warm dry seasons, the grapes at the bottom of the hills are best; in warm and moist ones, those at the top; such as grow in the mid region being always good. In dry summers, the grapes are sweetest, but least juicy: in rainy ones they abound with juice, which proves proportionably weaker and more dilute. Frosts in autumn promote their ripening; but frosts succeeding heavy rains make them apt to burst and shed their juice.

The grapes in America are remarkably apt to burst; which Mr. Miller imputes, either to the too great moisture of the air in that country, or to their receiving too much nourishment from its over rich soil. But gentlemen of America think that their air, except in marshy places, is drier than ours; and are therefore of opinion, that the bursting of their grapes is not owing to the too great moisture of the air. If it proceeds from too much nourishment, the remedy would seem to be easy, by training up a great number of branches to consume that nourishment. Others, perhaps with more reason, impute their bursting to their ripening too early, while the heavy rains, frequent in autumn, continue to fall. In this case, they may be raised against lofty trees, as was the method of the ancient Romans, and as still is the practice in many parts of Languedoc and Provence. The reflexion of the heat from the earth would then be less, and the leaves of the trees would shelter the grapes from the sun. By this means, being later before they fill, they would not be so apt to burst; and as the latter end of the autumn is generally fair, they may then have an opportunity of coming to their full maturity, without the danger of bursting. Or if it be thought more advisable to quicken their ripening, the warmest soil and situation should be chosen for the vines, and they should be kept low.

A due degree of maturity is essentially necessary in every kind of fruit, the juice of which is to be made into wine: because the juice of unripe fruit is a rough acid liquor, which cannot be made to undergo a vinous fermentation, without great difficulty. In some instances, as in verjuice, it will remain in the same state for years together. Nor is there less danger from the fruit's being over ripe; because the least taint or putrefaction will, as before observed, run through the whole process of the wine, in spite of every art that can be used to correct or remove it.

When a considerable portion of the grapes have attained their full maturity, these should be gathered with great skill and care, leaving the unripe for a future gathering. Most vintagers make it an almost general rule, to gather their grapes at a certain stated time, according to the custom of the country, without attending to their various degrees of ripeness; therein imitating other rustics, who seldom vary their operations as the seasons vary. Thus, in some countries they make it a general rule, to gather their grapes when dry, and in others they as carefully gather them when they are wet with dew. In both, the circumstances of the seasons should perhaps vary this custom: for example, when a warm kindly season has brought the grapes to a due maturity, such juice wants no addition; and if, on the other hand, the dryness of the season should have thickened their juice too much, the dew may remedy that defect. If a cold or rainy season has prevented their ripening thoroughly, and they still continue in an acid watery state, surely the warmest and driest hours should be chosen for gathering them.

In some places the grape is concentrated or rendered richer by suffering it to remain on the tree till great part of its watery moisture has exhaled; the stem of each cluster being cut half through, when the fruit is ripe, to prevent the afflux of any fresh juice from the plant. The sweet Hun-

garian and Spanish wines are made from grapes that have been thus half dried.

In order to make good wine, the grapes of the same vine should be gathered at three different times. The first gathering should consist of the ripest, finest, and most open bunches: they should be cut as close as possible to the fruit, the better to avoid the austere sharpness and bitterness of the stalk, and all their rotten or green berries be carefully picked off, or rather cut off with a pair of sharp scissars. Some are even so nice as to cut off the grapes at the ends of the bunches, because they are always weaker in quality, as well as less ripe, than those which grow higher upon the stalk. By this means they indeed diminish the quantity of their wine; but what they do make, is thereby vastly improved. An inferior wine is, however, made of the grapes which are so cut off. This practice is, indeed, attended with some trouble; but it answers extremely well, and deserves to be much recommended, as a means of obtaining at least some good wine, in years when, and places where, the grapes do not ripen perfectly. The second gathering should be of the large, close, and less ripe bunches; for close bunches never ripen thoroughly: and the third will of course consist of the refuse of the former gatherings; but no rotten grapes should ever be mixed with either. Each of these three cuttings should be pressed separately. It is highly necessary always to employ a sufficient number of gatherers, each of which should be provided with a basket and knife, and should lay the bunches, as fast as they are cut, gently in the baskets, without bruising or squeezing them; for the more expeditiously they are gathered, the finer will be the colour of the wine: and the sooner they are pressed, the better will be its quality. Women are most commonly employed for gathering the grapes, because their labour is cheaper than that of men, and this does not require any great exertion of strength.

This first work, which is of the utmost importance to the making of good wine, may be still more completely performed by duly attending to the following circumstance. The fruits of different vineyards are of different qualities; some, situated on very light and stoney land, yield exceedingly delicate and high-flavoured wine, which seldom is strong, whilst the grapes of vines growing on a richer soil, where they receive more nourishment, afford a wine which has more body. Both these good qualities may be united in the same wine, either by mixing the grapes of the different growths before they are pressed, or by mixing the different wines that have been obtained from them; but the surest way is to mix the grapes, because it is thought that these liquors do not easily incorporate perfectly after they are made: the weakest of them is said to change its colour, and to communicate its defects to the other, instead of being mended by the superior quality of that with which it is blended; so that, according to many who pretend to have had long experience in these matters, the least evil, and that least is a very great one, which can arise from thence, is a cloudiness in the liquor, a sort of floating lees which will always tarnish the beauty of its colour, spoil the perfection of its taste, and prevent its ever becoming perfectly bright. This does not happen when the perfect grapes of one vineyard are mixed with the perfect grapes of another: for, from the juices of these different fruits pressed out and fermented together, proceeds an exquisite, sound, delicate, fragrant, and bright-coloured liquor, which will keep several years without the least alteration. It is by a knowledge of the good effects produced by a judicious mixture of the grapes of three or four vineyards of different qualities, that the celebrated Champagne wines of Salleri, Ai, and Hautvilliers, have been brought to the perfection for which they are so famed. Every thing that can delight the palate seems to be united in them. But this knowledge can be acquired only by many repeated trials, and long experience.

One of the ways of making wine in the highest perfection of which it is susceptible, is to strip the grapes from off their stalks before they are thrown into the vat. By this means all the austere roughness which the stalks would communicate to the liquor, is guarded against; and the must may be suffered to ferment, without danger, till the fermentation has sufficiently opened the body of the fruit. The wine which is thus obtained is the mellowest, best coloured, soundest, and fittest for keeping.

The above directions for gathering and sorting the grapes are equally proper, whether white wine is to be made, or red;

red; for either of these differently-coloured wines may be, and generally is, obtained from the same grapes, that is to say, from black ones. As to the white wine which white grapes yield, it seldom has much strength or flavour, soon grows yellow, and, for want of body, rarely keeps well even till the next summer. All the white wines of Champagne, which look as bright and as clear as crystal, are made from the blackest grapes, and never preserve their colour better than when all the plants of white grapes have been rooted out of the vineyard. Formerly the wine of Aï would hardly keep a year; the thin sweet juice of the white grapes, of which the quantity was great in the vineyards of that district, turning yellow, gained the ascendant, and altered the whole mass of the wine. But since white grapes have been no longer used in the white Champagne wines, that of the mountain of Rheims lasts seven or eight years, and that of the river Marne keeps well for four or five.

The wine of black grapes may be made of almost any depth of colour that one pleases. They who desire to have it perfectly white, proceed thus. The gatherers go into the vineyard very early in the morning, and select the finest bunches, which they cut as close as possible to the fruit, then lay them gently in their small hand baskets, and when these begin to be full, put them, still as gently as can be, into panniers, commonly called dorfers, in which men or women carry them, with the greatest care not to tumble or bruise them in the least, to the end of the vineyard, where they are put carefully into large panniers, with all their bloom, or azure, as it is technically termed, and all the dew upon them. This dew increases greatly the quantity of the wine: but at the same time it weakens it considerably.

If the sun begins to be a little powerful, the vintagers spread wet cloths over the baskets, whether dorfers or panniers; because, if the grapes should be heated, the liquor drawn from them would be apt to contract a reddish teint. If the place where they are to be pressed is not far from the vineyard, men or women carry the dorfers gently on their backs to the press; but if the distance is considerable, the panniers, into which the grapes are in that case put, are loaded upon quiet easy-going beasts, which carry them slowly, and without shaking, to the cellar, where they remain covered and cool. When the heat of the sun is but moderate, the vintagers continue their work safely till eleven o'clock: but when it shines strongly, they leave off at nine.

For the making of white wine, of which we now speak, the grapes are thrown, as fast as the panniers arrive with them, not into the vat, as would be done for red wine, but into the press, of whatever form it be, and the first pressing is given immediately. The wine which runs from this pressing is the most delicate of any. The French call it *vin de goutte*, because it rather drops than runs, as but little force is used in pressing it. After this first pressing, which is but gentle, for fear of discolouring the liquor, the press is raised, the scattered grapes are thrown up upon the cake, and the second pressing, called the turning up (*la retroussé*) is given. Here the press is screwed down with much greater force than before, and if this second running is not quite so plentiful as the first, though it sometimes is more so, it is at least but little inferior to it in flavour or colour, and preferable in this, that it has a stronger body, and will keep a considerable longer time. The wine of the first pressing is, however, always set apart, if it has been drawn from quite ripe grapes and in very warm weather; because the juice of the fruit then runs very plentifully, and there might be danger of reddening it by mixing it with that of the second pressing: but this mixing of them is useful, and sometimes necessary, on account of the greater strength of the second running when the year is not a warm one, and when the first pressing has not yielded plentifully.

After the two first pressings, the sides of the cake of grapes are cut down perpendicularly, with a steel spade, so far as they exceed the breadth of the upper part of the press which is let down upon the fruit; the grapes thereby separated are thrown up on the top of the cake; and the third pressing, commonly called the first cutting, is given. The juices of this first cutting are excellent to make a perfect liquor; and they may also be added to the red wine, if any of this is made separately. A fourth pressing, a fifth, and so on of others, which are called the second, third, and fourth cutting, are given after this; the sides of the cake being cut down and thrown up each time, till the grapes cease to yield more juice.

The liquor of the cuttings becomes gradually more and more red, because the action of the press becomes more and more forcible upon the thin skin which envelopes the berry; and the particles detached from thence are what render the wine red. Sometimes too the heat of the sun, or the shaking of the fruit in the carriage, are so great, and act so powerfully upon the outside of the grapes, that the tingeing particles, which are in the skin of the berries, being let loose, mix immediately with the juice of the grape at the very first pressing, and then a perfectly white wine cannot be made; but it will be the colour of a partridge's eye, or even deeper. The wine itself is not, in fact, at all the worse for this: but the fashion is to have it either perfectly white, or of a full bright red.

The wines of these different cuttings (as the latter pressings are called) are collected separately, and afterwards mixed according as they contain more or less of the quality that is wanted. Those who have many grapes, press them at two, three, or even four different times, and collect each of the runnings separately. For the first they constantly choose the most perfect grapes, and this wine is always worth a third part more than the second, and so on in proportion.

It is essential to observe, that the pressings for white wine, if it be wished to have it very pale, should be performed as quick as possible one after the other, in order that the grapes may not have time to heat, nor the liquor remain long upon the mark. Particular attention should be paid to this for the two first runnings, because they yield the finest wine.

Of the same black grapes, namely, the black morillons, the pinaous, and the Avernats, with which we have seen that white wine is made in Champagne, red wine is made in Burgundy; and indeed, the same has, of late years, been attempted also in Champagne, with no bad success; though not so as by any means to equal the fine white wines of that country, or the best red wines of Burgundy.

As much as the heat of the sun is avoided by the vintagers who make white wine, so much it is sought after and wished for by those who make red wine. These always choose to gather their grapes when the sun shines hottest; because they find that its action upon the outside of the berries produces more effect than several days steeping in the vat would do; for that the grapes then ferment very speedily. As to the rest, the cautions before directed for gathering the grapes for white wine, in regard to their ripeness, the sorting of them, cutting the branches off with as short stalks as possible, clearing them of all damaged, rotten, and unripe berries, &c. should be equally observed here. Some expose the juice of these grapes in the open air, either in the vineyard itself or close to it, by throwing the bunches into large tubs, and there mashing or bruising them to pieces with sticks, or by putting children into the tubs to tread out their juice. Others carry them home, with care not to bruise them by the way, and put them in a vat, in which they are trodden and mashed. This, in either of these cases, is repeated till the vessel is full; and after that, the broken grapes are let lie in their liquor more or less time, according to the heat of the weather, the flavour of the must, and the degree of colour that is intended to be given to the wine. During this time, the whole must be frequently stirred together, the better to raise a fermentation, and tinge the liquor with a due degree of red; for it is known by experience, that the redness of wine proceeds from the more or less intimate mixture of the colouring which is in the skin of the grape, with the juice which is contained in the pulpy body of the berry. It is, in fact, chiefly to give this dye to the wine, that the trodden grapes are let lie to ferment in the tub or vat before they are pressed.

Some advise, as a general rule for all red wine, to let the grapes lie in their liquor forty-eight hours; whilst others, going on in the beaten track of their forefathers, without daring even to suspect that there may possibly be errors in the stated practice of their country, talk of letting the grapes infuse during seven or eight days, or even longer, and act accordingly: but the author of the *Maisons Rustique*, who seem to have taken their directions from more judicious and more accurate observations, say positively, that the duration of this infusion of the husks should be proportioned, not only to the heat of the weather, but also to the natural quality of the grapes, and to the usual, or intended colour of the wine that is to be made. Thus, for the Coulange wine, which is one of the most esteemed growths of Burgundy, only four hours, or at most five, are allowed for the

the steeping of the husks, unless the weather be chilly and rainy, in which case they are sometimes suffered to remain all night in the liquor. This is likewise, now, the practice of the best vintagers throughout the whole province of Burgundy, in most parts of that of Orleans, and, in short, in almost every part of France where the finest, highest flavoured, and most spirituous red wines are made: and the reasons for it are, that this time is found to be sufficient to give the wine a duly deep colour; that it is apt to contract a roughness from the stalks if it remains too long upon them (to guard against which, as much as can be, care be taken to pull the stalks out with the rake or stick, with which the must is stirred in the tubs or vat, whilst others, more cautious, pick the grapes from off them before it is trodden out): and also, because too much fermenting of the must always renders the wine harsh and coarse, deprives it of its most volatile parts, and the quantity of the must is considerably diminished by the loss of what flies off, or is otherwise wasted in the fermentation. Others again make it a rule not to draw off their must till its head begins to fall. But in this they are evidently wrong; because a great part of the most active spirit of the liquor is certainly evaporated thereby. It may indeed be true, and probably is, that the liquor which has lain long upon the murk, acquires the most strength, and is therefore fittest for keeping: but at the same time it also acquires a roughness and bitterness of taste, communicated from the stones and stalks of the grapes, which are far from rendering it the more palatable.

Might not the surest way of judging when the liquor has lain a sufficient time upon the bruised grapes be, to thrust one's hand pretty deep into the vat, to take from thence a handful of the murk, and to smell to it, as the dyers do, to judge of the disposition of their vats? One might then, perhaps, especially with the help of some experience, know pretty exactly whether the liquor be sufficiently concocted, and whether it has acquired colour enough. If it smells sweet, it should be let work a little longer in the vat; at least till it has lost that smell, and has acquired so strong a scent as to affect the nose. Then may probably be the right time for drawing it off. A good bodied wine will never taste of the grape-stone, if it be taken in its proper degree of the vat: but it will keep sound for many years, and be always fit to drink.

To the different ways of managing the must is certainly owing, in a great measure at least, that some people make much better wine than others from grapes of the very same sort, of equal ripeness, and of the growth of equally good and well situated vineyards. Indeed, for thicker, heavier, and coarser wines, than those of either Burgundy or Orleans, of which chiefly we have now been speaking; such, for example, as the Bordeaux claret, of which we are so fond in this country, and of which the French themselves do not drink at home, a whole day is frequently allowed for the steeping the husks, and some times more, before the press is recurred to. But as to the rule of letting the grapes lie to steep in their liquor forty-eight hours, and much less the longer time which some recommend and practise, we cannot, for the above reasons, think it properly applicable to any sort of wine, unless it may, perhaps, be in very cold unfavourable weather, or for such thick, heavy, dark-coloured, and very heady wines, as those of Oporto, which, as is well known, are scarcely drinkable even here, till age has depurated them, and softened their natural roughness. It is true, that wine which has fermented long upon the murk may always be best for keeping; but it will never be the most pleasing to drink.

We consequently do not approve of this part of the method of making red wine in Chianti, from whence we may probably judge of the general practice in Italy. When the grapes there are of a due ripeness, and the weather warm and dry, they are cut as soon as the sun or wind has dried up the dew that was on them, and are put into little barrels commonly called piggins, in which they are carried to the wine vat, on mules if it be distant, but between two men if it be near. They are then bruised to mash in those barrels with a club, and thrown directly into the vat, or else into a kind of very large hopper placed over the vat, with a grate lengthwise, through which the juice, husks, stones, and stalks all pass into the vat, upon their being trodden; and this is continued till the vat is full: when immediately, or sometimes even hours before it is full, the must thus made, ferments. By this means the husks, stalks, and stones, are thrown up to the top of the liquor, where they

form a thick crust; and this ebullition, which will continue for many days if the liquor be strong, for its duration depends on the strength of the must as well as on the temperature of the air, is suffered to proceed till the wine is judged to be fit for drawing off. This fitness is determined by the palate; and herein consists the greatest skill in the art of making wine. Old practitioners know precisely, by the colour, smell, and taste of the must, the exact time that best suits their method of proceeding: but it cannot be learnt without great attention, and long experience. The wines of the plains are generally deemed ready for turning in about ten days, those of the hills in about fifteen, and those of the mountains in Chianti in about eighteen or twenty, or sometimes more; for in this way of proceeding, the weather has always a very great influence on the ripening of the must. When it is judged to be near ready for running, those who are skilled in those matters taste it every eight hours. The longer the ebullition is continued, the drier and deeper coloured will the wine be: and the less it is continued, the sweeter and paler will be the liquor.

The vats are proportioned to the quantity of wine that is to be made at one pressing, and they frequently are several of them in the same vineyard; for the Italians press all their red grapes in the open air. The vats on which the hoppers are set are covered with boards, and a coarse linen cloth, the better to prevent the evaporating of the wine, and other accidents.

When the Italians make their strong white wines, or muscadines, they gather their grapes carefully, and lay them in the sun for three or four days, or more; always housing them at night, or at least covering them, so that no dew may fall on them. They call the ebullition which these undergo in the vat, a short one, because it does not exceed five or six days; after which they run up the wine, and shift it twice or thrice from one cask to another, to make it become fine. As to the Verdea or white Florence, as it is called, they draw it off from the vat almost as soon as an ebullition begins to rise in it, and has thrown up the husks, stones, &c. so as to form a crust at top. They then let the ebullition continue for a day and a half, or at most two days, in the cask into which it has been drawn, from which they afterwards shift it into another; and in a few hours more into a third and fourth, to check and prevent the fermentation. By this means it is made to retain that sweetness which the ladies in most countries are fond of: but wine thus managed never is perfectly fine.

When the must has fermented upon the husks of the grapes in the tubs, or vats, as long as is thought proper, it is poured off from the former into other vessels, and drawn off from the latter by means of a brass cock placed about three or four inches above the bottom of the vat, from whence it runs into a receiver, which, as well as that under the press, generally is a very large cask, open at one end, and placed upright directly underneath the cock or channel through which the liquor flows. A bundle of pretty close-tied twigs, commonly of vine cuttings or of the haulm of a paragus run up to seed, is placed within the vat, before the grapes are put into it to be trodden, close to the entrance of the cock, to prevent the husks from running into it, so as to choke it up; and a large stone or two is laid upon this bundle, to keep it down. Besides this precaution to retain the husks, &c. of the grapes, and prevent their mixing with the liquor that is drawn off, some, for greater security, let their must from the cock through a sieve, into the receiver, from whence (as also from the above-mentioned tubs, in the using of which the same precaution of keeping back the husks, &c. is carefully observed when the liquor is poured out of one into another) it is laded by hand, in bowls, jugs, jets, or pails, and poured into the casks, through pewter funnels.

After the must has been thus poured or drawn off, the murk, that is to say, the remainder of the grapes at the bottom of the tubs or vat, is collected together and put into the press, where it is squeezed very hard, three or four times, in short, till it is perfectly dry, its sides being cut down each time, and thrown up, as before directed, for the latter pressings of the grapes; and the liquor obtained from thence, especially if the press be screwed so tight as to crack the seeds of the grapes, has a stronger body than any of the preceding runnings, but not any part of their fine, high, or delicate flavour. Some, however, mix a little of it with their other wines, to strengthen them, and thereby make them keep the better: but certainly not to mend their taste.

Others,

Others, in whom the spirit of œconomy is very prevalent, pour as much water as they think proper upon the murk in the vat, immediately after the must has been drawn off. They do this immediately, for fear of the murk's turning sour, as it would be very apt to do, if they should wait longer. They then stir it about, and leave it upon the murk a longer or shorter time, according to the heat of the weather, till they find it pretty highly coloured, and judge that it has incorporated all the remaining particles and spirit of the wine. They then draw this water off into another vessel, and carry the remaining murk to the press, where they squeeze it till not a drop of moisture remains in it. The liquor thus extracted is mixed with that which was drawn off before, and is then barrelled. This is principally intended for common use, or rather for servants: but it must be drank in the ensuing winter; for it will turn sour by the next summer. It is brisk and pleasant enough whilst it lasts good, and is much preferable to water cyder; though not equal to the refuse wine, as it is called, of which a vat, or more, is generally made by itself, of the damaged, rotten, or unripe black grapes that were left at the last gathering, as not being fit for the finer wines.

Another use too, which the French make of the murk of their grapes after the must has been drawn off from the vat, is to amend such of their wines, whether red or white, old or new, as are deficient in colour or strength. To this end they empty them out of their casks into the vat, immediately after the must has been drawn off, stir the murk up so as to mix it thoroughly with them, and then let them remain upon it, at most, twenty-four hours if it be new wine, and twelve hours if it be old. When they find it has taken a sufficient degree of colour, and that it is not sweet to the taste, but agreeable to drink, they draw it off, barrel it up separately, in order to know it again, and then put the remaining murk in the press, where it is squeezed as dry as possible.

As to the white grapes that were rejected at the former gatherings, they are let hang upon the vines till the latter end of October or beginning of November, that they may be a little bitten by the frost. They are then gathered, and a wine is made of them which is sold quite warm from the vat, and does well enough to mix with coarse red wine.

The newly pressed murk of grapes soon contracts a heat; and as it contains many spirituous parts, it is then used as an effectual remedy for rheumatic pains, stiffness of the joints, and numbness of the limbs. The way of applying it is to bury the part affected under a heap of fermenting murk.

By the time that the murk has undergone the utmost dint of pressing, it will be as hard as a stone: but even then it will yield, when diluted with water, fermented, and distilled, a spirit which has its medicinal as well as domestic uses. Or it makes a good manure for land; particularly, say some, for vines and for asparagus.

The too great propensity to fermentation in hot countries has laid the inhabitants of those parts under the necessity of using means to retard it: but the method which they practise for this purpose renders their wines, as Dr. Neuman justly observes, scarcely deserving of that name; because they hardly undergo any degree of fermentation at all, and are, in fact, no better than boiled must. Several of the Italian wines are of this sort, and are called by the general names of *vino cotto*, "boiled wine." It is to thin watery juices, extremely prone to ferment, and in which fermentation, when once begun, can scarcely be suppressed till it has run beyond the vinous state, that the process of boiling over a fire is applied. The fermentative quality is thereby restrained, and the liquor becomes richer, and continues fit for drinking at least a year or two, though it is never so wholesome as the fermented wines. The effects of must and of wine upon animal bodies are diametrically opposite: for must relaxes and liquefies, and, if drank immoderately, is apt to produce dangerous fluxes; whereas perfect wine, on the contrary, corroborates and constricts. This the Doctor reckons the first of three classes into which he very properly divides wine, with respect to its fermentation.

The second class comprehends those wines which have undergone fermentation, but not a complete one. Of these there are two kinds. The first is the thin sweet wines; which are no other than must partially fermented, or whose fermentation is checked, while it can be checked, before the sweetness has gone off. These wines can

scarcely be kept above a year. Such as the Tyrol, some of the Savoy, and several of the Italian. The second sort is the strong, full-bodied, rich, sweet wines, which are generally a mixture of fermented and inspissated must; the latter being added to increase the richness of the liquor, and prevent the fermentation from running beyond its due limits. These kinds of wines greatly heat the constitution, and ought to be very sparingly drank: such are Malmsey, Canary, and some of the Spanish and Hungarian wines.

To the third class belong those wines which have been completely fermented, and have thrown off their gross matter. These are the most perfect wines, and for common use the most wholesome.

In cold countries, where, for want of the sun's having force enough to mellow and enrich the juice of the grape, the must is thin and poor; sugar, or dried grapes, should be added to the must, to give it a body. Authors name a variety of other ingredients for this purpose; but they are useful only as they contain a saccharine substance. It is therefore most advisable to use good sugar, which requires no other care than dissolving it in the juice in the proportion desired, or found to be wanted. If part of the juice is evaporated by fire, as is sometimes practised, a ferment must be added, to make up for the inaptitude to ferment, which experience has shewn to be in all juices that have been boiled.

When we here advise the adding of sugar, in particular, we do it on a supposition of its being the substance most easily come at; and also because it has been proved by some late experiments, that all juices are more or less fermentable in proportion to the quantity of saccharine matter contained in them.

If the juice is so sour that it will not ferment kindly, no alkaline salts should be recurred to, though greatly recommended by several authors; because they raise so strong an effervescence, that they deprive the liquor of much of its most volatile and active principles, and thereby leave it vapid. Instead of these, such calcareous substances as will give the least taste to the liquor, or dissolve the least in it, should be preferred. Such are, extremely well cleaned oyster or other shells, and hard lime-stone or marble reduced to powder. These should not be calcined or burnt; because they would then communicate a disagreeable taste to the liquor, and be besides attended with the disadvantage of raising too great an effervescence. Next to these, chalk bids the fairest to answer the desired end. But a caution necessary to be observed when these or any other such like substances are used, is, that the too great acidity of the liquor should be only lessened; for a certain degree of acidity is essentially necessary in all wines. If the juice is otherwise rich in substance, and faulty only in being too acid, warmth alone has, in many instances, been found to be a sufficient cure. Madeira, for example, is always harsh, till it has been mellowed by heat: and thus again, some gentlemen in England and America, when the juice of their grapes has not fermented kindly, have obtained a very good wine by exposing the containing vessels, in a warm situation, to the sun, with an intention of turning it to vinegar. Chemists know that all vegetable acids are volatile in certain degrees of heat; and it is highly probable that the effect of this summer exposure may be the evaporation of the acid, and thereby the conversion of the whole into a mild vinous fluid. Instances are not wanting, of the roughest verjuice being turned to a strong pleasant cyder, or vinous fluid, by means of a warm situation accidentally given it. Habit has made a gently acid even desirable in some wines, as in Rhenish.

In several parts of Germany where the grapes seldom come to full maturity, and are therefore gathered somewhat green, the makers of wine have iron stoves in their cellars, and keep in them a constant fire, at least during the time of fermentation. This, by heightening the fermentation, ripens and meliorates the wines, and renders them much more palatable and agreeable than they would otherwise be. We have already seen that keeping the wines in places considerably warmed either by the sun, or by fire, will have the same effect, even so late as in the summer after the vintage: for acid liquors remain long without either fermenting thoroughly, or putrefying.

As the wines drawn from the last gathering of the grapes cannot be so perfect as the others, for want of due maturity in the fruit, the people of Champagne and Burgundy have recourse to the following method, to accelerate their ripening:

When

When the wines have been about three weeks in the casks, and have been drawn off their first lees, they roll them up and down for some time, five or six times a day, for four or five days running; then two or three times a day, for three or four days; and afterwards twice a day, for about four days; then once a day for about a week; and after that, once in four or five days. If the grapes were gathered very green, the rolling in this manner is continued, in all, for about five or six weeks: but if they were tolerably ripe when gathered, rolling once in four or five days, for about a month or six weeks, is found to be sufficient. This rolling of the liquor in the casks is intended to supply the defect of its first fermentation.

It now appears evidently, from the foregoing account of the practice of making wines in hot and cold countries, that a means to counteract the inconveniencies of the climate is wanting in each. If they had proper cellars and vaults, as before observed, the too quick and too great fermentation in hot countries might be restrained and kept within due bounds; and a proper degree of heat during the fermentation in a cold country, might give the juice that rich mellowness which the too weak sun could not.

The new wines will generally ferment of themselves, within a few days after they have been put into the casks. Those that do not, should be helped, by putting into them a little of the froth, or yeast, which works from the others. The finest wines will ferment the soonest: and this fermentation will continue for about ten or twelve days, according to the sort of wine, and the season of the year.

While the wine ferments, the bung-hole of the cask must be left open, or only covered with a thin linen cloth, to prevent any dirt from falling in: and this cloth should be laid hollow, so that the froth arising from the fermentation may have room to work off.

When the fermentation is pretty well over, which is known by the froth's ceasing to rise so fast as before, the bung may be closed down, after filling up the cask with liquor to within two inches of the top; and a vent-hole should then be opened and left, to carry off whatever may be thrown up by any subsequent fermentation. This filling up of the cask to within two inches of the vent-hole, should be regularly performed every two days, for about ten or twelve days running: for the fermentation will continue a considerable time, though in a less degree; and if the casks are not kept so full as that the foulness thrown up by the fermentation may be carried off at the vent-hole it will fall back again into the wine, and prevent its becoming clear. After filling up each cask in this manner to within two inches of the bung, for about ten or twelve days, it must be filled up to within an inch every fifth or sixth day, for the space of a month; after which, once a fortnight will be sufficient during the next three months.

Though the fermentation will be over long before this last mentioned time, yet the casks must be filled up once a month so long as they remain in the cellar: for as the wine will waste insensibly in them, it will grow flat and heavy, if they are not kept constantly filled up. It were needless to say, that the vent-holes must be stopped when the fermentation is over.

About the middle of December, the wines may be drawn off from their lees into fresh casks, for the first time; taking care to fill the casks up and to place them so that they may not be shaken or disturbed until the middle of February, when it will be right to draw them off again into other casks. If the quantity of lees is then found to be so considerable as to endanger their contracting a putrid taint by remaining too long mixed with the wine, it may be advisable to draw it off again after a proper interval of time; or sometimes it may be necessary to repeat this racking even more frequently, though hardly so often as is practised in Champagne, viz. even twelve or thirteen times in the space of four years; because, though this may render the wine very clear, bright, and pleasing to the eye, it must surely diminish its strength, and consequently make it be the less fit for keeping.

A leathern pipe, about six or seven inches in circumference, well sewed with a double seam, to prevent the wine's running out, is, at the distance of every five or six feet, very tightly bound with strong waxed twine around brass rings of the same dimensions, made to screw into other rings fastened in the same manner to other similar pipes. The number of these pipes may be suited to whatever distance is found proper or necessary: or, when the di-

stance between the casks is always nearly the same, the leathern pipe may be made of one single piece, with only a brass screw-ring at each of its ends. To these screws the extremities of the leathern pipe should be fitted, so as to screw exactly on or into them, two brass strong cocks, which are however first to be thrust as lightly as possible, by their more taper ends, the one into the usual tapping place of the cask which is to be emptied, and the other into the usual tapping-place of that which is to be filled; that is to say, each of these cocks is to be firmly and closely fixed at about two or three inches above the lowest part of the head of the cask to which it is applied. It were needless to observe that these cocks must be quite strait, the better to complete the communication from one cask to the other. When every thing is thus prepared, the cocks being duly fixed in their respective casks, are both opened, and the wine then flows naturally from the full casks into the empty one, till the liquor becomes of an equal height in each, without in the least disturbing the lees of the wine in the cask that is to be emptied. When the wine ceases to run spontaneously, the rest of it is forced out by means of bellows constructed as follows:

These bellows are about three feet long, and a foot and a half broad at their widest part. They are made and shaped in the common manner to within about four inches of their smaller end, from whence the remainder of them is but three or four inches wide. In the inside of the place where their breadth is thus altered, the air passes through a hole of an inch bore; and upon this hole on the side of it that is next to the nozzle of the bellows, is a piece of leather, like the valve of a pump, so fitted that when the bellows are lifted up to take in fresh air, that valve instantly closes upon the hole, in such manner that none of the air which has passed through this hole, and entered into the cask, can be drawn back again; but the bellows take in fresh air by their holes below.

Instead of ending with a strait nozzle like other bellows, these terminate in a tube or pipe of wood, a foot long, closely jointed into their smaller end, and there well glued and strongly fastened by good pegs, in a direction perpendicular to that of the body of the bellows, in order to its conducting the air downward. This nozzle, for such we shall now call it in compliance to custom, is round, and about nine or ten inches in circumference over its outside at the top, from whence it diminishes gradually towards its other end, the better to fit it for entering some inches in at the bung-hole of the vessel, and also to close up that hole so exactly, that no air may get in, or come out, at its sides. The upper part of this nozzle rises about two inches above the level of the small end of the bellows, and is there cut somewhat flat, that it may be the more easily struck with a wooden mallet, and thereby forced the closer into the bung-hole of the cask: and also at about two fingers breadth below the upper part of this nozzle, is nailed an iron ring, through which is passed an iron hook or brace, a foot long, by means whereof the bellows are cramped down to the hoops of the cask: for without this precaution, the force of the air would drive the bellows out of the bung-hole, and the operation of emptying the broached vessel would not be performed.

It is now easy to conceive the manner in which these bellows force the remaining wine out of the cask that is to be emptied: for, upon opening the bellows, the air rushes in at the holes in their bottom; and upon shutting them, it is forced through their nozzle into the cask; the valve just above their nozzle prevents its returning back; and thus a quantity of air sufficient to counteract the weight of the atmosphere on the wine in the cask that is to be filled, is easily forced into that which is to be emptied.

When the wine is drawn off to within about two or three gallons, a hissing is heard in the cock of the then almost empty cask. The cock in the other should then be turned, so as to close it, and the pipe of communication should be taken away. That done, all the remaining clear wine is drawn off from the cask that is to be emptied, but with great care to stop when it becomes in the least cloudy. This bright wine is then poured into the bung-hole of the cask that is to be filled, and the entire filling of it up is completed with sound wine of the same quality as that which has been drawn off. It is then closely bunged down; and when this has been done, the cock may be taken out and a plug put in, with very little loss of wine. Or, if the owner is so curious as to desire not to lose any of his liquor, the little air necessarily left near the bung-hole may be drawn off

off with a small hand-air-pump, and then scarcely a drop of wine will run out when the cock is drawn.

At every racking of this kind a peg-hole is made in the cask, if there be not one before, in order to examine the degree of waisting of the wine: for wine wastes sensibly in keeping, how closely soever the cask be stopped; a part of it transpiring through the pores of the wood: but, as Dr. Neumann observes, it is not the spirituous, but the watery part that is thus lost; for the remaining wine proves stronger than at first, and the strength continues to increase as the quantity diminishes. In filling up the vessels, for it is necessary that they should be kept full, care must be taken never to mix wines of dissimilar qualities.

The Hungarian, for example, does not well bear any other wine, particularly Rhenish: for if the spontaneous diminution of a cask of Hungarian wine be made up with Rhenish, though both of them keep extremely well by themselves, the mixture will presently spoil: and so it is of other wines.

The lees in the several casks that have been racked off may be collected together, and when their thicker part has subsided, a spirit may be drawn from the thinner.

Distempers seldom happen to fermented liquors, but from some fault in the manner of managing them. If the fermentation has been duly carried on, the wine racked off the lees before they can contract a putrid taint, and afterwards kept in an equal degree of heat, the wine will answer the expectation of the maker. When it is to be transported, and thereby necessarily brought into a warmer air, brandy is often added, to check the propensity to a new fermentation. This is also sometimes done to give strength to the wine: but it is not a practice by any means to be recommended.

It is necessary for the preservation of some wines, particularly of such as are apt to be frequently on the fret, to fumigate the casks with burning brimstone, to which some add, perhaps uselessly, vinous spirits and aromatic ingredients. The fumes of brimstone strongly resist fermentation, but wines which are largely impregnated with them cannot be recommended as wholesome. The colour of red wine is destroyed by them. What is called stum, is no other than must, whose fermentation has been prevented, or prematurely suppressed, by fumigation with sulphur.

The colour of wine is frequently artificial. A pale yellow may be natural, but a fine deep yellow proceeds from an addition of burnt-sugar, or other colouring matters, or from the oaken cask in which the wine has been kept. Wine may be naturally of a pale diluted red; but a deep red is almost always the effect of artificial additions, as of the red-woods, elder-berries, bilberries, &c. In France, no secret is made of these practices, the colouring matters being publicly thrown out after they have been used. Turbid wines are fined by a mixture of whites and shells of eggs, powdered alabaster, and isinglass. The use of the shells and alabaster is to correct any small degree of acidity that the wine may have contracted: and indeed if we look into the many compositions made use of by vintners, we shall see that they are all framed upon this principle; wherefore it would be needless here to particularise them. If the wine is grown very sour, the best way of correcting it, so as to preserve the spirit and flavour, is by adding a quantity of salt of tartar sufficient to neutralize the acid, just before it is to be used. It then becomes a pleasant wholesome liquor: but if salt of tartar is mixed with any fermented liquor long before it is to be used, the effervescence which it raises will deprive the liquor of its spirit, and leave it quite vapid. Isinglass is used only for clarifying the wine. Weak wines are improved by an addition of spirit, particularly before the fermentation is completed, for after this period it is apt to spoil the vinosity. Poor wines are enriched by sweets, and flavoured by various additions so as to emulate the more costly: thus elder-flowers give the flavour of Moselle, and the flowers of the yellow clary will make almost any common white-wine resemble new Rhenish. Even the most delicious wines have been imitated also without a drop of the juice of any grape; with solutions of sugar, juice of currants, figs, and other fruits.

After the wine, and particularly that of countries where the sun is not very powerful, has passed its fermentation in the vat, and is drawn off into casks, it will require something to feed upon. To this end, it will be right always to preserve a few bunches of the best grapes, which may be hung up in a room till there be occasion for them; when they should be picked off the stalks, and two

or three good handfuls of them should be put into each cask, according to its size.

The French recommend strongly the two following methods; the one for giving additional strength and colour to red wine, and the other for clarifying wines in general.

For the former, a sound well-hooped cask is set upright on one of its ends, the other end is taken out, and a layer of vine-cuttings is spread at the bottom of the cask, to the depth of about three inches. Some of the finest and ripest black grapes are then chosen, and their berries are cut off from the stalks, as close as possible to the fruit, which the utmost care is taken not to burst or damage. The grapes thus selected are put gently upon the layer of vine-twigs, and the cask is filled with them up to the beginning of the bung-hole. Another layer of vine-cuttings is placed gently upon these grapes, till it reaches the upper part of the bung-hole, and the cask is then filled with grapes, culled as before, to within a foot of the top, where another layer of vine-cuttings is spread over them, and the head of the cask is then replaced. The cask thus prepared is filled with good coarse red wine, to within three fingers breadth of the bung-hole, that the liquor may have room to ferment without much loss, and in this state it is carried gently to the place where it is to remain. Great care is taken to keep this vessel constantly filled up with wine of the same sort, both whilst it ferments, and afterwards as it is used: for if the grapes in it were at any time to be left long without a sufficient quantity of wine upon them, the whole would grow vapid and be spoiled. The principal use which the vintners make of this liquor, is to supply their customers constantly with wine of the same taste and colour, by mixing it with what they sell.

The other method, which is practised only when wine is to be fined very speedily, consists in this. A parcel of very thin chips, the longer the better, or of pretty thick shavings, of new but well dried beech, is steeped for two days in water, which is changed at least twice a day, the better to take off the taste of the wood. These chips are then well drained; and after they have been thoroughly dried in the air, as many of them are put lightly into a cask, of which the head has been taken out for this purpose, as will fill it to within about a finger's breadth of the top. The head is then properly replaced in the cask, so as to fit it for holding liquor, and a pint of good brandy is poured in at the bung-hole, upon the chips. After this, the bung-hole is stopped closely with a bung, and the cask is rolled about till the chips have imbibed all the brandy. The cask is then carried to its allotted place, and immediately filled with some of the wine that is to be speedily fined. The wine will soon be fit for drawing off; and when that is done, the casks with the chips in it should be filled up again directly, because the chips, like the grapes and vine-cuttings before-mentioned, will lose all their virtue if they are left long without a sufficiency of liquor upon them.

When the wine that is poured upon these chips begins to require a length of time in order to its becoming fine, it is a sign that they are overloaded with lees. The head of the cask is then taken out anew, the chips are washed in water till they are cleared of the lees, they are then dried in the air as before, and after being again soaked with brandy, or washed in perfectly clear wine, they are replaced in their former cask; after that this also has been well washed and cleaned, and they continue to answer the same purpose as at first.

All the above-mentioned practices are innocent enough; but, as Dr. Neumann rightly observes, some of the dealers in wine have had recourse to such dangerous artifices as have been pernicious to thousands. They have sweetened acid wines by litharge, or other preparations of lead; and impregnated sweet ones with mercury sublimate and with arsenic. Lead is discovered in wines by adding a decoction of orpiment made in lime-water. If the wine is genuine, it does not sensibly change its colour on this addition, though on standing, a yellowish white powder falls to the bottom: but if it has any saturnine impregnation, its colour becomes immediately darker, brown, reddish, or blackish. Arsenic may be detected by a solution of lead in aqua fortis; and mercury sublimate, by volatile alkaline spirits, or by a solution of fixed alkaline salts.

As to the concentrating of wines by cold, commonly called condensing or congealing of them, it seems to us so much a matter of mere curiosity rather than of use, that, though Dr. Stahl has taken the pains to give a full and accurate account of the manner of performing this

process, by which the wine is not only freed from its superfluous humidity, so as to be greatly diminished in bulk, and of course rendered more convenient for transportation, but also, say the advocates for this practice, infinitely enriched and ennobled in its quality, and rendered so much more perfect and durable, as to be from thenceforth unalterable by any accident or changes of the weather; for by this means, "the philosophic spirit of the wine," (to use the language of the adepts) is obtained.

"When wines, says Dr. Neumann, are exposed to the action of a freezing air, a part of their water congeals, and the unfrozen part proves proportionably stronger and more spirituous. By repetitions of this process, first pointed out by Paracelsus, and since carried to a greater length by Stahl, the best wines are reduced to about one sixth of their original volume. Wines thus concentrated or freed from their redundant phlegm, are no longer the delicate liquors they were before. They are too unpleasant, as well as too strong, to be drank by themselves; and when mixed with other wines, they communicate to them also a disagreeable taint. The phlegm which congeals retains a part of the truly vinous matter, as appears from its being convertible into vinegar; but this phlegm, mixed with the unfrozen wine, does not restore its pristine qualities: both the phlegm by itself, and the mixture, soon corrupt. When once the principles of wine are separated from one another, no art can reproduce wine by joining them together again. When barely the inflammable spirit has been distilled off, the addition of that spirit to the residuum does not restore its vinosity. The residuum itself often suffers a new separation upon this addition, its tartareous parts precipitating."

When the wine is of an age at which it usually is bottled, care should be taken to examine whether it be sufficiently bright; because a natural brightness is the most certain indication of the liquor's having undergone a due fermentation, and consequently of its being rendered most wholesome. If any small degree of cloudiness is observed in it, the whites of eggs will easily remove that imperfection; and if it inclines to tartness, the shells of the eggs should be mixed with their whites: but if the degree of cloudiness is thought to be greater than the whites of eggs will cure, recourse is had to isinglass, the quantity of which should be proportioned to the quantity of the liquor, and to its degree of foulness; for wine that becomes bright of itself does not need any. The proper way of using the isinglass, is to dissolve it over the fire in so much water as will form it into a jelly; then to dilute it sufficiently with some of the same wine as it is intended to clarify, afterwards to strain it through a flannel bag, and finally to pour it into the cask, and stir it well about with a whisk that reaches only to about half way down the cask. For wine that is very tart, the proper corrective is powdered marble, alabaster, or un-burnt lime-stone, as before directed.

A quite fashionable gentleman would hardly have vouchsafed, a few years ago, to taste a glass of Champagne which did not sparkle or froth strongly: but that notion of its excellency is now pretty much laid aside. Opinions have been so greatly divided in regard to the cause of this sparkling, some ascribing it wholly to the force of drugs used for that purpose by the dealers in this wine; others imputing it to the unripeness, or as some call it, the tartness of the wine, because, in fact, most of the wines that do sparkle and froth are extremely tart; and others again attributing this effect to the influence of the moon, according to the times of bottling these wines, that we cannot do better than copy here the substance of what the authors of the *Maison Rustique* have said on this subject.

"It is true that many dealers in wine, seeing how immoderately fond most people were of this sparkling liquor, did often put into it alum, spirit of wine, pigeon's dung, and many other drugs, to make it froth exceedingly; but it is certain, from experience, that the bottling of it at any time between the vintage and the month of May, will also make it froth. Some pretend that it froths most when it has been bottled nearest to the time of gathering the particular sort of grapes of which it was made; but many deny this. There is no time of the year in which it froths more than at the end of the second quarter of the moon in March; and that without any artifice at all. One may always be sure that the Champagne wine which has been bottled between the tenth and the fourteenth days of the same moon will froth perfectly. This has been proved by such reiterated experience, that it cannot be doubted. It is, however,

proper to observe, that the wine does not froth immediately after its having been bottled. It must have been at least six weeks, and often two months in bottles, before it will froth well. If it has been transported to any distance, it must be let rest for a month in the vault, especially in summer, to recover itself.

"But as the Champagne wines, and particularly those of the mountain of Rheims, are not in general sufficiently ripe for bottling at the above mentioned time, but still retain too much tartness and hardness, if the season has been cold and moist; or too much sweetness, if it has been hot; the surest and best way to have exquisite wine which shall froth perfectly, is not to bottle it till the rise of the sap in August. Experience has certified that it froths excessively when bottled between the tenth and the fourteenth of the moon in August: and as it will by that time have lost its too great tartness, or its over great sweetness, one may be assured that the wine which is bottled then will be the ripest and most frothy.

"Another experiment has been tried, which is, not to bottle the Champagne mountain-wine till the spring of the second year, that is to say, eighteen months after it has been made; and it has been found to froth sufficiently, though not above half so much as that which was bottled while the spring-sap of the preceding year was rising. It is not thought that the river wine, which has less body than that of the mountain, can froth so much in the second year.

"They who would have Champagne wine that does not froth at all, must bottle it in October or November of the year after the vintage. If it be bottled in June or July, it still will froth a little, though but very little.

"As these wines, especially in their first year, work continually in the cellars and vaults, and still more in bottles than in casks, according to the different seasons and the different impressions of the air, it is not surprising that the same wine, particularly the new, should sometimes appear different to the taste. A wine, for example, which is fit for drinking in January and February, shall seem hard in March and April; because of the rising of the sap which then agitates it: and this same wine, after seeming to be perfectly ripened in the next June and July, shall again have, in August and September following, a hardness which could not be perceived in either of the two preceding months; because the rising of the sap in August will have increased the motion of its parts, or in other words, have set it on the fret. Thus the same Champagne wine of the first year, if it be of the river growth, and frequently that of two years old, if it be of the growth of the mountain, will appear more or less ripe or mellow, more or less exquisite, more or less forward, according to the different motions it receives from the different impressions of the air, which vary most sensibly in the different seasons of the year."

What is here implied, though perhaps not quite clearly expressed, is, we apprehend, the true cause of the sparkling or frothing of wine; namely, its not having been perfectly fermented, and consequently not had a thorough assimilation of its constituent parts. The want of this certainly makes it fret in the bottle: and accordingly we see, that the better to secure its sparkling, the people of Champagne bottle it in the very season when it is most likely to be on the fret; viz. at the time of the weather's turning from cold to warm. Several other causes will likewise put wine on the fret, and among these a principal one is the want of cellars in which an equal temperature of the air is preserved all the year round. This, and the imperfectness of the fermentation of the liquor, are undoubtedly the real cause of the sparkling or frothing of wine.

As a general rule, if it be intended that the wine should not froth, the best time for drawing it off, whether into bottles or into casks, is when the weather is extremely fair and clear, the barometer high, and of choice, during a northerly wind; because the air is then coolest, and the wine least apt to be on the fret. By inverting these rules, and drawing off the wine in warm damp weather, when the barometer is low, and the wind southerly, what is bottled at this time will froth; for wine in the cask is always cloudy then, and consequently disposed to fret.

It may not be uninteresting, and certainly cannot be unentertaining to our readers, if we copy here Dr. Neumann's account of, and curious remarks on, the principal wines that are drank in Europe. "1. The Madeira islands, and Palma, one of the Canaries, afford two kinds: the first called Madeira Sec; the latter, which is the richest and best

best of the two, Canary or Palm Sec. The name Sec (corruptly written Sack) signifies dry; these wines being made from half-dried grapes. There is another sort of Sec wine, inferior to both the foregoing, prepared about Xeres in Spain, and hence called, according to our orthography, Sherris, or Sherry. 2. The wines of Candia and Greece, particularly the latter, are of common use in Italy. Malmsey was formerly the produce of those parts only, but is now brought chiefly from Spain: it is a sweet wine, of a golden or brownish-yellow colour: the Italians call it *Manna alla bocca e balsamo al cervello*, "Manna to the mouth and balsam to the brain." Zant and Cephalonia send also to Venice some good, and no small quantity of indifferent wines: almost all the wines indeed made use of in the Venetian territories come from Greece and the Morea; of which there are some sorts so bad, and so cheap, that large quantities are made into vinegar for the preparation of cerusse. 3. Italy, not Greece, produces the *vino Greco*: this is a gold-coloured unctuous wine, of a pungent sweetness, the growth of Mount Vesuvius, greatly sophisticated by the Neapolitans. In the neighbourhood of Vesuvius is made the Mangiaguerra wine, as also a thick blackish one called Verracia; and at the foot of the hill, the delicious *vino vergine*. The Italians apply this last name likewise to all the other wines made without pressure. The kingdom of Naples affords the Campania or Paullippo and Muscatel, the Surrentine, Salernitan, and other excellent wines, as also the Chiarello, much drank at Rome. But the principal of all these wines is the red, fat, sweet, and gratefully poignant one, called *Lachryma Christi*. The ecclesiastical state produces the light, pleasant Albano; and the sweet Montefiascone, a yellowish not very strong wine, which comes the nearest to good Florence, but does not keep well; together with several of less note, as the Nomentan, Monteran, Velitrin, Prænetic, il Romanesco, d'Orvieto, &c. 5. In Tuscany are the excellent white and red Florence; the celebrated, hot, strong red wine of Monte Pulciano; the Montalneo, Porte Hercole, &c. But along the coast of the Adriatic, at Ancona, Rimini, Pesaro, and as far as Bologna, one meets with exceeding bad wines, chiefly of the boiled unfermented kind, heavy, disagreeable, and unwholesome. 6. In Lombardy also there is abundance of bad wines: the Modenese and Montferrat are tolerable; the Marzemino, produced about Vicenza and Padua, pretty good. The other wines most commonly drank in that province are the Brescian, Veronese, Placentine, Lumelline, and Pucine; and in the Genoesse, the *Vino di Monte Vernaccia*, *Vino amabile* or *Vino di cinque terre*, and *Vino Razzese*. Between Nizza and Savona is produced an incomparable Muscadine: near Aquileia is the Rosatz, and near Pavia the *Vino Piccante*. 7. Piedmont, and part of Savoy, have excellent light wines. 8. The Sicilian, Sardinian, and Corsican wines are also good: the first, as particularly the Catanian, Panormitan, Messinian, and Syracusan, are accounted the best, and are chiefly bought up by the knights of Malta. 9. Most of the Spanish wines are composed of fermented or half fermented wine, mixed with inspissated must and variously manufactured, or of an infusion of dry grapes in weak must. No wines freeze more difficultly than the Spanish; these abounding both with unctuous matter and with inflammable spirit. The principal of them are, the Alicante, which is a thick, strong, very sweet, and almost black as well as nauseous wine; Sherry, Spanish Malmsey, Malaga, commonly called mountain, and what is simply termed Spanish wine. These, at least, are the sorts most generally imported here: but in Spain itself there are many more, such as, the Tarragon, Salamanca, Cordova, Galicia, Andalusia, sundry bastards, *Vino de toro*, &c. 10. In Portugal there is plenty of red Port, a cheap but not a very excellent wine, drank in large quantities in England, and often dreadfully sophisticated. The best *Vino tinto*, a blackish red wine used by the coopers for colouring other wines, is said by some to be the produce of Portugal. So largely do the Portuguese deal also in Madeira, that their king receives yearly twelve thousand pipes of this wine by way of tythes. 11. In France, there is a great variety of wines; of which the strong, sweet, full-bodied, spirituous ones are called *Vins de liqueur*. There is scarcely a province in France that does not produce wine: Languedoc and Provence afford the sweetest: and the same provinces, with Champagne and Burgundy, the strongest. The wines of the northern parts of that kingdom, as Picardy and Bourdeaux, are the worst; and those about its middle, as

Paris and Orleans, of a middling kind. The most celebrated of the French wines are those of Champagne and Burgundy, the Coterotie, St. Lawrence, Frontinac, Muscat de Lion, Cahors, Hermitage, Grave, &c. 12. In Switzerland, the best are the Neufchatel, Velteline, La Cote, and Reiff wines. The Velteline straw-wine, so called from the grapes being laid for some time upon straw before they are pressed, is particularly celebrated. 13. The dry-grape wines of the Upper Hungary are in general excellent, and greatly superior to those of the Lower. They have a delicious aromatic smell and taste, a notable diaphoretic, and corroborating virtue, and when drank freely occasion no head-ach, heaviness of the limbs, or other inconveniences. They do not easily become vinewed even in open vessels; and retain their sweetness and agreeableness for a length of time, though they lose a little of it from year to year. 14. Among the German wines, the Tyrol are very delicate, particularly those of Tramin and Etsch; but they do not keep. 15. Good Austrian wine is not to be rejected. Those of Kloster-Neuberg and Brofenburg are counted the best, and, in the opinion of some, excel in taste that of Edenburg in Lower-Hungary. There are also good wines in several other parts of the imperial dominions. 16. In the Palatinate, the best wine is that of Worms, especially the sort called woman's milk; and next to this, those of Edinghoff and Ambach. 17. Among the more esteemed German wines are to be reckoned also Rhenish, Mayne, Moselle, Neckar, and Elsass. A certain writer calls the Rhenish made in Hockheim (hock) the prince of the wines of Germany. 18. The Bohemian, Silesian, Thuringian, Misnian, Naumburg, Brandenburg, and other German wines, are generally inferior to the foregoing. Some, however, of those of Misnia and the Marche, made from ripe picked grapes, have this advantage, that they are greatly meliorated by age, so as to be preferred by many to the Rhenish, Neckar, and Franconia wines, and frequently mixed with other of greater note. The tartish German wines keep the longest of any: some of them have been kept two or three hundred years; and in Strasburg there is a cask of it fourteen hundred years old, and many above seventy; the wine being occasionally racked off into smaller and smaller casks, that the vessel may be constantly full. These very old wines are preserved rather for curiosity than use, as they not only grow too strong for drinking, but at last quite disagreeable. The best are those of a middle age, from twenty to about fifty years."

We cannot close more properly than with the above quoted excellent chemist's definition of the characters of good wine.

"The goodness and wholesomeness of wines are judged of, from their being bright, clear, and sparkling in the glass; of an agreeable reviving smell and taste; leaving, when held in the mouth for some time, a slight sense of astringency; being moderately strong and spirituous; passing freely by urine; exciting appetite; producing a gentle sweat in the night; keeping the belly open the next day; without being followed by any head-ach, heaviness of the limbs, or other uneasiness. Such a wine, moderately used, is a very valuable cordial. The sweet rich wines are either new, or very strong and fiery: they heat the body much more, and, if drank to any degree of excess, their effects continue much longer than those of the thinner wines, which contain an equal quantity of spirit. The red wines, in general, have the greatest astringency."

The following directions for making domestic wines, taken from the *Museum Rusticum*, will, we are persuaded, be agreeable to our readers.

"As to the art of making wine, I think the rendering it more generally known, and practised here, may not only afford a convenience with regard to expence, and a security with regard to health, to private persons; but an advantage to the public, in the balance of trade, a principle at present overlooked: though, in a short time, it will probably be seen in a more interesting light.

"Among the various articles of foreign luxury, wine certainly makes one of the most capital; and yet what with the taking such extreme great quantities, as oblige us to receive, as well the product of inferior, as good vintages; and what with adulterations, as well practised before the wine is imported hither, as after, we in general drink very indifferent natural wines, or very exceptionable artificial mixtures of liquors, called so. Though for these we either pay great annual sums to foreign countries, or

to those who make it their business to impose upon us at home.

"This is the more to be regretted, because we have it in our power wholly to avoid it; and, by a little attention and trouble, to provide ourselves with wine that is superior in flavour, cordial effect, wholesomeness, and every other quality, with a saving of at least fifty or sixty *per cent.* of the expence. The means by which I suggest it to be in our power to do this, is by the domestic production of wine in our own families: which, were the art well known, and the advantages, as I have here enumerated them, well understood, could not surely fail to be a much more general practice than it is at present.

"It may be said to appear from experience, that wine thus made here, is not so good as the foreign: and that we find, in the instances of those who have tried to introduce it, the success is not equal to my representation. To this I answer, that experience has verified what I advance, in the few instances of those who have made domestic wine with skill, and kept it to be of a due age; without which, even foreign wine would not be good. But the reasons why great numbers do not succeed, is the want of knowledge; a fardiness with respect to expence; or the drinking the wine before it be fit; which is almost universally the case. For, where this art has been practised without any of these disadvantages, such wine has been produced as not only has equalled the foreign, in all general good qualities, but has even been mistaken for several of the most valuable kinds, even by the most skilful judges.

"The want of knowledge in the art of making domestic wine being, therefore, one principal cause of the neglect of doing it more frequently, I shall here endeavour to remove it, by furnishing such instructions, as can scarcely fail to enable any attentive person to practise it with ease and certainty. And, I am persuaded, that, to middling people, especially those living in villages and places remote from sea-ports, where it is difficult to procure even indifferent wine in small quantities, I shall do a material kindness: though the advantage of making domestic wines is, by no means, confined to such persons, or situations; but even all others might find their account in it, both with respect to expence and health.

"I will therefore, first give a recipe for making the most perfect wine, that can be produced, by composition, in this country. By composition, I mean, such as is not made of the simple native juice of any one kind of fruit. But this kind is, indeed, in great degree native, as the water added to the dry fruit is only, in fact, the restoration, of what evaporated in the drying and ripening the fruit: and the produce of this process is, therefore, in reality a natural wine, and superior to any that can be made of the native juices of the fruits of our own country; or perhaps equal to the best of those of any other. This recipe will serve, also, as a basis for the showing afterwards how other, and cheaper kinds, may be made.

"Take thirty gallons of soft water, either rain, or river water. It should be obtained in as clear a state as possible, but boiling is needless. Put this water into a vessel, at least one third bigger than will contain that quantity: and then add to it one hundred weight of Malaga raisins, grossly picked from the stalks. Mix the whole well together, that the raisins may not remain clotted in lumps: and then cover it partly, but not entirely, with a linen cloth; and let it stand in a warm place, if the season be not hot. It will soon begin to ferment, and must be well stirred about, twice in twenty-four hours, for twelve or fourteen days. It must be then examined, by the taste, to try if the sweetness be nearly gone off: and if that be found so, and the fermentation be greatly abated, which will be perceived by the raisins beginning to lie quietly at the bottom, the fluid must be strained off; and pressed out of the raisins, first by the hand, and afterwards by a press, if such be easily procured. But, if there be no press, two boards may be used, with the assistance of a large weight, or other strong compressive force, which must be continued as long as any fluid can be made to drop from the mass. The fluid, thus separated from the skins, or marc of the raisins, must be then put into a good sound wine cask, well dried and warmed, together with eight pounds of Lisbon sugar, and a little yeast: but some part of the liquor must be kept out, to be added, from time to time, as the abatement of the fermentation, that will come on again, may admit, without the wine rising out of the cask. In this state it must continue for a month, with the bung-hole open: and then the whole

of the liquor kept out, having been now put in the vessel, must be closely stopped up, so that no air may enter: and in this state it must be kept for a year or longer. At which time it may be bottled off.

"This wine may be drunk, and will be very good at the end of a year and a half: but will be much better, if kept longer: and will improve for four or five years. When it has a proper age, it will equal any of the strong cordial foreign wines: and may, by the addition of proper substances to flavour and colour it, be made to resemble them.

"This is the most perfect kind of what may be called artificial wine; but others may be made cheaper. There are two methods of making a saving in the expence. The one is, to substitute, instead of the whole quantity of raisins here directed, a greater proportion of sugar, leaving out four pounds of raisins for one of sugar added: or the quantity of both sugar, and raisins, may be diminished, and a proportion of clean malt-spirits added, when the bung of the cask is closed up. The use of distilled spirits, in this manner, is not so objectionable as it may at first appear to persons who are not unacquainted with these matters. For such spirits will lose their fiery quality, and be rendered soft and mellow, by their incorporation with the oily part of the wine. And there is nothing more certain than that the practice of using them is general in the preparation of all the foreign wines for our market; and most particularly those stronger kinds, which are most esteemed by us.

"Any other kind of large raisins, which are cheap, may be used as well as the Malaga: and the thinner the skins, and the sweeter the pulp, the stronger will be the wine.

"It has been practised formerly to bruise the raisins; but it is unnecessary with respect to the common sorts, as they will soon burst with the fermentation, and freely give out their contents. But there are some small kinds with tough skins, which, if employed for this purpose, should be bruised, or they will resist the penetration of the water. These kinds are not, however, so good for the purpose of making wine as the larger; or, at least, if they be chosen for any particular flavour they may give the wine, there should be only a certain proportion mixed, added to some of the other kinds: and, in this case, they should be first bruised.

"The practice of a double fermentation, as here directed, first of the raisins themselves, and afterwards of the sugar, is not the common method: and very good wine may be made, by fermenting both at the same time. But this method is, nevertheless, preferable; for it sometimes happens, from some unknown circumstances in the fermentation, when such method is not practised, that the wine will turn out cloudy, and not admit of being fined, by any means at present understood: which accident is prevented by this double fermentation remaining, as the second perfectly works all the remaining half-fermented part of the pulp. Moreover, in consequence of this more perfect fermentation, the wine is lighter, and becomes wholesome and perfect with less age, the glutinous matter of the raisins being entirely resolved.

"Of this wine, by adding the proper flavour, may be formed imitations of all the natural wines, of a very strong body: and, by abating the proportion of raisins, sugar, or both, other smaller kinds may, by the same means, be produced.

"If this wine be perfectly fermented, and kept a long time, so that no sweetness remain, it will resemble Madeira; and has very frequently passed for it.

"An imitation of Frontinac may be made by this wine, in which the proportion of sugar, or of malt spirits, to the raisins, is large, and the whole body weaker. The muscadell flavour of Frontinac, being exactly to be imitated by an infusion of the flowers of meadow-sweet, in some of the wine: and added in that proportion, which may be found sufficient to raise the due degree of the flavour. In the making this artificial Frontinac, the fermentation should be stopt, by closing the cask, and adding the spirit, while a considerable sweetness yet remains: and the wine may be drunk after it has been a short time in bottles.

"Cyprus wine may be imitated, also, by the same means: the infusion of the meadow-sweet being added to the wine prepared in the best manner above directed. But, in this case, three or four pounds more of sugar, than the quantity given in the recipe, should be used; and the fermentation stopt while a considerable degree of sweetness remains. This kind will be the better for age: and, if properly managed, can never be distinguished, even by ac-

tual.

tual comparison, from the true Cyprus: as I can assert from the fact itself.

"The imitation of mountain is to be made, by preserving a small degree of sweetness, giving the nut-like flavour, and keeping the best kind of the above wine to a due age. This nut-like flavour may be obtained, by the infusion of the Florentine orris root, powdered with a very small proportion of orange and lemon-peel: and the wine may be rendered more dry or sweet, by continuing the fermentation a greater or less time; and adding a correspondent proportion of clean malt-spirits, when the fermentation is stopt sooner. The adding some of the stoney feeds of the raisins well bruised, also, give the nut-like flavour: and the putting in a part of the stalks of the raisins, gives a sharpness, found in general in this kind of wine.

"The racy taste of Canary, now commonly called sack, may be counterfeited by the addition of a proper quantity of the juice of white currant-berries to the wine, made with a large proportion of sugar to the raisins, and left very sweet in the fermentation. But it is said, that a spirit distilled from the leaves of clary and clean malt-spirits, and put to the wine, will give to it such a strong resemblance of sack, as renders it absolutely undistinguishable from that wine.

"It is said also, that the juice of the bramble-berries, added to the mixture of the wine, before the fermentation, gives both the exact colour and flavour of claret. But, in this case, the quantity of raisins should be considerably diminished, and that of the sugar increased, though not to the full proportion, as the fermentation must be continued till all sweetness be destroyed; and this wine is not intended to have so great a body as the others.

It is better, therefore, for this imitation of claret, to work it only of moderate strength, and to add some proportion of distilled spirit: it will be perfect at the end of two years. This, and the imitation of sack, by the spirit of clary, I have never seen tried; but have them on very good authority. I should be apt to believe, a small proportion of red-argol, or tartar, dissolved in some of the wine, and added together with the spirit, when the bung is closed up, would assist the imitation very materially.

"Any intelligent person may easily collect, from these instructions, sufficient lights to qualify them to make better or cheaper kinds of wine, according to their inclination. But whatever kind is made, at least a year should be given to it; and, in most cases, a longer time. For nothing has so much contributed to the discrediting, and excluding the use of domestic wines, as the drinking them too new, especially after an injudicious, and undue management of the fermentation; by which means they have been made to appear flatulent, accefcnt, and foul. But the very opposite of these qualities will be found in them, when properly treated and kept." See the article VINE.

To WINNOW, to clear corn from the chaff, &c. See the article THRASHING.

WINNOWER MACHINE. See THRASHING.

WITHERS, the part of a horse where the shoulder bones join at the bottom of the neck and mane.

All pinches of the saddle on the withers, should be treated with repellers; for this purpose bathe the tumour well with hot vinegar three or four times a day: if that does not succeed alone, an ounce of oil of vitriol may be put to a quart of vinegar, or half an ounce of white vitriol dissolved in a little water, and added to the same quantity. These are generally very effectual repellers for this purpose in horses, and will frequently prevent imposthumation: when the swelling is attended with heat, smarting, and little hot watry pimples, the following mixture will then be more proper to bathe with:

Take two ounces of crude sal ammoniac, boiled in a quart of lime-water; where that cannot be had, a handful of pearl or wood-ashes may be boiled in common water; pour off the decoction when settled, and mix with it half a pint of spirit of wine: anoint the part afterwards with linseed oil, or elder ointment, to soften and smooth the skin.

But when these swellings are critical, the consequence of a fever settled on this part, you must avoid the repelling method, and assist in bringing the swelling to matter, by means of suppurating poultices; experienced farriers advise never to open these tumours till they break of themselves; for if they are opened before they are ripe, the

whole sore will be spongy, and discharge a bloody ichor, which soon degenerates into a sordid ulcer. But take care to enlarge the openings and pare away the lips, that your dressings may be applied easily; and avoid the ligament which runs along the neck to the withers: if a gathering forms on the opposite side, open it in the same manner, but take care they incline downwards, for the sake of depending orifices, and letting the matter flow off easily, and if the bones should be found foul, they must be dressed with tincture of myrrh till they scale off: if the fungus is very troublesome, and the discharge oily, yellow, and viscid, pledgets soaked in the following, made hot, have been found very effectual, bathing the swelling round with spirit of wine and vinegar.

Take half an ounce of blue vitriol, dissolved in a pint of water; oil of turpentine, and rectified spirit of wine, of each four ounces; white wine vinegar, six ounces; oil of vitriol and Ægyptiacum of each two ounces.

These sharp liquid applications are often found more efficacious dressings than ointment with precipitate, or verdigris, or indeed any other digestives; as they insinuate themselves more readily into the interstices of the funge, or little quag-holes, so commonly observed in these kinds of ulcers; and at the same time, level and destroy the rising and exuberant papillæ; whereby the ulcer grows more smooth and dry, soon heals up, and cicatrises.

When the cavities are truly fistulous, the callosities must be cut out, where it can be done with a knife; and the remainder destroyed by corrosives; viz. precipitate, burnt allum, and white vitriol. *Bartlett's Farriery*, p. 273.

WITH-WINE. See the article BIND-WEED.

WOAD, the English name of a plant, called by botanists, *Isatis sativa*, vel *latifolia*.

This plant puts forth stems about three feet high, and of the thickness of a man's finger: these divide at their top into several branches loaded with many leaves irregularly placed; and these leaves, which resemble pretty much those of dog's-tongue, are sleek, and of a bluish green colour. The branches bear also great numbers of flowers composed of four yellow petals disposed cross-wise: the pointal becomes a capsule flattened on the edge, and each capsule contains two oblong seeds; the root is large, woody, and penetrates deep into the ground. This plant delights in a warm climate, such as Italy and the southern parts of France: though it has likewise been cultivated in Normandy, and is said to succeed in Germany; as experience has shewn that it does also in this country.

A light, black, kindly, and rich soil, or a meadow newly broken up, is chosen for the cultivation of woad; but it must not by any means be sown on stoney or shallow land. It thrives well in plains, but still better on the south side of a hill: the essential point is, that the soil be good, and that it have the above-mentioned qualities.

Though the land which is intended for woad be ever so good, it must be dunged a year before it is sown with this plant, and be made at first to bear a crop of wheat, or of onions, &c. After these are taken off, three deep stirrings should be given with the plough, or which is much better, with the spade: the first stirring should be in November, and the other two in February, March, or April. If the land which is intended for woad lies flat, and has not slope enough to carry off the wet, channels must be cut of a greater or less size, according as the ground is more or less disposed to retain the water.

In warm climates, woad is sown so early as the beginning of April, unless the weather chances then to be too cold, in which case this sowing is deferred till the beginning of May: but for countries like ours, where the spring is attended with frosts, particularly in the night, Mr. Miller is certainly right in advising to lay the land up in narrow high ridges just before winter, that the frost may mellow it: to cross plough it in the spring, laying it again in narrow ridges, and between this time and the ensuing month of June, to harrow it well twice, at different intervals, in order to root up whatever weeds may have appeared; then, in June, to give the ground a third ploughing as deep as the plough will go, making the furrows narrow; after this to harrow it again when any new weeds are come up; and finally, towards the end of July, or the beginning of August, to plough it for the last time, laying it as smooth as possible.

possible. A good harrowing after this will fit it completely to receive the seeds, which if rain fall soon after their being sown, or if they are steeped in water during the night before the sowing, as Mr. Miller advises, will appear in a fortnight, if the season be favourable. They should be but lightly covered, and should be sowed so thin as that the plants may stand six inches asunder. Some strew pigeon's dung on the land just after having sown it with woad, and the plants become much the finer for this manure.

It is a common custom to sow woad in broad cast: but all plants which require being hoed should certainly be sowed in rows, because this method greatly lessens the labour and time of hoeing; and besides, it is much easier, in this case to give each plant its due distance.

When the woad is grown large enough to be distinguished, it should be carefully cleared of all weeds, for these would hurt it greatly; and at the same time the plants should be thinned where they stand too close: without this precaution, the woad would produce but very few leaves, and would remain extremely stunted in its growth.

The intervals between the plants should be stirred whenever the season requires it; and in the doing of this, by which the weeds thereby rooted out will soon be destroyed in dry weather, care should be taken to lay a little earth up around the stems of the woad. M. Du Hamel, whose account we have here resumed, says he has been assured, that, in countries where there is a convenience of water, the woad-grounds are flooded; but to reap any benefit from this practice, the water should be in sufficient plenty for the husbandman to be able to repeat the flooding frequently; for otherwise the heat of the sun, after having exhaled the water too soon, would harden the surface of the earth, and thereby greatly injure the plants.

Woad generally affords two crops in the same year, and sometimes when the season has been favourable, it has yielded even four. The two first are the best, and these are commonly mixed together in the manufacturing of this plant: but the after crops are always kept separate; for if these are mixed with the other, the whole will be spoiled. The two first crops will sell for from twenty-five to thirty pounds a ton; but the latter will not bring more than seven or eight pounds, and sometimes not so much. An acre of land well husbanded will produce a ton of woad, and in good seasons near a ton and a half. The first crop is gathered towards the end of August, and the last at the end of October, or in the beginning of November: but this last crop must be got in before the first frosts comes on; for the leaves that might be gathered afterwards would not be worth any thing. When the plant is ripe, which is known by its first leaves beginning to dry, all the leaves are cut off by a man who grasps the plants by handfuls, and they are then laid up to wither. Whilst they are in this situation, they must be sheltered from the sun and rain, and they must be frequently turned, in order that they may heat equally: they are then carried to a mill somewhat like that which is used for pressing the oil out of linseed, and are there ground till they are reduced into a paste, which is afterwards formed into cakes of about a pound weight, and these are laid to dry in a covered place, where neither the sun nor rain can come to them. This paste is dried thus for about a fortnight, that is to say, till it has acquired consistence enough to be formed into small roundish lumps, by means of little wooden moulds into which it is put for that purpose. As fast as these lumps are taken out of the moulds, they are laid upon wicker hurdles loosely woven, so as not to touch one another, and in such manner that the air may come at every part of them, as is practised in the drying of starch. These lumps become very hard, and in this condition it is that they are sold. When they are to be used, they must be steeped a long while in water before they can be broken.

The woad thus prepared yields an excellent blue dye, very lasting, and with which all the degrees of this colour may be made. It is not long since this plant was preferred to indigo; afterwards, through a kind of toleration, the dyers were allowed to put a small quantity of indigo into their vats of woad; but now that the making and manner of using indigo have been greatly improved, it is looked upon as a matter of indifference whether that or woad be used for dying blue.

At the last cutting of the woad, and with that cutting, the crown of the root is taken off; whereas only the leaves were gathered in the preceding cuttings. When it is intended to save the seed of woad, a small portion of the plantation

should be allotted for this purpose at the last cutting, and then a part only of the leaves there should be taken from the plants: but it is proper to retrench some of them, because experience has shewn that the plants on which all their leaves are left run to seed soon, and that their seeds have in this case often been destroyed by the cold of the ensuing spring. Thus woad, being a biennial plant, should not be suffered to seed before the month of August in the second year after it has been sown; and therefore some of its leaves should be cut off in October, to prevent its being too forward.

Besides cold, weeds and drough, which are very pernicious to woad, locusts will sometimes devour a whole field of it in an evening. When these enemies are observed, all the leaves should be immediately cut off, that the plants may put forth new ones.

The same field should not be made to bear a second crop of woad immediately after the first; for this plant is a great impoverisher of the ground: but after it has been taken off, wheat may be sown the first year, millet the second, and in the third it may be laid down again to woad, if it has been well manured.

WOLVES TEETH, a name given to those teeth, which grow in such a manner, that their points prick, or wound either the tongue or gums, in eating. Old horses are most liable to this infirmity, and whose upper overshoot the under teeth in a great degree.

To remedy this evil, you may either chop off the superfluous parts of the teeth with a chisel and mallet, or file them down; which is the better way, till you have sufficiently wasted them.

WOOD, a large and thick plantation of trees.

The two most substantial timbers of this country are the oak and chesnut; though the latter has been of late years almost entirely destroyed in England, so that there are scarce any remains of trees of size in the woods at present; but there can be no doubt of this tree having been one of the most common trees in this country, as may be proved by the old buildings in many parts of England, in which the greatest part of the timber is chesnut. Next to these, the elm is esteemed as a profitable timber; but of these there are few cultivated in woods, especially in the south part of England, where they chiefly grow in hedge-rows, or plantations near houses; but in the north-west part of England, there are numbers of very large trees of the witch-elm, growing in parks, and some in woods, as if that tree was a native of this country, which has been much doubted; though as this tree propagates itself by seeds, it may be deemed an indigenous plant in England.

The beech is another tree common in the woods, especially upon the chalky hills of Buckinghamshire, Kent, Sussex, and Hampshire, where there are some very large woods entirely of this sort; some of which have been of long standing, as appears by the age of the trees; but whether this tree is a native of this country, has been a point often disputed.

The ash is a very profitable tree, and of quick growth; so that in less than an age, the trees will arrive to a large size from the seeds; therefore a person may hope to reap the profits of his labour, who sows the seeds; but this is not a beautiful tree to stand near a habitation, being late in the spring in putting out its leaves, and the first that sheds them in autumn; nor is it a friendly tree to whatever grows near it, the roots drawing away all the nourishment of the ground, whereby the trees or plants which grow near are deprived of it; so that where the ash grows in hedge-rows, the hedges in a few years are entirely destroyed; and if they are in pasture-grounds, and the cows browse on them, the butter made with the milk will be bad; for which reason the ash should be sown separate in lands which are inclosed, where cattle are not permitted to come, and at a distance from the habitation.

Upon sandy or rocky soils, the Scotch pine will thrive exceedingly, and turn to great advantage to the planter, provided the plants are planted young, and treated in a proper manner. There are also several aquatic trees, which are very profitable to those who have low marshy lands, where the harder kinds of timber will not thrive: these are the poplars of several sorts, the willow, alder, &c.

Where there are young woods, great care must be taken of the fences; for if cattle should get in among the trees, they will, in a short time, do infinite damage to them, by browsing on their branches, or barking their trees; and during the first ten years of their growth, they should be secured

secured from hares and rabbits, otherwise, in severe frost, when the ground is covered with snow, whereby they are deprived of other food, they will get into the woods, and eat off the bark from the young trees, and gnaw all the branches within their reach; so that in a few days, where there are plenty of these animals, there may be such destruction made among the young trees, as cannot be retrieved, but by cutting them down to the ground, which will be a loss of several years; therefore those persons who have the care of young woods, should be very diligent in frosty weather in looking over the trees, and stopping holes in the fences to keep out the vermin.

Another care to be taken of young woods, is the thinning the trees from time to time, as they increase in their growth; but in doing of this, there must be great caution used, for it should be gradually performed, so as not to open the trees too much, to let the cold air among them, which will greatly retard their growth; nor should the trees be left so close as to draw each other up like May-poles, but rather observe a medium in this work, cutting down a few each year, according as there may be necessity for it, being careful not to permit those to stand, which may spoil the growth of the neighbouring trees, always observing to leave those trees which are the most promising.

The young trees in these woods should not be lopped or pruned, for the more they are cut the less they will increase in bulk; every branch which is cut off will rob the tree of its nourishment, in proportion to the size of the branch; therefore the hatchet should not be suffered to come into young woods, unless in the hands of skilful persons.

Where persons have more regard to the future welfare of the timber than their immediate profit, the underwood should be grubbed up as the trees advance, that the roots may have the whole benefit of the soil, and their stems enjoy the free air, without which their stems are generally covered with moss, and their growth greatly stunted; as may be observed in all such woods where there is any quantity of underwood remaining, in which places it is rarely found that the trees do ever grow to a large size; therefore when large timber is desired, the trees must have room to extend their roots and branches, without which it cannot be expected: but from a covetous temper, many people let their underwood remain as long as it will live; for as the timber increases, the underwood will be gradually decaying by the shade and drip of the large trees, so that by this method the timber suffers more in a few years than the value of the underwood; therefore by endeavouring to have both, neither of them can be so good as where they are separately preserved.

If persons who have estates would be careful to nurse up trees in their hedge rows, it would in time become a fortune to their successors; as hereby the timber growing in the hedges may be worth more than the freehold of the estate, which has often been the case with estates from which their possessors have cut down timber for fortunes for their younger children; the frequency of this should encourage persons to be a little more attentive to the growth and preservation of young woods, since the expence and trouble is not great, and the future profit very certain; besides, the pleasure of seeing trees of a man's own sowing make yearly advances, must be very great to those who have any relish for country amusements.

There are several persons who plant copses for cutting every ten or twelve years, according to their growth. These are usually planted in autumn, either with stools or young plants, which are drawn out of the woods; the latter should always be preferred to the former. These copses are commonly planted with several sorts of trees, as oak, beech, chestnut, ash, birch, willows, &c. But the ash and chestnut are the most profitable, where they grow kindly, because the poles of ash are very valuable: these

also are good for hoops, so that there is no danger of having sale for these copse woods when they are fit for cutting; but where the copses are intended to remain, there should be no standard trees left for timber, because as the heads of the trees spread, and overtop the underwood, it will cause that to decay, and where the standards are left upon the stumps of the copse wood, they will never grow to a large size, nor will the timber be so valuable as that produced immediately from a young root; therefore whoever will make the experiment, will be convinced that it is more for the advantage of both to keep them in distinct woods.

But where persons plant copses upon land free from trees, it will be the better method to sow the seeds, especially if chestnut, oak, or beech, are the trees intended; for although it is a prevailing opinion with the generality of persons, that by planting they save time, yet I am sure of the contrary; for if the seedling plants are kept clear from weeds, they will, in eight or ten years, out-grow those which are planted; and these unremoved copses will continue much longer in vigour than the other: so that for either timber or copse wood, the best method is to prepare the ground well, and secure the fences and sow the seeds, which is so far from losing, that in twenty years it will be found to gain time, which is what every planter wishes to do.

The usual time of felling timber is from November to February, at which time the sap in the trees is hardened; for when the sap is flowing in the trees, if they are cut down, the worm will take the timber, and cause it to decay very soon; therefore if the durability of the timber is considered, the trees should always be cut in the winter months; but as the bark of the oak is so very valuable for tanning leather, there has been a law passed to oblige persons to cut these trees during the spring-season, when the bark will readily peel off, by which the timber is rendered unfit for building either ships or houses, as it will be very subject to cast, rift, or twine, and the worm will soon take it; therefore it will be more for the public benefit, if a law was enacted to oblige every person to strip off the bark of such trees as are designed to be cut down in the spring when the bark will run, leaving the trees with their branches standing till the following winter, which will be found to answer both purposes well. *Miller's Gard. Dict.*

WOOD-COCK Soil, ground whose soil under the turf is of the colour of a wood-cock, and is not good.

WOOD-LAND, ground covered with woods. It is also a term used by the farmers of many counties of England, for a sort of soil, from its constant humidity and dark colour, resembling the soil in woods, which, of whatever nature it originally is, will always be made to appear thus from the continual dropping of trees, and the want of a free air and sun, together with the fall of leaves, destroyed and washed to pieces by the wet.

This soil in the open countries has a considerable quantity of clay in it, and holds the water a long time that once falls upon it: in wet weather it sticks firmly to the ploughshare; and, in dry, is very apt to crack. In uncultivated places it usually produces rushes and rush grass. A moist and dripping year is extremely detrimental to this sort of land.

WOODEN HORSE COLLARS. See **COLLARS.**

WOODY, abounding with wood.

WOOL, the covering of sheep. Each fleece consists of wool of several qualities and degrees of fineness, which the dealers therein take care to separate.

The English and French usually separate each fleece into three principal sorts, viz. 1. Mother-wool, which is that of the back and neck. 2. The wool of the tails and legs. 3. That of the breast and under the belly. The wool most esteemed is the English, chiefly that about Leominster, Coltsfold, and the Isle of White; the Spanish, principally that about Segovia; and the French about Berry.

An account of three experiments made to discover whether wool, laid up in the fleece, alters in its weight.

It has been a matter of some doubt amongst graziers, farmers, and dealers in wool, whether or not wool, after it is shorn and laid up in the fleece, alters in its weight. The following experiments were made to decide this question.

EXPERIMENT I.

This wool was shorn dry, and laid up in a two-pair of stairs room on a boarded-floor.

		Weight	
		lb.	oz.
1746,	Aug. 10	76	6
	Sept. 7	76	8
	Oct. 14	77	11
	Nov. 18	78	0
1747,	Jan. 26	80	0
	Feb. 20	80	4
	Mar. 23	79	8
	Apr. 18	77	13
	June 24	76	8
	July 28	76	8
	Sept. 16	75	15
	Nov. 2	78	1
	Dec. 8	78	14
1748,	Feb. 15	79	1

The weight was increased from Aug. 10, 1746, (when it was first laid up) to Feb. 20, 1747, in the proportion as 100 to 105.

EXPERIMENT II.

This wool was shorn dry and laid in a lower room, with a brick floor one foot above the floor.

		Weight	
		lb.	oz.
1749,	Oct. 15	100	4
	Nov. 18	101	2
1747,	Jan. 26	102	8
	Feb. 20	102	11
	Mar. 23	102	9

The weight increased from October 15, 1746, to February 20, 1747, as 100 to 102½.

N. B. It is something difficult to account for this parcel of wool not increasing more in its weight, as it lay so near the ground floor: but very probably the air had been very damp and raw from the time it was shorn till the 15th of October, 1746, when it was first weighed, so that the wool had then very likely gained weight considerably.

EXPERIMENT III.

This wool was shorn dry, and laid up in a two-pair-of-stairs room with a boarded floor.

		Weight	
		lb.	oz.
1756,	Aug. 30	36	9
	Nov. 19	37	2
	Feb. 19	37	12
	Mar. 24	37	6
	April 1	37	4
	Ditto 21	36	14
	May 2	36	13
	June 1	36	8½
	Ditto 13	36	4
	July 8	36	1½
	Ditto 27	35	12
	Sept. 30	36	4
1758,	Jan. 25	37	11½

The weight of this wool increased from the time it was laid up, August 30, 1757, to Feb. 19, 1757, as 100 to 103¼.

Both wool, and woollen rags, make an excellent manure

WORKING HORSES. See HORSE.

WORKING OXEN. See OXEN.

WORMS are very prejudicial to corn fields, eating up the roots of the young corn, and destroying great quantities of the crop. Sea-salt is the best of all things for destroying them. Sea-water is proper to sprinkle on the land, where it can be had; where the salt springs are, their water does; and where neither are at hand a little common or bay-salt does as well. Soot will destroy them in some lands, but is not to be depended upon, for it does not always succeed. Some farmers strew on their lands a mixture of chalk and lime; and others trust wholly to their winter-fallowing to do it, if this is done in a wet season, when they come up to the surface of the ground, and some nails with sharp heads be driven into the bottom of the plough. If they are troublesome in gardens, the refuse brine of salted meat will serve the purpose, or some walnut leaves steeped in a cistern of water for a fortnight or three weeks, will give it such a bitterness that it will be a certain poison to them. A decoction of wood-ashes, sprinkled on the ground, will answer the same purpose; and any particular plant may be secured both from worms and snails by strewing a mixture of lime and ashes about its roots. It is a general caution among the farmers to sow their corn as shallow as they can, where the field is very subject to worms.

WORMS, a well known species of insects, very troublesome to horses.

Authors have described three different sorts of worms that affect horses, viz. bots, which young horses are often troubled with in the spring: the rotundi, or those resembling earth-worms; and the ascarides, or those about the size of the largest sewing needle, with flat heads.

For the method of curing the bots, see the article BOTS.

As the source of worms in general proceeds from a vitiated appetite and a weak digestion, recourse must first be had to mercurials, and afterwards to such things as are proper to strengthen the stomach, promote digestion, and by destroying the supposed ova, prevent the regeneration of these animals. Thus, two drams of calomel may be given with half an ounce of diapente, and mixed up with conserve of wormwood over night; and the next morning the above purge: these may be repeated in six or eight days. Or the following mercurial purge may be given, which will be less troublesome, and no less efficacious.

Take crude quicksilver, two drams; Venice turpentine, half an ounce; rub the quicksilver till no glistening appears; then add an ounce of aloes, a dram of grated ginger, thirty drops of oil of favin, and a sufficient quantity of syrup of buckthorn to make a ball.

One of these balls may be given every six days, with the usual precautions in regard to mercurial physic: and these powders intermediately.

Take powdered tin and Æthiops mineral, of each half an ounce: give every night in a mash, or his corn.

The various preparations of antimony and mercury must be given several weeks together, in order to get entire rid-dance of these vermin. The Æthiops mineral may be given to the quantity of half an ounce a day; the mercurius alkalifatus to two drams a day, incorporated with a bit of cordial ball. The cinnabar powders, as directed in the farcy, are no less effectual: and when worms are bred from high feeding, or unwholesome food; rue, garlick, tansy, favin, box, and many other simples, may be given successfully; being for that purpose mixed with their food; as also cut tobacco, from half an ounce to an ounce a day.

As the generation of worms perhaps principally proceeds from a weak stomach, and bad digestion, if the horse be of a tender constitution, and a bad feeder, the following bitter drink should be given to strengthen his stomach, and mend digestion, which will prevent the formation of these animals, interposing now and then a gentle stomach purge, prepared with an ounce and half of hiera picra made up into a ball, with syrup of buckthorn.

Take gentian root, zedoary and galangals of each two ounces; chamomile flowers, and tops of centaury, of each two handfuls; Jesuit's bark powdered, two ounces; filings of iron half a pound; juniper berries four ounces: infuse in three gallons of ale for a week, shaking the vessel now and then: and give a pint of this night and morning.

To answer this purpose also, an ounce of filings of steel finely powdered, has been successfully given every day for a fortnight or longer, in the horse's corn. Bartlett's Farriery, p. 150.

WOUND, a hurt given by violence.

In all fresh wounds made by cutting instruments, there is nothing more required than bringing the lips of the wound into contact by suture or bandage, provided the part will allow of it; for on wounds of the hips, or other prominent parts, and across some of the large muscles, the stitches are apt to burst on the horse's lying down and rising up in the stall; in such cases the lips should not be brought close together; one stitch is sufficient for a wound two inches long; but in large wounds may be at an inch or more distance; and if the wound is deep in the muscles, care should be taken to pass the needles proportionably deep, otherwise the wound will not unite properly from the bottom.

Should

Should the wound bleed much from an artery divided, the first step should be to secure it, by passing a crooked needle underneath, and tying it up with a waxed thread. If the artery cannot be got at this way, apply a button of lint or tow to the mouth of the bleeding vessel, dipped in a strong solution of blue vitriol, styptic water, oil of vitriol, or hot oil of turpentine, powdered vitriol, or colcothar, &c. and remember always to apply it close to the mouth of the bleeding vessels, and take care that it is kept there by proper compresses and bandage, till an eschar is formed; otherwise it will elude your expectations, and frequently alarm you with fresh bleedings.

I purposely avoid setting down any famous receipts for fresh wounds, whether ointments, or Fryar's balsams, being well assured, that in a healthy sound constitution, nature furnishes the best balsam, and performs herself the cure, which is so often attributed to the medicine; when it is otherwise, and the blood is deprived of its balsamic state, as will appear from the aspect of the wound, and its manner of healing, it must be rectified by proper internal medicines, before a great foundation for healing can be laid by any external applications whatever.

The lips of the wound then being brought together by the needle or bandage, it needs only to be covered with rags dipped in brandy, or a pledgit of tow spread with the wound ointment, and the wounded part kept as much as possible from motion.

Remember to dress all wounds of the joints, tendons and membranous parts, with terebinthinate medicines: to which may be added honey and tincture of myrrh; and avoid all greasy applications whatever; fomentations and poultices are also generally here of great use; the former thin and attenuate the impacted fluids, greatly promote a free perspiration in the limb, and facilitate the unloading the surcharge on the vessels, by quickening the motion of the fluids; while the latter, by relaxing the vessels, abate their tension, and relieve the obstruction, by promoting digestion.

Punctured wounds from thorns, or any other accidents, should be treated in the same manner; applying the beer, or bread and milk poultice over the dressing, till some signs of digestion appear; and fomenting the part well every day. This method is also very successfully used to those swellings, which often arise on the neck from bleeding, the sores being sprinkled with precipitate, and burnt allum powdered, to fetch out the core, or fungus, which choaks up the orifice. The usual method is to introduce a piece of vitriol, or sublimate, which often brings on a plentiful discharge, fetches out the core, and makes a cure; but it is often with the loss of the vein, and it sometimes leaves a large swelling and imposthumation.

In gun-shot wounds, when the ball has not penetrated too deep, it should be extracted, if it can be fetched away without disturbance, together with any extraneous bodies that might pass in with it; the wound should be dressed with the old digestive of Venice or common turpentine,

divided with the yolks of eggs, to which may be added some honey and tincture of myrrh. The entrance of these wounds frequently requires to be enlarged, and a depending orifice should always be procured if possible; and if the wound should not digest kindly, apply the beer poultice, and foment with the discutient fomentation.

In scalds, or burns from gun-powder, or any other cause, when the skin remains entire, bathe the part well, and keep it soaked with rags dipped in spirit of wine camphorated: salt bound thick on the part has been found very effectual for this purpose: and indeed all saline and spirituous applications excel others, while the skin is yet unbroke; but when the skin is separated, anoint the part, and keep it constantly supple with linseed or fallad oil, and a plaister spread with bees-wax and oil; if the skin is so scorched, that sloughs must be digested out, dress with the wound ointment and oil of turpentine, and finish the cure with any drying ointment. Should the horse be feverish from the pain, bleed him, give cooling clysters, and treat him as we have directed in simple fevers.

The fire supposed to be left in the part after injuries of this kind, is nothing more than the inflammation, which is the natural effect of such causes; so that the whimsical notions and conceits concerning fire remaining in the burnt part, is extremely absurd.

Wounds in the Feet from Nails, Gravel, &c.

Accidents of this sort are very common, and sometimes for want of early care, prove of bad consequence: for the parts being naturally tender, are very susceptible of inflammation; and when matter is once formed, if a free discharge is not procured, the bone which is spongy, soon becomes affected, and the whole foot is then in danger.

When any extraneous bodies, such as nails, stubs, thorns, &c. have passed into the horse's foot, you should endeavour to get them out as soon as possible; and after washing the part with oil of turpentine, dress the hole with lint dipped in the same, melted down with a little tar; the foot may be stopped up with bran and hogs-lard heated together, or put into the turnep, or any soft poultice: this method is generally successful, when the nail, &c. is entirely removed; but if any piece, or particle, should remain behind, which may be suspected by the degree of pain, and discharge of matter, after paring away the sole as thin as possible, introduce a bit of sponge tent in order to enlarge the hole, that it may be drawn out by a small pair of forceps, or brought away by digestion: if this method should not succeed, but the lameness continues, with a discharge of a thin, bloody, or stinking matter, you must no longer delay opening the wound with a drawing knife to the bottom, and then dress as above directed, or with the turpentine digestive, divided with the yolk of an egg, and a little tincture of myrrh, afterwards with the precipitate medicine. *Bartlett's Farriery, p. 246.*

Y.

YARD-LAND, a quantity of land, in some countries fifteen acres, in some twenty, and in others, twenty-four, thirty, and thirty-four acres.

YELLOWS, a disease incident to horses and other cattle, and more properly called the jaundice. See the article JAUNDICE.

"Having, says a correspondent of the editors of the Museum Rusticum, noted the frequent fatal effects of the disease in cattle, called the yellows, I some years since resolved to let no opportunity slip of being acquainted with this complaint, in order to assign its cause, inasmuch as I apprehend it to be the forerunner of most chronical diseases,

to which great cattle are subject, as the murrain in the guts; scowering, asthma, or wheezing, dropsy, and loss of milk, &c.

"I have not hitherto been able to find any author who has treated of this complaint in a manner suitable to the consequence thereof, so as to trace the symptoms in its several stages, in order to effect a cure; and, where this complaint has been quite neglected or ill cured, to point out the consequence, by shewing how it may appear under the above-mentioned shapes, which, being mistaken for originals when they are only consequents, are rarely cured, through the first cause being unknown.

"This complaint, I apprehend, proceeds from a waste of bile, that is, a preternatural running out of what is called gall; occasioned by the rugæ, which are in the inner membrane of the neck of the bilious duct, becoming, by some accident, too weak to perform their office, so that the gall runs out of the bladder nearly as fast as it runs in; by which means it forceth itself, or a considerable part at least, into the porus bilarius, instead of being discharged by the ductus communis cholidochus into the intestines, and, by the means of the vena porta, mixes again with the blood, filling that with its sharp pungent quality; which causeth that fluid to become of a fizy nature, and, consequently, to move slowly in the channels through which it passes; whence arises that sluggish disposition the beast in this complaint is subject to, and which is one of the first symptom of the disease.

"And the liver, being deprived of the natural heat and weight thereof, is, together with the fiziness of the blood, rendered incapable of performing its office, so that the supply of bile is not equal to the expence; nor is the blood purified from it as it ought, but passes on together till it fixes in some part, and there (if not timely prevented) forms a tumour very prejudicial to the beast.

"These tumours I have seen appear externally in the glands behind the ears, in the shoulders, and in the flank, in the dewlap, round the corner of the hoofs, and in the udder, or milk-bag; internally, in the form of water, in the veins of fat between the muscular parts of the body, in the kidney fat, and even between the coats of the guts.

"When these tumours, which appear externally, come to suppuration, the beast commonly recovers, though frequently it be a long time first.

"The seasons of the year in which cattle are most subject to this complaint, are for about the five first weeks after they are put out to graze in the spring, during which time the season is apt to be very warm at days and cold at nights; the grazes being also tender, and abounding with moisture: and in like manner in autumn; at which time the days are also warm and nights cold; and the grazes, on account of autumnal rains, tender as in the spring and more so, if the preceding summer was tolerably dry.

"The cattle at these seasons being faint and very subject to perspire much, by which the pores are greatly opened in the day, and sudden cold coming on at night hastily contracts them; and before the warmth of the next day becomes sufficient to set the parts thus contracted at liberty, the matter, which should have been discharged by perspiration, returns into the blood in order to pass off by urine, by which means a much greater quantity of bile is secreted than otherways would; which passing into its receptacle, the gall-bladder, causes it to extend to a preternatural size; thereby extending the passage by its pressure, till the rugæ are scarcely to be seen: whereby the resistance made by them is not equal to the pressure of the bile, which consequently forces its way hastily into the blood, in the manner before observed, instead of passing off as excrement by the guts.

"The early symptoms attending this disease, are, a shaking of the beast in a morning, and more particularly the hinder parts, as the loins, thighs, and legs; hollowness of the eyes, and the hair staring; a dry nose, and if the cold taken be great, hanging of the ears, the swelling of the dewlap, of the glands of the ears, the shoulders, or the flanks, and of one or more quarters of the udder, or milk-bag in cows; with a sudden decrease of milk, what remains becoming, after a few days, more yellow than usual, and will, if boiled, curdle: the fore teeth are generally loose, as tho' they would drop out.

"If these symptoms, especially the first, remain unobserved, as is often the case in barren cattle, and such as range at large, it frequently happens that the disorder settles in some inward part; as on the pericardium, which

causes wheezing, and the hark, and uncommon poverty; when in the guts and mesentery, (or sweet bread) causes the hark and scowering; and when in the vein of fat, between the muscles, causes the dropsy and uncommon weakness.

"In this last complaint, on opening a beast, the milt or spleen was very small, and thin, not half so large as in a healthy state, as was also the liver; but other ways sound and perfect, the gall-bladder of an uncommon thickness, and its contents very little.

"In opening a beast which was wasted, and subject to wheezing and the hark, the pericardium was become hard, and inclined to callosity towards the part which joined the heart: the heart unusually large, but sound: the lights very sound, but small: the milt or spleen thin and withered: and the liver dryish, with a few small hard knots therein: the gall-bladder near as the former.

"I have observed these knobs in others, and generally found the gall-bladder, liver and spleen less or more affected; those which had the hark, and scowered, generally having their guts covered, the inside with a large quantity of mucus resembling frogs spawn: the flesh of these is always of a yellow cast.

"Having said thus much of what I apprehend the cause, I will now prescribe what I have very many times known used with good success for a cure.

"First, Suffer no blood to be taken away from the beast.

"Take a handful of rue tops, the like quantity of the greater celendine; shred them small, and mix with them one ounce of turmeric root in powder (or instead thereof red sanders); put these in three pints of stale old ale or beer, and cause it just to boil up; when it is cold enough, give it the beast warm: there is no occasion to keep the beast in before or after, unless the inclemency of weather oblige.

"Two of these drinks, at forty-eight hours distance, will perfect a cure, if the disease be not of long-standing.

"Should a scowering be come on, then, after the first drink, give the following on the intermediate days.

"Take two pounds of oak-bark, boil it in one gallon of water till one fourth be consumed; strain it; in this water boil two pounds of rice till it be soft; mix with it half a pound of the burnt crust of bread, taken from the underside of the loaf; and to all this put two quarts of milk; let it boil for twenty minutes; divide it in two parts, and give one to the beast at a time warm." *Museum Rusticum*, vol. II. p. 144.

YEOMAN, the first or highest degree of the plebeians of England. The yeomen are properly freeholders, and who cultivate their own lands.

YEW-TREE, the name of a well known tree, common on cold soils in many parts of England. The timber of the yew-tree is much esteemed for various uses.

These trees may be easily propagated by sowing their berries in autumn, as soon as they are ripe, upon a bed of fresh undunged soil, covering them over about half an inch thick with the same earth.

In the spring the bed must be carefully cleared from weeds, and if the season prove dry, it will be proper to refresh the bed with water now and then, which will promote the growth of the seeds; many of which will come up the same spring, but others will remain in the ground until autumn or spring following; but when the seeds are preserved above ground till spring before they are sown, the plants never come up till the year after, so that by sowing the seeds as soon as they are ripe, there is often a whole year saved.

These plants, when they come up, should be constantly cleared from weeds, which, if permitted to grow amongst them, would cause their bottoms to be naked, and frequently destroy the plants when they continue long undisturbed.

In this bed the plants may remain two years; after which in autumn, there should be a spot of fresh undunged soil prepared, into which they should be removed the beginning of October, planting them in beds about four or five feet wide, in rows about a foot asunder, and six inches distance from each other in the rows, observing to lay a little mulch upon the surface of the ground about their roots,

as also to water them in dry weather until they have taken root; after which they will require no farther care, but to keep them clear from weeds in summer, and to train them according to the purpose for which they are designed.

In these beds they may remain two or three years, according as they have grown, when they should again be removed into a nursery, placing them in rows at three feet distance, and the plants eighteen inches asunder in the rows, observing to do it in autumn, as before directed, and continue to trim them in the summer, for what they are intended; after they have continued three or four years in this nursery, they may be transplanted where they are to remain, always observing to remove them in autumn where the ground is very dry; but on cold moist land it is better in the spring.

These trees are very slow in growing, but yet there are many very large trees upon some barren cold soils, in divers parts of England.

YOAK, or YOKE, a frame of wood, fitted over the necks of oxen, whereby they are coupled together, and harnessed to the plough.

Horses and oxen are the animals used for drawing ploughs. Sometimes the one, sometimes the other, and sometimes both together. It is impossible to determine which of these is the most proper. This depends upon the kind of food most easily obtained, the kinds of work required, and the expence of breeding, or purchasing. If the real labour is to determine this, without any other consideration, then oxen are to be preferred; because as they stand to the draught, they will overcome a resistance which horses will yield to.

As it cannot be determined, what kind of cattle are most proper for the plough, so neither can it be determined, what number is necessary. This depends upon the strength of the cattle, and the nature of the soil. The number varies according to the work in which the plough is to be employed, and often according to the custom of the place, and fancy of the farmer.

The methods of yoking cattle in ploughs, vary almost as much as the number used. Some of them at first sight are so awkward, that it is needless to consider them. The only thing worthy of being enquired into, is, whether the cattle should be yoked in pairs, or in a line before each other? We shall therefore consider the advantages and disadvantages attending each way, and compare them together.

The most common way of yoking cattle in ploughs is in pairs. There are some disadvantages attending this way that are obvious. In ploughing the furrows betwixt ridges, the land-cattle go upon the ploughed land, and tread it down with their feet: this, especially if the land is wet, hurts it very much.

There is another disadvantage very obvious. When there is but as much of the ridge unploughed as to allow the land cattle to go upon it with difficulty, they are frequently either going into the opposite furrow, and thereby giving the plough too much land; or, which is worse, they are justling the furrow-cattle upon the ploughed land.

To remove these inconveniences that attend the ploughing with cattle yoked in pairs, some yoke them in a line before each other. It is obvious, that cattle yoked in this manner, going always in the furrow, neither tread upon the ploughed land, nor jostle one another. In these respects the yoking the cattle in a line before each other, seems to have the advantage.

It is to be observed, however, that this method is not quite free from inconveniences. When examined it may perhaps be found attended with as great inconveniences as the other.

When cattle are yoked in a line, they go all in the furrow. This makes it necessary to give the plough more land than ordinary, either by the foke or the muzzle; for if this be not done, the head and foke being in the same direction with the beam, and the cattle yoked to the middle of it, the plough will directly follow the cattle, without taking any thing off from the land. Now it is inconvenient to be obliged to give the plough land either by the foke or muzzle; for, when the foke is turned out of the plane of the beam, it makes the plough heavy to draw; and when the muzzle puts the draught too much to one side of the beam, it prevents the plough from going upright. The yoking the cattle in pairs is attended with none of these inconveniences; for, in this case, the quantity of land, which the

plough has naturally, when right made, is sufficient to make it take off a proper furrow.

There is another inconveniency that attends yoking cattle in a line, arising from the nature of the animals. Horses and oxen, like men, love their ease, and are disposed to throw the burden upon their fellows. This they have a better opportunity of doing when yoked in a line before each other, than when yoked in pairs. When yoked in a line, each pulls by the traces of the one behind him; and therefore, though it may be known when the foremost neglect his work, by the slackening of his traces, yet it cannot be known when any of the rest neglect their work; for though one of them does this, yet by the pulling of the one before him his traces may be fully stretched. But this is easily discovered, when the cattle are yoked in pairs; for then every one of them has a separate draught. The goadman, or driver, knows, by the position of the yokes or cross-trees, whenever one does not draw equally with his fellow; and the ploughman perceives by the going of the plough, whenever any of the two pairs does not draw equally with the other: for if the pair that goes foremost neglect their work, the plough is pulled out of the ground; and if the pair that go hindmost neglect their work, the plough is pulled in too deep. The reason is obvious; the plough is made to go at a proper depth, when the two forces by which different directions are given the plough, act at the same time. If one of them then should cease to act, the plough cannot go right. If the foremost pair should cease to draw, the plough having too little eard for the direction of the draught of the hindmost pair, will come out of the ground: and if the hindmost pair cease to draw, the plough having too much eard for the direction of the draught of the foremost pair, will go in too deep. This does not hold in an ox-plough: for as the beam by which the foremost pair draw is fixed to the yoak of the hindmost pair, the whole force applied to the plough is in the same direction: and therefore, though any of the pair cease to draw, there is no alteration in the going of the plough.

There is yet another inconveniency that attends the common way of yoking cattle in a line before each other. When the fore cattle are all yoked to the traces of the hindmost, it is obvious, that as the beam, to which the draught is fixed, is much lower than his shoulders, by which the rest pull, such a weight must be laid upon his back or shoulder, as must render him incapable of giving any assistance. Besides, as the whole force is applied in the direction of the traces of the hindmost horse, it cannot have such influence on the plough, as when a part of it is in a direction more horizontal. When a body is to be moved forward in any direction, the nearer that the direction of the force applied approaches to the direction of the body, it acts with greater influence. And therefore, as the plough moves horizontally, and as the direction of the united draught of a plough with the cattle yoked two abreast, is more horizontal than the direction of the draught in a plough with cattle yoked in a line, the same force applied will have greater influence.

When these two different ways of yoking cattle in ploughs are thus considered and compared together, it is difficult to determine which ought to be preferred. Each of the two seems preferable to the other in a certain situation. When the land is stiff and the labour severe, the yoking the cattle in pairs seems preferable, as it is certainly the strongest draught; and when the land is wet, and in danger of being much hurt by the treading of the cattle, the yoking them in a line before each other seems preferable; as thereby they are confined to the bottom of the furrow, which is the firmest part of the land, and prevented from doing harm.

When a person uses two or more ploughs, it is a very proper way to have one with the cattle yoked in a line, and the rest with the cattle yoked in pairs. The ploughs with the cattle yoked in pairs continue as long as the land-cattle have room to go easily upon the firm land; and the plough with the cattle yoked in a line, follows, and clears up the furrows. In this way the cattle yoked in pairs do no damage, and the cattle yoked in a line are never used but where they are of real benefit.

To persons that incline to yoke the cattle in a line before each other, it will not be amiss to point out a way to remove the inconveniency last mentioned, and show how the cattle may be yoked so as to lay no additional weight on the back or shoulders of the hindmost horse, and to make the direction of the draught more horizontal. This is done by making the

the traces of the horse next to the plough but one very long, and fixing them, not to the shoulders of the horse behind him, but to the cross-tree, and by fixing the traces of the horse before him, not to his shoulders, but to his traces at the place where the back-rope is fixed. By this the hindmost horse is delivered from the burden laid upon him in the other method; as his draught is entirely independent of that of the rest. There is indeed some weight laid upon the horse immediately before him, to whom the others are yoked. But this is but small; for his traces are nearly in the same direction with theirs, and they are yoked to him at a place lower than his shoulder. By this, likewise, the direction of the united draught is more horizontal, when there are three or more horses yoked: it is even more horizontal than when the cattle are yoked in pairs. In a four-horse plough yoked in pairs the two forces are equal; but in a four-horse plough, yoked in this manner, the force most horizontal is to the other, as three to one.

The traces of the horse hindmost but one being long, will incommode the hindmost horse in turning, if they have nothing to support them. To prevent this, two links must be fixed to the shoulders of the hindmost horse, and the traces passed through them; the links long enough to allow the traces to be stretched.

When two horses are sufficient for the draught, the yoking them in this manner described for the two hindmost, removes also the second inconvenience mentioned, that attends the yoking cattle in a line: for the ploughman discerns, by the going of the plough, when any of them neglect their work, in the same manner as when there are four horses in the plough yoked in pairs.

The ordinary method of yoking oxen, is attended not only with all the inconveniencies of yoking cattle in pairs, but also with the last-mentioned inconveniency, of yoking cattle in a line. For the foam, by which the foremost cattle draw, is fixed to the yoke of the hindmost pair. Their yoke being higher than the beam, a great weight is laid upon their necks by the drawing of the foremost cattle. This inconveniency may be removed, and the oxen yoked in such a manner, as to give two directions to the plough, as is done when horses are yoked in pairs; by which the draught will likewise be made stronger. To do this, the foam of the pair immediately before the hindmost must be fixed, not to their yoke, but to the beam; and, to prevent this foam from incommoding the hindmost in turning a link must be fixed to their yoke for it to pass through, the link long enough to allow the foam to be fully stretched. When there are more than two pair in the plough; as is most common, the largest-sized cattle should be placed next the plough, and the smallest-sized immediately before them. For the lower that the yoke of these last is placed, the nearer will the direction of their foam be to the foam of those before them; and thereby the less weight laid upon their necks. This method of placing the cattle is contrary to the ordinary way: for it may be observed that the smallest-sized oxen are always placed next to the plough. But these different ways of placing the cattle are both founded upon the same reason: for the smallest-sized oxen are placed next the plough in the

ordinary way of yoking, that to their yoke, to which the foam of the pair before them is fixed, may be as low as possible: for the lower that it is placed, the nearer the directions of the two foams approach each other, and the less weight is laid upon the necks of the hindmost pair. And, for the same reason, the lowest-sized oxen should be placed in the middle, when yoked in the manner proposed, that so they be less incommoded by the pair before them.

If, in considering the most proper method of yoking cattle in ploughs, we had nothing in view but the strength of the draught, and conveniency of the cattle, we would always recommend the yoking the cattle in such a way, as to apply two forces to the plough in different directions. But as we must also have in our view the going of the plough, hence it becomes necessary to observe, that sometimes it is an advantage to have the draught of the whole cattle in the same direction.

In ploughing sea, where the sward is tough, or any kind of land, where there are interruptions from roots or the hardness of the bottom, the plough, if two forces are applied to it in different directions, goes very unsteadily, sometimes too deep, and at other times too shallow, and is very difficult to manage. The reason is obvious: when the plough meets with such interruptions, as tend to make it go deeper, or shallower, than its ordinary way of going; if at the same time, the force that acts contrary to the interruption ceases, then the plough, in spite of all the attention of the ploughman, will either start out of the ground or go in too deep, according to the tendency of the interruption. But when there is only one force acting upon the plough, it is, in some respect, like the wheeled plough; it goes steadily and at a certain depth; at last, it is not so difficult to manage it, as when there are two forces acting in different directions: for though some of the cattle at the time when the interruption is given, should cease to draw, yet the draught continues still in the same direction, and the ploughman has only the alteration occasioned by the interruption, to rectify. Every person knows, that an ox-plough goes much more steadily than a horse-plough: and this is occasioned, not only by the nature of the animals, oxen being more steady in drawing than horses, but also by the manner of yoking them, oxen being yoked in such a manner, as that one force only is applied to the plough.

Thus it appears, that no absolute determination can be given, which of these two ways of yoking cattle in ploughs is to be preferred. Men must weigh the advantages and disadvantages attending each way, and determine according to circumstances. If the land is of a kind not easily ploughed, the cattle not well trained, and the ploughmen not expert, the work will be best performed, if there is only one force applied to the plough. But if the land is easily ploughed, that is has few things in it to incommode the plough in going; if the cattle are well trained, and the ploughman expert, the work will be well enough performed, and the labour less severe upon the cattle, if two forces are applied to the plough in different directions.

Yoke of land, the quantity of land which a yoke of oxen might plough in a day.
